The Stevenson Creek model dam was undoubtedly selected by the engineers designing it as an average type of structure. The relative proportion of length to height and the slope of the base at the sides determine predominant action. With an angle of less than 45° to the vertical, with a height from the base to the crown two or more times the chord, the arch would modify the resistance such that the twisting of the plate would transfer a major portion of the applied force to the sides rather than to the bottom. Then, the relative moment of twisting resistance, as compared to arch resistance, would decrease so greatly for median or upper layers, that the dam with some propriety might be treated as if the predominant resistance were that of arch strips.

As engineers become more convinced of the economy of combining metal and concrete, making the concrete able to resist tension and withstand temperature stress without disintegration, and the ease with which the base of a reinforced concrete dam may be anchored into a rock foundation, construction of gravity dams will become less frequent and the monolithic reinforced structure will replace the concrete gravity dam.

The objections commonly raised to such a design may be summarized, as follows:

First.—That the steel is likely to rust and the expansion of the rust will crack the concrete and cause it to disintegrate even if the embedment is relatively deep.

Second.—That the concrete may be disintegrated by frost and, therefore, plain mass concrete is less objectionable from this standpoint. The writer's observation has been that while reinforced concrete disintegrates by the expansion of scale rust on bars that have been exposed and have not been properly cleaned before embedment, there are no well authenticated examples of such disintegration where proper care and precautions have been taken. Along the coast, where the salt air tends to increase the formation of rust, the labor involved in properly cleaning the steel is much greater than the cost of giving it a protective coating before shipment from the mill such that no rust may be formed upon it during the time it is exposed to the weather before embedment. As such coating of the proper kind increases rather than decreases the bond between the concrete and metal, it may be regarded as advantageous and economical.

A dam 3 000 ft. long, well reinforced, without expansion joints, subjected to a range of temperature from 50° below zero to 100° Fahr., above, has remained tight after a number of years, so that the objection to monolithic action on the ground that temperature changes would prevent such action, seems to be without foundation.

The engineer desires a precise mechanical theory for the computation of the elastic behavior and for the resistance of the structure he designs whether it be a frame or a concrete dam; but the computed elastic behavior depends on the values assigned to the elastic coefficients of the material.

The assumption that a plane normal cross-section of the unit strips treated by Mr. Jakobsen remains plane after flexure without rotation from the normal, requires an infinite value of the shear modulus, F.

Because deflection of the crest at the center of the dam is greater than that at the quarter-point, or toward the end, shear distortion is involved and the value of the modulus of shear which would permit distortion in the assumed absence of stress on the vertical normal plane between unit strips is zero. Hence, Mr. Jakobsen's premise consists in treating the shearing modulus, F, as varying in the same identical concrete from zero in a vertical plane to infinity in a horizontal plane. The inconsistency thus involved renders the theory without foundation or value as an elastic analysis.

While arch action and bending are affected by cracking of the concrete, torsional resistance may be transmitted by keying adjacent sections together as is customarily done by those who are prejudiced in favor of expansion joints.

B. F. Jakobsen,* M. Am. Soc. C. E. (by letter).—Mr. Rich has checked Equation (7) by a more elegant derivation and agrees that curvature should not be disregarded unless the dam is properly grouted under pressure.

Mr. Floris presents a somewhat different method of arriving at the same result.

Mr. Jorgensen's discussion will be studied with considerable interest especially his Figs. 5 and 6.

Mr. Werner develops formulas for the interesting condition of a dam curved up stream instead of down stream.

Mr. Bauman insists that gravity dams are monolithic structures, homogeneous and isotropic, and that arch action, therefore, must take place and may be determined in the usual manner. If shrinkage did not occur, there would be no reason for providing contraction joints and there would be no explanation for the large cracks which have appeared in the Mulholland Dam. This dam was not provided with contraction joints, but an effort was made to produce a monolithic structure. Unless the writer knows definitely that arch action must be present, he prefers to neglect it, because this is the safe assumption—and a safe assumption regarding arch action is particularly requisite for gravity dams, such as the Exchequer Dam. Uplift was neglected at this dam, although it may exist in spite of the drainage pipes provided.

* Cons. Engr. (LaRue & Jakobsen), Los Angeles, Calif.

Commenting on this subject, Alfred D. Flinn,* M. Am. Soc. C. E., Director of Engineering Foundation, writes,

"Some reduction of uplift may be gained also, but drainage passages cannot be depended on permanently because the leaching and depositing of salts from the masonry tend to seal the designed and accidental passages."

Likewise, in arch dam design the writer prefers to ignore the effect of the cantilevers,† and assume that the arches carry the entire load.

Mr. Bauman considers the deflection of only one cantilever, that at the crown, which is hardly sufficient,‡ and he appears to have applied Professor Cain's deflection formula for arches to the primary or original arches instead of to the secondary arches, which procedure may be equivalent to assuming that tension can be transmitted across contraction joints.§ In this manner Mr. Bauman estimates the arch action as much greater than it actually is.

Professor Cain shows that when the up-stream face is sloped, as is customary, the effect of curving the dam is to decrease the compression, and this checks what the writer found for a vertical up-stream face. Professor Cain concurs in the writer's conclusion, that it is dangerous to neglect curvature in a curved gravity dam.

Mr. Hanna quotes Wegmann to the effect that the Habra and Bouzey Dams were not arched in plan and that poor foundation was the main reason for their failure. The writer did not state that they were arched in plan, but that they failed from tension in the up-stream face and, as he knew nothing about the matter from personal observation, he referred to the source from which he quoted.‖

Dr. Unwin has stated that both dams were built of somewhat inferior material and that in each the line of the resultant fell considerably outside the middle third, so that, on the ordinary theory, there was considerable tension in the up-stream face. Both dams, he has stated, failed about half way up the dam, along a line such as AB in Fig. 19, and he was agreed with the French engineers that in both dams the initial fracture was a tension fracture which occurred at the point where the tension was greatest, according to the law of the middle third.

Mr. Hanna takes the writer to task for using a radial-sided slice, 1 ft. wide, at the up-stream face and contends that this method cannot yield reliable results. He states further:

"* * * they should not be allowed to displace the customary and reliable method of computing stresses in arched gravity dams by the parallel-sided slice theory."

A dam designed by the radial-sided slice method is safe when tested by the parallel-sided slice theory, but the reverse is not true. The writer showed this for a vertical up-stream face, and Professor Cain has shown that it

* *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 249.

† *Loc. cit.*, Vol. 90 (1927), p. 520.

‡ "Etude sur les barrages arqués," Extrait du *Bulletin de la Suisse Romande* (1922), by Alfred Stucky.

‖ American Civil Engineers' Handbook, Fourth Edition (1920), Section 7, Article 8, p. 686.

remains true when the up-stream face is sloped. Therefore, in the absence of some conclusive proof that the parallel-sided slice theory is correct, the writer prefers the radial-sided slice theory, because it is the safer of the two assumptions.

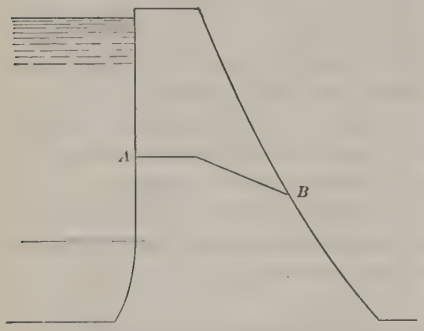

FIG. 19.

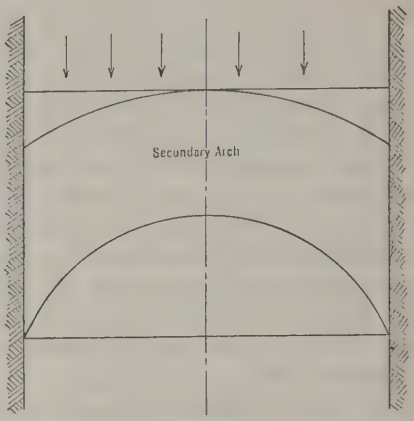

FIG. 20.

Mr. Hanna assumes a monolithic structure, that is, he denies that shrinkage occurs, and then reasons that a radial-sided slice cannot deflect without encountering arch resistance. That is absolutely correct, but he overlooks the essential fact that it is equally correct for a parallel-sided slice; that is, for a straight gravity dam, provided it is monolithic. A parallel-sided slice of a straight gravity dam is not independent of the remainder of the structure for two reasons:

1.—A set of secondary horizontal arches, free from tension, exist and will resist displacements of the cantilevers in a radial direction; and,
2.—The adjoining cantilevers are not generally of the same length or height as the one under consideration, and, therefore, the deflections at the same level of these three cantilevers are different, so that one re-acts on the others.

As an illustration, take a straight gravity dam, 200 ft. high, with 50 ft. between the vertical abutments.* Such a dam would act mainly as an arch dam, notwithstanding its straight up-stream face (see Fig. 20), provided it is monolithic, as assumed by Mr. Hanna.

Equation 55 gives the deflection of a cantilever due to bending and shear. Assume that the adjoining cantilever is longer by $d\,x$, so that, for this cantilever, $H + d\,x$ and $h + d\,x$ should be substituted for H and h in the equation in order to obtain its deflection at the same elevation, $H - h$ ft. from the crest (see Fig. 14). The difference between the deflections may be obtained most conveniently by differentiating Equation (55), bearing in

* Résal, "Formes et Dimensions des grands barrages en maçonnerie," *Annales des Ponts et Chaussées*, II, 1919, p. 26.

mind that the ratio, $\frac{H}{B}$, remains constant. This gives the additional deflection, $d\,\Delta_h$, due to the additional length, $d\,x$,

$$d\,\Delta_h = \left(\frac{62.5\,H^3}{E\,B^3}\,2\,h + \frac{46.9}{E\,B}\,2\,H\right) d\,x \ldots\ldots\ldots\ldots\ldots\ldots (76)$$

This means, even if arch action is not present, that when the abutment is steep, so that in a short horizontal distance a considerable change in height occurs, the longer cantilever tends to deflect more than the shorter one. Under this condition an overloading of the shorter cantilever may occur, which may result in uplift under the shorter cantilever. For this reason, also, it is well to insist, as does Professor Cain, that the base should always be thicker than the middle-third theorem prescribes.

Mr. Hanna develops formulas for the effect of curvature on stresses (Fig. 15), for a slice of any width instead of one having a width of only 1 ft. as was considered by the writer. In order to integrate his equations, however, Mr. Hanna assumes that H is constant, and his formulas, therefore, have a very limited application. When H is variable, shear stresses are present in the vertical radial planes, because Δ_h also varies and the calculations become quite complicated, even when arch action is ignored. Of course, this holds also for a straight gravity dam, provided it is monolithic.

Mr. Wiley's discussion is of particular interest, because the Exchequer Dam was accepted by him as Consulting Engineer for the Merced Irrigation District. The gravity design was given preference over an arch dam, which required 60 000 cu. yd. less material. With reference to his Fig. 5, Mr. Jorgensen stated:

"The Exchequer Dam sustains a higher unbalanced water pressure than any other dam, and it possesses the slimmest cross-section thus far attempted for high dams."

When this gravity dam is properly analyzed, it is found to have considerable tension in the up-stream face. The writer was informed by the engineer in charge that the concrete weighed 152 lb. per cu. ft., which checks well with his own experience for this locality. The value of 158 lb. per cu. ft. used in the design, according to Mr. Wiley, seems too high and has the appearance of being an assumption on the side of danger.

The expansion of the arch ring due to lateral deformation, is, according to Mr. Wiley, 0.000032 ft., while the least contraction in a 50-ft. joint, measured 22 ft. from the surface, is, 0.0324 in., or a unit shrinkage of 0.000054, which is nearly 70% greater than the lateral deformation, as computed by Mr. Wiley. In addition, he states that there was still some setting temperature in the dam, when these measurements were taken.

In determining the lateral deformation, Mr. Wiley assumes Poisson's ratio as $\frac{1}{5}$ and that the modulus of elasticity is 2 000 000 lb. per sq. in. The writer believes that both these values are much too favorable. Turneaure and Maurer* give for Poisson's ratio, for 1:2:4 concrete, 60 days old, $\frac{1}{6.25}$ to $\frac{1}{10}$.

* "Concrete Construction," p. 25.

and for 1:3:6 concrete, 60 days old, $\frac{1}{12.5}$; and this last value would probably be more nearly correct for the very lean concrete in the Exchequer Dam. A value of $\frac{1}{8}$ for Poisson's ratio and 4 000 000 lb. per sq. in. for the modulus of elasticity is more nearly correct and at any rate more conservative, for a concrete having a compressive strength of 2 000 lb. per sq. in., or probably more* and with these assumptions the lateral deformation near the toe of the base is 0.000010, or one-fifth of that required to annul the smallest measured shrinkage. For points at this elevation, but farther away from the toe, the lateral deformation becomes smaller, because the vertical compression is smaller, and for higher elevations the lateral deformation also becomes smaller. For these higher elevations the shrinkage is possibly greater, because the section is thinner and not so well protected against drying out and cooling, and it is the arch action in the upper parts of the dam and not at the base, that is of importance.

Mr. Wiley's figures show that the contractions decrease with increasing distance from the face, and he concludes that a little farther inside the dam, it may be assumed that no contraction takes place. There is another explanation which seems more reasonable, or at any rate more conservative, that is, that the contraction inside the dam is delayed due to the fact that the setting temperature remains longer in the interior. Mr. Wiley admits that when the measurements were taken, there was still some setting temperature in the dam. All authorities seem to agree that Poisson's ratio is exceedingly difficult to measure for concrete and, therefore, if it is to be seriously considered, a very conservative value should be used. Moreover, for the upper part of the dam, where arch action might be of considerable importance, the lateral deformation is at any rate quite negligible compared to the shrinkage.

Mr. Wiley thinks that because very little leakage appears through shrinkage and contraction cracks, that shrinkage does not penetrate more than about 20 ft. below the surface. Where water-stops are provided in the up-stream face, leakage cannot very well take place, but when the writer last visited the Mulholland Dam (which was not provided with contraction joints), there was some leakage through the vertical-radial cracks and the foreman stated that an attempt was being made to stop the leakage by introducing sawdust. It is quite true that two surfaces may be in contact and transmitting heavy stresses, as Mr. Wiley contends, and still there may be some leakage. However, it is equally true that two surfaces, as at a shrinkage crack, may not be in contact and yet very little leakage may be in evidence. This latter is the safe and conservative assumption. Why accept the unsafe assumption merely because it may sometimes happen to be correct? The writer has made some calculations to determine what the leakage would be through a shrinkage crack $\frac{1}{16}$ in. wide under such heads and length of paths as would occur in the Mulholland Dam and finds that the discharge

* Stanton Walker, Assoc. M. Am. Soc C. E. "Modulus of Elasticity of Concrete," *Bulletin No. 5*, Structural Materials Research Laboratory, Lewis Inst., Chicago, Ill.

would be exceedingly small. If account is taken of the fact that the channel formed through a shrinkage crack is not uniform, being obstructed by small particles, etc., and that the crack is not a plane, the computed leakage is practically negligible. Therefore, the fact that there is only a very small leakage does not justify the conclusion that there must be arch action in the dam.

In summing up, the writer feels that Mr. Wiley has failed to show that there probably will be arch action in the Exchequer Dam, after the setting temperature is gone; and much less has he proved that it must be present, as would be required before any claims can be made for arch action. It is undoubtedly true that arch action might prevent a complete failure, but as the writer sees it, this cannot be relied upon until after the cantilever has failed and uplift must then also be admitted.

Mr. Kramer's discussion is very able and most fair. He admits that shrinkage will take place and then proceeds to show that the cantilever may possibly deflect sufficiently to bring about arch action, when certain reasonably advantageous assumptions are made. Mr. Kramer considers a block 50 ft. wide and assumes that the shrinkage is that corresponding to a temperature drop of 20° Fahr. This corresponds to a unit shrinkage of 0.000110 which should cover both temperature and setting shrinkage and the writer believes this may not be quite enough.* Mr. Kramer assumes the modulus of elasticity to be 2 000 000 lb. per sq. in., and states that this is a rather low value, which will give high values for the deflections. Stanton Walker, Assoc. M. Am. Soc. C. E., gives the following formula† for the relation between the initial tangent modulus of elasticity, E_i, and the compressive strength, S:

$$E_i = 40\,000\,S^{0.6} \qquad (77)$$

Equation (77) gives the following values:

Compressive strength, in pounds per square inch.	Modulus of elasticity, in pounds per square inch.
1 000	2 520 000
2 000	3 820 000
3 000	4 800 000
4 000	5 900 000

These values represent the grand average of a great many tests. At Exchequer Dam there was no control over the quantity of water used in mixing, but an effort was made to secure the proper mix, and by the time the dam was ready for loading, it is fair to assume that the average strength was probably 2 000 lb. per sq. in., or more, considering that most of the concrete would be at least one year old. This would give a modulus of elasticity of about 4 000 000 lb. per sq. in., or twice that assumed by Mr. Kramer, which would reduce the deflections of the cantilever proportionately.

* See, Mr. Wiley's discussion, pp. 822–823, bearing in mind that the measured contractions cannot be considered as final. See, also, "Stresses in Multiple-Arch Dams," *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 310.

† *Bulletin No. 5*, Structural Materials Research Laboratory, Lewis Inst., Chicago, Ill., p. 65.

The writer will elaborate on Mr. Kramer's analysis and carry the calculations a step farther. When the cantilever is bent, it is able to compensate for shrinkage and the amount of this is given by the difference in length between $A\,B$ and $A'\,B'$ in Fig. 21, in which, $A\,B$ is the length of a short element of the crest before the deflection, y, takes place. That difference is,

$$2\,\phi\,R_u - (R_u - y)\,2\,\phi = 2\,\phi\,y$$

If $A\,B$ is 1 ft., $2\,\phi = \frac{1}{R_u}$, and,

$$e = \frac{y}{R_u} \qquad (78)$$

in which, e is the unit shrinkage that a deflection, y, can compensate for, when the up-stream radius is R_u. The compensation, therefore, depends directly on the deflection. Mr. Kramer determines the crest deflection at the crown, $y_{\max.} = 0.1154$ ft.; and with $R_u = 674.7$ ft., he obtains $e_{\max.} = 0.000171$, which is 1.55 times greater than the assumed shrinkage.

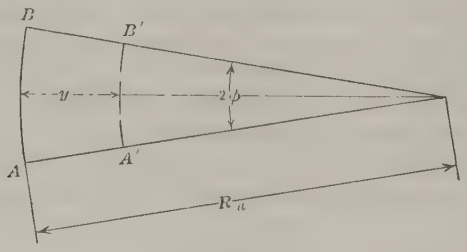

FIG. 21.

However, the maximum deflection is applicable to only one single point in the structure and is not a fair measure of the structure's ability to compensate for shrinkage. The writer calculated the bending and shear deflections for a gravity dam 200 ft. high, of triangular section and with the water standing level with the crest,* and found the deflection line to be approximately straight. Half way up the dam, therefore, the deflection is only one-half of what it is at the crest (in reality, it is somewhat less than that), while the shrinkage is not materially less, although it may take a longer time for the thicker sections to reach their final shrinkage. At the lower elevations, especially near the toe, some compensation will be derived from the lateral deformation.

Even at the crest the maximum deflection is not a fair measure, since the crest deflection at the abutment is zero. The crest deflection due to bending and shear, as developed for the 200-ft. dam previously referred to, is,

$$y = \frac{0.434}{E}\,(a^3 + 0.72\,a)\,h^2 \text{ ft.} \qquad (79)$$

in which, E = modulus of elasticity, in pounds per square inch, h = the height

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 101, Fig. 32.

of the cantilever, and $a = \frac{\text{height}}{\text{thickness}} = 1.59$ for the Exchequer Dam. Assuming $E = 2\,000\,000$ as does Mr. Kramer, the crest deflection is,

$$y = 1.12 \times 10^{-6} \times h^2 \text{ ft} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (80)$$

This checks Mr. Hanna's Equation (55). For $h = 320$ ft., Equation (80) gives $y_{max.} = 0.1146$ ft., which checks Mr. Kramer's value of 0.1154 ft.

In order to have definite ideas, assume that the developed profile of the site, taken along the center line of the crest, is a straight line and let h be the height corresponding to an angle, θ, measured from the crown, so that,

$$h = c\,(\theta_1 - \theta) \text{ ft} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (81)$$

in which, θ_1 is one-half the central angle. At the crown, $\theta = 0$ and $h_{max.} = c\,\theta_1$, which determines the constant, c. If $h = h_{max.}$ throughout (then, of course, Equation (81) would not apply), $y_{max.}$ would be the average deflection. Since, however, h is variable in accordance with Equation (81), the average deflection for the crest is,

$$y_{ave.} = \frac{1}{\theta_1}\int_0^{\theta_1} y\,d\,\theta = \frac{1.12 \times 10^{-6}}{\theta_1}\int_0^{\theta_1} c^2\,(\theta_1 - \theta)^2\,d\,\theta$$

or,

$$y_{ave.} = 1.12 \times 10^{-6}\,\frac{c^2\,\theta_1^{\,2}}{3} = \frac{1}{3}\,y_{max.} \quad \ldots\ldots\ldots\ldots\ldots (82)$$

Equation (81) represents an unusual profile. One that is more nearly representative is shown in Fig. 22 and is determined by:

$$h = c\left[1 + \cos\left(\pi\,\frac{\theta}{\theta_1}\right)\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (83)$$

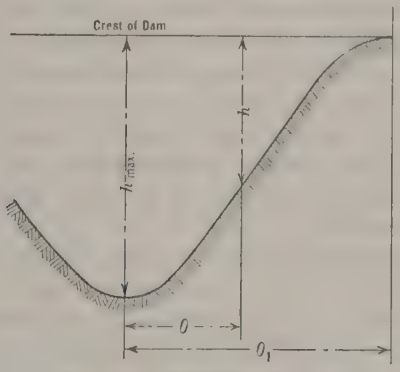

FIG. 22.

For the crown section, $\theta = 0$ and $h_{max.} = 2c$. Proceeding exactly as before, the deflection at any point is given by Equation (80) when the value of h from Equation (83) is substituted, and the average deflection, which determines, at least approximately, the average unit shrinkage that the deflections can compensate for, is,

$$y_{ave.} = 0.375\,y_{max.} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (84)$$

In other words, instead of using the maximum crest deflection, $y_{max.}$, only about 0.333 $y_{max.}$ should be used and that will compensate for a shrinkage of,

$$c = \frac{0.333 \times 0.1154}{674.7} = 0.00006$$

The shrinkage assumed by Mr. Kramer is 0.00011. The conclusion is, that even with Mr. Kramer's rather favorable values for shrinkage and modulus of elasticity, the deflection at the crest is sufficient to compensate for only about one-half the assumed shrinkage. At elevations below the crest, the deficiency is even greater.

From these considerations may be concluded that an arched gravity dam not provided with contraction joints is less likely to crack near the crown and more likely to crack nearer the abutments. This checks well with the location of the cracks in the Mulholland Dam. Likewise, dams provided with contraction joints would be expected to show larger openings toward the abutments than near the crown.

The writer agrees with Mr. Kramer that no allowance should be made for arch action, unless it be shown that it must be present under the most unfavorable conditions which may be reasonably expected, and that the burden of proof should be on the designer.

As has been shown it appears questionable whether the Exchequer Dam, after it has cooled, can develop arch action before the cantilevers fail and introduce uplift; so many indeterminate factors enter into the calculations as to make these uncertain. To the factors already mentioned, may be added the deflections due to the yielding of the foundation, which are by no means negligible* and which will influence both the arch and the cantilever deflections, the influence of swelling of the up-stream face† due to water-soaking, the rapidity with which the reservoir is filled, temperature during construction, method of construction, when the dam was pressure-grouted, etc. The writer also agrees with Mr. Kramer that when properly calculated much higher stresses can be used in design than has been customary in the past. The allowable stress should be dependent on the actual strength of the concrete as determined by test. This will encourage the production of good concrete.

Mr. Creager believes the Exchequer Dam would probably hold as an arch dam irrespective of its strength as a gravity dam. This is to be hoped, because as a gravity section, it has considerable tension in the up-stream face with only the water load, and if an earthquake shock, traveling up the river bed, should occur while the reservoir was full, the gravity action could not be depended upon for any material assistance. If, in the last analysis, the Exchequer Dam derives its stability, or its factor of safety, from arch action or mainly from arch action, would it not have been wiser to have taken account of this in the design? Mr. Bauman gives the central angles for

* "Stresses in Thick Arches of Dams," *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 520, and Dr. Vogt's discussion, p. 554.

† *Loc. cit.*, p. 517, and Fig. 26.

the Exchequer Dam* and Mr. Jorgensen gives the central angles for the proposed arch dam (Fig. 6). A comparison shows that the central angles are much larger and the radii much smaller for the arch design than for the gravity design, and the conclusion is inescapable that from the point of view of arch action, the Exchequer Dam is hopelessly inferior in spite of its much greater cost.

Referring to Dr. Unwin's statement, it seems to the writer quite likely that the Bouzey and Habra Dams carried a portion of the load on the secondary arches during the first years of their existence. As shrinkage and cooling became effective, the arch action was greatly reduced, tension made its appearance in the up-stream face and eventually led to failure (see pages 813-814).

The writer agrees with Mr. Godfrey and Mr. Kramer that uplift merits serious consideration and that drainage systems are not always dependable.

Mr. Turner's discussion takes him somewhat far afield. The writer stated expressly in his paper that he was aware of the limitations involved and gave his reasons for accepting the usual assumptions. He had no intention of formulating an elastic theory. Mr. Turner seems to be under the impression that there is a principal distinction to be made between straight and curved gravity dams. This question has already been discussed herein. The twisting stresses to which Mr. Turner refers, have been discussed by others, but as far as the writer knows, consideration of them has not gone beyond the conversational stage, and what engineers need are figures by which to design, based on conservative assumptions. A complete solution of the stresses in a gravity dam, straight or arched, is so complicated that it may not be attempted for some time to come. A good and conservative approximation, however, will satisfy most engineers. As study and experiments go on, knowledge of the stress distribution will be perfected.

General Remarks.—There is one factor, which has not been brought into the discussion, but which cannot be ignored, when calculating deflections that occur under prolonged loading. This is the so-called time effect. The modulus of elasticity is defined as the ratio between stress and strain, when both are measured immediately after the load is applied. Tests show that when the stress is maintained for some time, the deformation continues to increase and that it approaches its maximum value asymptotically. This continued yielding under constant stress is known as the time effect. Due to this characteristic of concrete, the stress multiplied by the modulus of elasticity, as ordinarily measured, gives only the deformation, which occurs at once, when the load is applied and this deformation is much smaller than the actual deformation due to the load acting over a considerable period of time.

F. R. McMillan, M. Am. Soc. C. E., has tested† a reinforced concrete beam in bending over a considerable period of time. The concrete was of good quality and was 6 weeks old when the test was started. Immediately

* See p. 789, Table 1, Column (4); for the crest, the central angle is about 80 degrees.

† "Shrinkage and Time Effect in Reinforced Concrete," Univ. of Minnesota, Studies in Engineering, No. 3, March, 1915, Fig. 8.

after the load had been applied, the deformation of the concrete was 0.0021 in. on an 8-in. gauge length. This was measured in the center of the span and on the compression face of the beam. After nearly 60 days under the same load, the deformation was 0.0039 in., an increase of nearly 100 per cent. At this time an additional load was applied, increasing the deformation to 0.0047 in.; 60 days later this had increased to 0.0063 in. and after an additional 60 days to 0.0072 in. Expressing the last three figures as percentages, they are 100, 134, and 153. Another beam* had a deformation of 0.0027 in. in an 8-in. gauge length, immediately after the load had been applied; 20 days later, it was 0.0064 in., and after another 20 days, it was 0.0069 in. About a year after the test was started the deformation was 0.0101 in. and this is 3.74 times the deformation which took place at once and from which the modulus of elasticity would be derived. In all these tests the shrinkage was measured separately and allowed for, so that the change in deformation given, is that due to time effect only.

Mr. Charles M. Montgomery reports† a compression test on an 8 by 16-in. concrete cylinder, which was about 4 years old at the time of test. It had been stored in damp sand for more than 3 years and the remainder of the time it had been exposed to air. The mix was approximately 1:2:4 and the crushing strength was 3 550 lb. per sq. in. A load equivalent to a stress of 300 lb. per sq. in. was applied on March 22 and the deformation was 0.0014 in., measured immediately after the load was applied. After 24 hours the load was removed and immediately replaced and the deformation was 0.0024 in. After another 24 hours, it was 0.0028 in. The results of the test are shown in Fig. 23. After about 12 to 14 days, the concrete seems to have taken its final deformation and this is about three times as great as the one first measured. The concrete appears to have been of a good grade and the stress was less than 10% of the ultimate strength. No allowance was made for shrinkage in this case, but it seems very unlikely that this could have affected the deformations more than a few per cent.

A. H. Fuller and C. C. More, Members, Am. Soc. C. E., loaded three cylinders‡ cut from the floor of a building. The cylinders were from 101 to 137 days old. With a stress of 650 lb. per sq. in., the deformation of one of the cylinders, 14 days after load had been applied, was 15 dial units, and 54 days later it was 42, or 2.8 times the first measurement. The deformation was still increasing, but at a slower rate. Another of the cylinders was tested under a stress of 1 150 lb. per sq. in.; 14 days after test started, the deformation was 33 dial units and 54 days later, it was 78, or 2.36 times the first measurement. The first reading taken on this cylinder was about a week after applying the load, when a deformation of 22 dial units was found; 250 days after starting the test, the deformation was 120, or nearly six times as large as the reading after one week of test.

These tests will suffice to show the very great influence of the time factor; it appears that part of the deformation is plastic and part elastic and that time is also a factor in the recovery. The rapidity of filling of the reservoir will determine to what extent the time effect may be counted on to compensate for shrinkage.

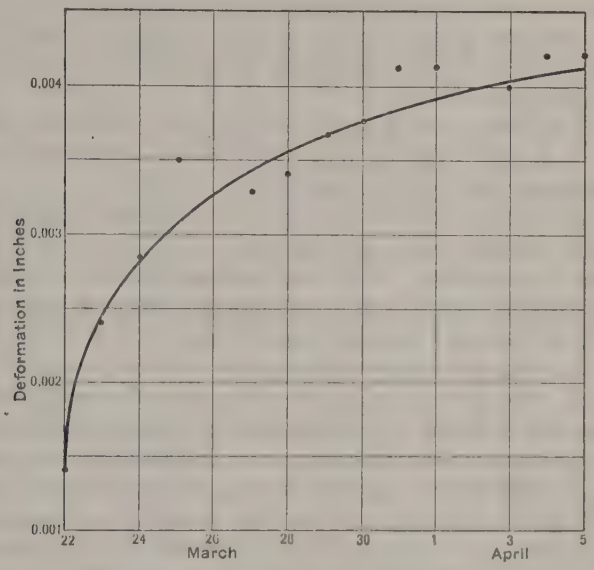

FIG. 23.—INCREASE IN DEFORMATION DUE TO TIME EFFECT.

These tests on small samples bring up the question as to whether concrete in mass will obey the same law. In discussing the Lake Spaulding Dam, F. A. Noetzli, M. Am. Soc. C. E., computed the deflection at crest* as 0.36 in., based on a modulus of elasticity of 2 000 000 lb. per sq. in. and he states that the measured deflection is 3.44 in. and, further, that: "This * * * shows, that the cantilever deflected, as measured, about ten times as much as the laws of elasticity really would permit."

Mr. Noetzli did not take account of the swelling of the up-stream face, the yielding of the foundation, and the shear deflection, but these omissions are not sufficient to account for the very great discrepancy, although they may more than double the calculated deflection. If, in addition, the time effect is sufficient to increase the deformation from three to four times, then there is a very fair agreement between calculated and measured deflections. The tests previously referred to indicate that such an increase is quite possible.

Mr. Noetzli concluded that the cantilever must have cracked at the base, since otherwise he could not account for the fact that the measured deflection was ten times larger than his computed deflection. Mr. Jorgensen, however, stated † that if the cantilever was cracked to any depth, leakage should

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 54.
† *Loc. cit.*, p. 70.

occur through the 6-in. drain pipes placed in the up-stream third of the dam, but that virtually no leakage had occurred. He also stated that the zero point for deflection was probably located before the chemical heat had been dissipated and while the cantilever was bent up stream by the swelling of the arches due to heat; but this effect, combined with the effect of swelling, yielding of the foundation, and deflection due to shear, is not sufficient to account for the very great discrepancy and it seems to the writer that it must be admitted that time effect was responsible for a considerable portion of the additional deflection.

On the other hand, the leakage through the Mulholland Dam, already referred to, indicates that the total deformation is not sufficient to compensate completely for the shrinkage effect.

It must be evident that the problem is a complicated one and engineers designing dams should be careful to make only such assumptions as are known to be conservative. It is also evident, that the relation between stresses and deformations in a large concrete structure, is not a simple linear one, as it is for steel, and that much care is necessary in order to draw correct conclusions regarding stress distribution from deformations in concrete.

It was the writer's intention to show that arched gravity dams should be calculated as such and not as straight gravity dams and after reviewing the discussions, he believes that, hereafter, they will be so treated. He intended to limit the investigation to gravity action, but nearly every engineer who took part in the discussion brought in the question of arch action. That is interesting, because it indicates a shifting of preference from gravity to arch dams. If arch action must be depended upon to provide the real factor of safety, this should be given due consideration in the design and that will mean large central angles and small radii; that is, arch dams. Gravity action must exist in any dam to some extent; yet engineers designing arch dams do not have to bring in gravity action to show the existence of a factor of safety, while, as this discussion has shown, the reverse is not true.

The writer feels amply rewarded for the time he has devoted to this subject by the interest shown by other engineers and in closing he wishes to thank those who have participated in the discussion.

Paper No. 1673

MODERN CRUSHED STONE AND GRAVEL SURFACING*

By J. W. Hoover,† Esq.

With Discussion by Messrs. Roy A. Klein, C. H. Purcell, and O. E. Stanley.

In his address at the Washington Convention of the National Sand and Gravel Association, on January 25, 1923, E. W. James, Chief of the Division of Design of the United States Bureau of Public Roads, stated that, of the roads constructed with the assistance of Federal Aid funds, 40.4% of the mileage was gravel surfaced and that such roads had absorbed approximately one-fourth of the Federal Aid funds expended to that date. States, counties, and townships construct independently, or without Federal assistance, several times the road mileage built with Federal aid. The subject, therefore, is of considerable importance to the Nation and to each individual community.

Much might be said of the economic value of stone and gravel surfacing; of the volume of traffic that will justify the change from a dirt road to a gravel or crushed rock surface and from such surfaces to more expensive and satisfactory pavement. The time at which each change becomes advisable must be determined for each road. To state as a general proposition that a traffic of 300 or 400 cars per day, or so many tons per day, justifies a change of type of surfacing, is to err. The cost of maintenance of the existing surface and the expense of the construction and maintenance of a higher type of surface differ for each locality. The value for a highway in the State of Washington would not serve in another State except as a coincidence; the principle involved is the same, however, and should be based on the various costs as affected by sub-grade, traffic, and climate.

The most important consideration is service to the public. Just how good a road is the public entitled to have? As a general rule, the automobile owner is supplying the funds; it is his money and his road; how good should it be?

A number of engineers state that the paving of a highway is warranted when the traffic has reached 400 to 500 cars per day, or approximately the

* Presented at the meeting of the Highway Division, Seattle, Wash., July 15, 1926.
† State Highway Engr., Olympia, Wash.

same number of tons per day based on certain average conditions in certain localities. None has attempted to fix the volume of traffic that would be considered sufficient to justify gravel surfacing; the general idea seems to be that if a road is worth building at all, a gravel surface is justified. The writer doubts if many paved roads are carrying less than 1 000 cars per day, and thousands of miles of gravel roads are carrying more than 1 500 cars per day.

After all, the question of the time to change the type of surface is dependent on the funds available and seldom on the real economics of the situation for the reason that improvements are far behind the requirements of traffic. A great majority of the highways are now carrying more traffic than the width and type of surface justify, considering the economic value and the service to which the public feels entitled. The question of which road shall be improved first may be answered on the basis of traffic, although often the decision is made by the legislative body making the appropriations, disregarding the merits of the respective roads.

The sub-grade on which the surfacing materials are to be placed should provide a well-drained stable foundation. The soil, as well as practical drainage, and the climate should be considered before the surfacing materials are selected and before the width and thickness of surface are determined.

After the sub-grade has been studied and the present and probable future traffic has been determined, the metal—either gravel, crushed gravel, or crushed rock—may be selected. The criterion for such selection should be that the material selected furnish the service required at the least cost. Hand in hand with the selection of the metal is the design of the cross-section.

A surface 12 ft. wide and 6 in. thick may be all that is necessary for light traffic. However, there is, and no doubt will be for some time, a large mileage of unpaved highway that is subjected to traffic sufficient to justify paving. The writer would recommend a width of not less than 18 ft., a thickness at the edges of 9 to 10 in., and a center thickness of 7 to 8 in. If the sub-grade is unstable, additional thickness should be provided. A design similar to that described is of more importance where water-bound macadam and dust-prevention methods through oiling or other surface treatments are contemplated or probable in the near future.

At first, the maximum size of gravel or crushed rock was rather large, often as much as 3 in. With more improved and extensive maintenance methods, the size was reduced until 1½ in. for the base course and ¾ in. for the top course became common, with occasional specifications limiting the base rock to a maximum of 1 in. and the top course to ¾ in.

Practically all these roads were maintained by frequent dragging, and the ideal was expressed as a smooth compact base covered with ½ in. to 1 in. of loose material to be worked back and forth across the road by the drag or grader. Highway surface construction passed through the coarse rock stage and there is now a large mileage of fine rock surfacing that may be treated to give a surface free from dust.

A tendency is now developing to change to coarser rock or gravel in surface treatments in order to secure a smooth, compact road free from loose material where the travel is heavy and where dust prevention is desirable.

The selection of gravel, crushed gravel, or crushed rock as a surfacing has been based largely on the cost of the material on the road. This has resulted in natural gravel surfaces or crushed gravel surfaces in the glaciated areas and crushed rock surfaces in unglaciated areas. In general, crushed rock has given the best service, with crushed gravel and pit-run, screened gravel in the order named. Deposits of natural fine gravel, however, sometimes give as good results as the best crushed rock.

The question of hardness of gravel or rock for surfacing has been studied a great deal and, in general, the limits set forth in the specifications of the various States produce good results. It is not practical to use the same specifications in all the States on account of differences in the materials available, the soil, traffic, and climate. Very often, the material available would not pass the specified tests, nevertheless, it makes the best of road surfacing under the circumstances. The policy of the State of Washington is to test the materials before the contract is advertised. Through the specifications the bidders are then advised of the requirements for each grade of material. In this way the contractor is fully advised before making his bid as to the sources of gravel or rock, uncertainty is greatly reduced, and the State receives a better bid for the work.

The following is a brief review of gravel or crushed-rock surfacing specifications for a roadway that is to be maintained by dragging loose material back and forth:

(1) The sub-grade shall be smooth and true to the required cross-section and all large rock removed. The surfacing material shall be uniformly distributed on the sub-grade.

If the inspector should be lax in this requirement the surfacing will not be smooth and traffic will work depressions where the material is not uniform and considerable time may be required before the maintenance forces can furnish a first-class riding surface. The usual specifications also require that the contractor, as far as practical, shall do his hauling over the surfacing as it is placed.

(2) The surfacing material shall be dragged as much as necessary to keep it smooth. Where the surfacing is to be in two courses, the contractor is required to construct as much of the base course as possible from any one setting of bunkers before beginning the top course. If the entire product of the crusher is to be placed in the base course, the entire base course shall be constructed before starting the top course. If the product of the crusher is separated into two sizes only, the base course is constructed until the section of the bunkers for the finer material is filled, at which time the top course may be started.

In this way the hauling equipment is used to secure as much compacting of the two courses as practical. By dragging the surfacing and keeping it smooth the trucks do not follow the same tracks, and the traffic is distributed over a wider area. Few specifications give sufficient attention to the binding material for the surfacing. The average specification permits the use of side-of-the-road material, or any other material that is easily available, that has binding qualities. The binding material should be a water-resistant clay

which will harden when mixed with the surfacing material. The State of Oregon has given this part of the work a great deal of attention during the past few years and has secured good results.

Too much emphasis cannot be placed on the necessity for keeping the sub-grade and each course of surfacing smooth during the entire construction of the road and afterward by the maintenance organization. The best results are obtained in this type of surfacing by constructing it in at least two courses, the base course containing rock of a maximum size of $1\frac{1}{2}$ in. and the top course composed of rock which will pass a $\frac{3}{4}$-in. ring. The two courses should be of equal thickness, and each not less than 3 in. The thickness of the surfacing depends on the character of the sub-grade, the traffic, and the climatic conditions. In some places, such as the arid regions of Washington where the annual rainfall is only 6 to 10 in., light surfacing wears very well. In other parts of the State a very heavy surface course is necessary as the annual rainfall may be more than 100 in. per year and the sub-grade very soft when wet. The best results in the heavy rainfall area are obtained by using the product of the crusher in the base course as this forms a crust with comparatively little binder due to the interlocking effect of the crushed material. In the arid regions the product of the crusher may be separated into the two sizes, the base course being bound with clay after which the top course is placed and bound with clay. A great variety of specifications for the size of material in each course is possible, dependent on the materials that are available.

The available materials should be thoroughly studied for each project. In some localities there is no choice. Surfacing in more than two courses is often advisable on account of a soft sub-grade that cannot be drained or raised without excessive cost. In some instances a base course of large rock is advisable and economical.

Gravel or crushed rock surfaces are maintained by dragging with a grader or drag having a comparatively long wheel-base. Some roads must be dragged more often than others, depending on the stability of the sub-grade, the character of the surface, the kind and volume of traffic, and the climatic conditions. Additional material must be added as the original material is ground up and blown away or pounded into the sub-grade. The surface must be kept smooth, for if it once becomes rough a considerable cost is entailed in scarifying, re-shaping, and compacting.

Surface treatment with oils gives promise of eliminating the dust nuisance. In some States oil treatment will be costly, as the type of surfacing in use is not adapted to such treatment and is less expensive than surfacing on which oil works best.

There is no final answer—no one final specification for a modern crushed stone or gravel road; possibly there are but few fundamentals that will apply under all circumstances. Soil, climate, traffic, materials of construction, and funds fix the limits to which construction may be carried. Surfacing of the type discussed is being studied and will be improved. Highway engineering has made wonderful strides in the last ten years and gives promise of producing a road surface that will serve adequately in many places until higher types of pavement are warranted.

DISCUSSION

ROY A. KLEIN,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer agrees that crushed stone and gravel surfacing will continue for some time to be the dominant type of surfacing for the vast mileage of rural highways of the nation.

As to the selection of the most serviceable types of road surface, the saving in operation effected by the construction of higher types does not accrue to the agency that performs the work, but rather to the people who operate motor vehicles. Therefore, since the agencies that build the highways do not operate them, it is obviously impossible to plan highway improvements based on any theory of pure economics. However, since the highway engineer represents the public in the last analysis, he should plan to build and maintain carefully the best type of surface that the funds secured by taxation will provide.

It is difficult to determine the exact amount of motor-vehicle traffic or tonnage at which it is feasible or desirable to change to a higher type of surfacing, because there are a number of different factors that affect local conditions. Stage construction, that is, building standard graded earth road first, crushed rock or gravel surface next, and then pavement, as the demands of traffic increase, is a logical and economical program. When the crushed rock or gravel surface is worn out, the road-bed will have become well stabilized and the remainder of the surfacing material will form a good base for the pavement. On the other hand, if the demands of travel do not justify pavement, a re-surface can be added at a fraction of the original cost; thus, in either case, the annual cost for the use of the road surface is a relatively small amount.

The importance of foundations has been stressed by the author, and that is a point well taken. When there is any question as to the strength of the sub-grade, the best insurance is to provide a sub-surface course of large stone, crusher run, of 4 in. maximum size, in a layer ranging from 4 to 12 in., depending on conditions. The use of large base stone on sections where the soil shows excessive capillary action has been quite successful in Oregon, the larger voids between the rocks breaking up the capillarity. On sections where these foundation courses have been used, the maintenance cost of the surfacing has been considerably less than on other sections constructed under similar conditions, because the surface does not break through in the spring.

The construction of the thickened edge and the thinner center for macadams as well as pavements appears logical and is quite simple. The edge has always been the point of weakness of the "feather-edge" macadams; particularly under softened sub-grade conditions. The thickened edge will make it possible to maintain the full designed roadway width without loss by wearing away on the sides. The Oregon State Highway Department has several thickened-edge macadams completed and the results are very satisfactory.

On main traveled roads, the surfacing should not be less than 18 ft. wide and preferably 20 ft. The greater width, of course, permits and encourages

* State Highway Engr., Salem, Ore.

the traffic to spread over the entire road rather than confine itself to a single rut, thus reducing maintenance cost.

In reference to the selection of materials and the desirability of hardness of materials or resistance to wear, it may be said that the general practice is to classify materials by the standard abrasion tests. It should be remembered, however, that all abrasion tests are made on dry materials, while material in the road is subject to the greatest wear in wet seasons. In a recent test, made in the Oregon State Highway Department Laboratory wet material showed an abrasion four times as great as dry material.

A few years ago, it was standard practice to provide a thick layer of fine materials in the top course under the principle of providing a loose mulch which could be constantly kept in shape by blade graders. Intensive maintenance was necessary under these conditions to prevent corrugations from forming. This intensive maintenance, while it rendered the road smooth, resulted in a dusty condition that was very disagreeable and actually hazardous when the road carried much traffic. Many experiments were made to set up the top surfacing with clay and produce a hard, compact surface. These tests were quite successful and, in turn, led to the use of an oil covering on the clay-bound surface.

At first glance the value of fine material would appear to be minimized by the use of oil since it would no longer be moved about by the blade machine. It would then seem that the old specification of water-bound macadam, using the larger stones, might well be adopted. However, there are several important reasons for not using larger stone: First, there would be little economy, because the improvement in crushing equipment produces the smaller sizes at practically the same cost; second, experience indicates that it is necessary to scarify an oil-treated road at intervals and if the larger stones are used, the scarifying is more expensive and the cost of resetting the materials greater; and third, it is difficult to obtain a smooth, even surface, true to grade, crown, and cross-section, with coarse materials. For these reasons there should not be less than 2 in. of compacted materials, ranging from $\frac{3}{4}$ in. to dust, in the top course. The base course material should range in size from $1\frac{1}{2}$ in. to $\frac{3}{4}$ in., both courses being well graded between limiting sizes.

The practice in Oregon is to mix all courses with clay thoroughly with the blade machine, using the ridge method, the quantity of clay varying between 20 and 40%, depending on the quality. Care should be taken to secure a slow-slaking clay with a high tensile strength. In some instances, in order to secure the best clay, it has been found necessary to haul it a greater distance than the crushed rock. However, many pits and quarries contain a good natural binder by which it is possible to procure a compact surface without the use of clay. Surfacing, bound up with clay, will not be ready to receive an oil treatment until after it has gone through a winter season.

Mr. Hoover has stressed the necessity of having a smooth sub-grade before beginning construction. Generally, a rough surface is caused by a rough sub-grade, and it is very expensive to take out the irregularities on the last course of surfacing by using fine broken stone. The necessity for proper

maintenance during construction is also very apparent. The Oregon specifications state the kind and minimum amount of equipment that the contractor must furnish for the construction of a crushed rock or gravel surfacing project.

No mention has been made of the desirability of crushed gravel as compared with screened materials, but the advantage is so obvious as to preclude discussion. It should be the constant aim of all highway engineers to try to discover, by trial and experimentation, better methods of building these crushed rock and gravel road surfaces, commonly called macadams. The field is large and the opportunity great.

C. H. Purcell,* Assoc. M. Am. Soc. C. E. (by letter).—Attention has been called by Mr. Hoover to the large amount of Federal Aid money that has been expended on crushed stone or gravel construction. The fine-rock road is the contribution that engineers have made to the solution of automobile transportation problems. It might be well to emphasize further the important place that this type of road occupies in the development of a connected system of highways.

The financing of these highway projects has compelled engineers to make thorough studies of the crushed-rock road as a means of providing a large mileage as quickly as possible. Mr. Hoover is one who is faced with this problem and his paper brings the facts out clearly.

The great distances between towns, the necessity for roads that will carry traffic at high speed every day in the year, and the limited finances available to meet the increasing demand for mileage, have resulted in this pioneer type of road. It occupies a more important position in the West than in the wealthier and more densely populated sections of the country. There it has revolutionized travel and taken care of the great increase in motor transportation.

The fine-crushed rock road is peculiarly adapted to the region between the Rocky Mountains and the Pacific Ocean. It can be laid at low costs because of the quantity production of crushed rock and gravel. Suitable road material of various kinds is available practically throughout the entire section.

The engineer's problem has been to develop a type of surfacing that could be cheaply and rapidly built, and that could be easily maintained during the dry summer period when traffic reaches its peak. The success of this type in developing traffic has brought its own problems. Dust prevention is one of the most important construction questions confronting highway engineers in the West; for dust means a loss of road metal, discomfort, and perhaps danger to the motorist.

The suggestion made by Mr. Hoover that a section following pavement design more closely, and providing an increased thickness at the edge, is one step farther toward designing this fine-crushed rock road so that it can serve in the future as one stage of a higher type of road. If properly constructed and maintained, solving the loss of metal, it will serve as a base.

* Chf. of Div. and State Highway Engr., Div. of Highways, Sacramento, Calif.

For a future 18-ft. surface it would be better if the base were extended out at least 1 ft. on each side beyond the proposed top surface. The tendency (under maintenance) to increase the crown of fine-crushed roads has produced an unsatisfactory base for future surface. When preparations are made to put on a top surface the necessary scarifying to reduce the crown often destroys the bond between the rock at the center, and sometimes a thin base is the result.

The early fine-crushed rock roads in some of the Western States were designed with a feather-edge section. All recent construction is built in a trench section, thus securing a thicker edge. This change was brought about by the desire to have sufficient thickness at the edge to support the concentrated traffic. Experience with surface treatment has shown the importance of the thickened edge. For example, many of the roads in Oregon that have been surface-treated were originally constructed with feather edges. The relatively high cost of maintenance at the edges as compared to other portions of the surface has led to the change. Mr. Hoover's suggestion for a thicker edge is worth considering. In the West where long distances were surfaced with fine rock, many of the roads were built only 12 ft. wide and the road widened out, under maintenance, into a two-way road. It became necessary to re-shape these roads and add more rock before the surface could be treated.

In New England, where surfacing of the penetration type has been developed over a long period of years, old bases of water-bound macadam have been available. The fine-crushed rock roads in the West, built of sufficient width and maintained at a proper thickness for a base (9 in. loose) will carry a penetration surface under the moderate traffic encountered. In fact, such roads, correctly built, can be designed to serve as the first step in the evolution of several better types. If they have a carefully processed top with a moderate amount of sand-clay binder, they can be given the oil treatment. Later, when the need requires it, they can be finished with an asphaltic penetration surface; and, finally, as the traffic becomes heavier, this may be followed by even higher types of surfacing.

Many of the fine-crushed rock roads have been constructed with either a 4-in. or a 5-in. bottom course and a 4-in. top course. The State of Oregon has been a pioneer in oil treatment of fine-crushed rock roads. Since the development of asphalt surface treatment, it has been building a thicker base course and a thinner top course. This change has only been made, of course, in cases where it was reasonably certain that some plan of surface treatment was to be applied as soon as the surface had become sufficiently compacted under maintenance.

The author has pointed out one of the very essential items that enter into a successful fine-crushed rock road, namely, the matter of uniform distribution of material. No matter how well the present modern field crushing plants are designed, there seems to be a lack of uniformity of grading between the different truck loads as they are deposited on the road. It is also difficult to distribute the filler or binder evenly over the surfacing material without

adopting some means of mixing them after they are spread. The excellent results of surface treatment noted by the author in the section east of the Cascade Range, were due in no small measure to the attention given to this detail of construction. Great care was taken to insure a uniform mixture of material. Wherever water was available, the material was thoroughly soaked while being spread and processed on the road. If the surface is not wet down a large percentage of the binder is fanned out by the traffic and lost before the top has a chance to set up. As in the higher types of road, the most successful results can only be obtained by strict attention to the details of design and construction.

Too much stress cannot be placed upon the fact that actual service to the public is the determining factor. It is the duty of the highway engineer to emphasize continually the need of providing funds sufficient to furnish the public the highest possible type of service. The traffic volume is so large on many roads that the maximum expenditure will be warranted on the basis of service value to the traffic, and the saving in operation costs.

Many State and Government agencies have investigated the saving of cost of tire and gasoline consumption on the various types of pavement. The writer does not know of any investigation of the depreciation on automobile engine, body, and other mechanism, due to the jolting on a rough, unimproved, earth road. It may be learned that the saving in rubber and gasoline is a small sum compared with this other greater loss to the automobile owner. If this is the case, the fine-crushed rock road of the West, which has been extended so rapidly at the moderate cost of from $3 500 to $6 000 per mile, shows a remarkable saving. This accomplishment of the engineer, although not receiving as much attention as the paving, is far greater.

O. E. Stanley,* M. Am. Soc. C. E.—In Portland, Ore., there are about 200 miles of old macadam streets, built 10 to 20 years ago.

These streets are maintained by reshaping, when necessary, with a steam roller, and giving them a coat of oil. After the road is shaped to the proper cross-section (which the foreman gets with his eye, using the curbs as guides), it is sprinkled and rolled until the fine material, or "soup", is brought to the surface. The road is then left open to the traffic for probably two weeks until the fine material dries and blows away.

There are a great many complaints about dust, but as soon as the dust has worn off and the surface of the rock is exposed, oil is applied with very good results; these roads remain in good condition from 1 to 3 years. When little holes wear in the surface, after about this length of time, they are patched with a mixture of asphalt and crushed rock. Sometimes only two or three holes occur in a block.

With this oil treatment, results are obtained that make some of the contractors wish the process had not been discovered.

Paper No. 1674

RELATION OF ROAD TYPE TO TIRE WEAR*

By O. L. Waller† and H. E. Phelps,‡ Members, Am. Soc. C. E.

With Discussion by Messrs. Troy Carmichael, and O. L. Waller and H. E. Phelps.

Synopsis

The study of the wear of automobile tires has been made to determine the destructive effect of different types of road surfaces on the tread rubber in order that, as far as possible, surfaces may be so improved as to make the cost of building and maintaining road surfaces and of operating the traffic over them a minimum. The cost of tires is one element of the cost of operating motor vehicles and may well be studied.

The University of Kansas, co-operating with the United States Bureau of Public Roads, and the State College of Washington, have conducted a series of tests in an effort to determine the loss of tread rubber caused by several types of road surfaces. The surfaces studied have been concrete, brick, and bitulithic pavements, penetration macadam, and several types of gravel and broken stone. The results of these tests are given in this paper. The factors influencing tire wear are discussed, and an effort is made to evaluate some of these factors. The following tentative conclusions have been drawn from the few data now available:

1.—Tire wear increases with the speed. Sufficient data are not available to indicate the rate of increase.
2.—Tire wear increases with the temperature. Road tests indicate this relationship, but are not consistent and yield no information on the rate of increase. Laboratory tests by Professor W. C. McNown, at the University of Kansas, are likewise not conclusive,

* Presented at the meeting of the Highway Division, Seattle, Wash., July 15, 1926.
† Vice-Pres., State Coll. of Washington, and Head, Dept. of Civ. Eng., Pullman, Wash.
‡ Prof., Highway Eng., State Coll. of Washington, Pullman, Wash.

but indicate a moderate rate of increase in tire wear with increase of temperature. High temperatures are very destructive to tires.

3.—The wear of rear tires is greater than that of front tires, the relative wear of rear tires being 200% on smooth pavements and as little as 118% on gravel surfaces, probably averaging 150% of the wear on front tires.

4.—Tire wear per ton of car is probably constant for any given road surface, when size of tire, load, and inflation pressure are determined by a single standard.

5.—A few records of bus companies show actual tire-mileage life on different road surfaces in approximate agreement with tire wear tests on similar surfaces.

6.—Relative tire wear index numbers, based on average concrete pavement as 1.0, are approximately 2.0 for good gravel and macadam, 4.0 to 5.0 for average Western macadam or uncrushed chert gravels, and may be as high as 10 or 11 for unusually unfavorable surfaces. Based on tire wear alone, average sized cord tires should show a life of 20 000 to 24 000 miles on pavements, 10 000 to 12 000 miles on good gravel or macadam, and as little as 2 000 to 4 000 miles on unfavorable surfaces. The corresponding costs per vehicle-mile are about 0.5 cent for pavements, 1.0 cent for average gravel or best macadam, 2.3 cents for average macadam, and perhaps as much as 5 cents per vehicle-mile on road surfaces of loose, sharp-edged stones.

Introduction

The making and operating of automobiles and the building of roads on which they are run are major American industries. In 1925 automobile owners paid $260 619 621 for registration fees, licenses, fines, etc., and, in addition, a gasoline tax, effective in all but four States, totaling $146 028 940, or a total payment by automobile owners and operators of $406 648 561 almost all of which was expended for highway purposes.

The total funds expended in the construction and maintenance of roads and streets is about $1 000 000 000 annually. About 10 000 miles of Federal Aid roads were completed in 1925 and perhaps 20 000 miles of surfaced roads were built by States and counties without aid from the National Government.

Such an enormous investment in motor vehicles and highways makes the problem of securing the most economic surface for highway transport of the utmost importance. This problem will be solved when, for any particular highway, the road surface as well as the vehicles using the road are such as to produce minimum transportation costs.

In making economic comparisons between different road surfaces, costs which arise from the operation of the vehicle and those which arise from the highway itself must be considered in order that the total cost of highway transportation may be a minimum. The condition is rapidly being reached in which the automobile owner pays both the cost of operating his car and a large part of the cost of building and maintaining the roadways upon which it operates. He should be interested, therefore, in the effect of various roadway surfaces on motor-vehicle operating costs as well as in the cost of building and maintaining such surfaces.

Road money cannot all be spent on a few miles of exceptionally fine arterial highway. Such a plan would favor some and leave the less fortunate travelers to use unimproved dirt and mud roads.

If all roads could be paved, a great saving in operating expenses would be made, but this is not possible. Only roads carrying heavy traffic can be paved. On those carrying lighter traffic, gravel and broken stone surfaces must be used. The other millions of miles of plain dirt roads are usually not well graded nor well drained; but traffic which uses these poor roads must pay not only its share for constructing the paved roads, but also must then use the unimproved roads with the added expense per car-mile. The vehicle-mile should be made the measure of road expenditures. This is a measure of the traffic service rendered.

The cost of operating a motor vehicle is the sum of the costs of gasoline, oil, tires, maintenance, depreciation, interest, insurance, garage, and license, the first five being items influenced by the roadway surface on which the vehicle is generally operated.

The gasoline requirements of motor vehicles on various roadway surfaces has been investigated by T. R. Agg, M. Am. Soc. C. E., and others, and their findings are generally known and frequently quoted. It is generally believed that the maintenance and depreciation costs are likewise influenced by the character of the road surface over which the motor vehicle is most frequently operated, but no determination of the magnitude of this influence has yet been made to the knowledge of the writers. Tire wear tests have been made at the University of Kansas and the State College of Washington. These tests are brought together in Table 1, and summarized in Tables 2 and 3. The results summarized in Table 3 are given in two units, as tire wear in pounds per 1 000 miles and as wear on various surfaces relative to the wear on concrete pavements taken as a standard.

In making tests to determine the wear on tread rubber a considerable number of elements enter into the problem, some of which are as follows:

Factors Affecting Tire Wear.—

I.—Those pertaining to the road surface:
- (*a*) The kind of surface.
- (*b*) Its condition.

II.—Those pertaining to the car:
- (*a*) Weight of car:
  - (1) Sprung.
  - (2) Unsprung.
- (*b*) Number of engine cylinders.
- (*c*) Character of springs.
- (*d*) Alignment of wheels.

III.—Those pertaining to the driver:
- (*a*) The speed used and wind resistance.
- (*b*) The method of operating brakes.
- (*c*) Number of emergency stops.
- (*d*) Skids, acceleration, and deceleration.
- (*e*) General care and skill displayed in driving.

IV.—Climatic conditions:

(*a*) Air temperatures.
(*b*) Amount and distribution of rainfall.
(*c*) Amount of sunshine.

V.—Those inherent in the tire:

(*a*) Kind of tire.
(*b*) Quality of the tire.
(*c*) Character of the tread.
(*d*) Inflation pressure.
(*e*) Temperature of the tire.
(*f*) Age of the tire.

In order to study the effect of any one factor on the wear of tires all other factors should be kept constant during a single series of tests. This may be accomplished by using the same equipment and by making the tests over the same piece of road in the same condition of maintenance and under corresponding temperature conditions at the same speed, with tires of the same type and age and with the same degree of inflation, with the same driver and with the chassis in the same state of maintenance. In this way a considerable number of the unknown factors may be eliminated. There will still remain the type of road, the condition of the surface, both as to roughness, sharpness of material, compactness, and the quantity of uncompacted loose material floating over the surface.

The relationship between tire wear and gasoline consumption might profitably be studied. If such a relationship can be determined then every one will have a reasonably good gauge by which to measure the destructive effect of different types of road surfaces on tires and car upkeep. To do this, the gasoline should be metered by a recording device to show graphically the gasoline consumption as a continuous record.

The relationship between surface roughness and gasoline consumption and tire wear would supply much needed information on road surface types and on the best methods of maintaining earth and gravel roads. A continuous autographic record of the gas metered to the carburetor should be kept and made to synchronize with a graph showing vertical uneveness.

Preliminary to the tests at the State College of Washington, the tires and rims were removed from the wheels and were thoroughly cleaned with a brush and bellows. The valve cores were then removed and the deflated tires with the rims were accurately weighed. The valve cores were then replaced and the tires inflated to the proper pressure and replaced on the wheels. The car was then driven at uniform speed over the selected road, and at the conclusion of the test the tires were again removed, cleaned, and weighed.

The roads used for test purposes were of brick, concrete, bitulithic, penetration macadam, gravel, and Western type broken stone macadam. All the tests on brick roads were made in Kansas by Professor McNown, who likewise conducted tests on concrete pavements, penetration macadam, and gravel roads made of several different materials. The State College of Washington tests were made on bitulithic and concrete pavements, water-worn gravel, and Western type broken stone macadam.

Crushed Stone Roads in Washington

The crushed stone highways of Washington, owing to lack of water in many localities, are not water-bound. Water has been available for only a few roads. The general practice is to use finer material than is common in water-bound macadam, both in the bottom and the top courses. After construction, the roads are left for the traffic to roll. The crushed stone used is generally basalt of good quality as to hardness, toughness, and resistance to abrasion. It is usually screened into two bins, one receiving the material from $\frac{3}{8}$ in. to $1\frac{1}{2}$ or 2 in. in size, and the other bin receiving the finer material.

TABLE 2.—Summary of Tests.

	Loss, in pounds per 1 000 miles.
Best results on concrete, Washington	0.0825
" " " " , Kansas	0.0904
Average of all tests, Washington concrete	0.0852
" " " " , Kansas concrete	0.1689
Poorest results on Washington concrete	0.2080

" " " Kansas concrete, balloon tires	0.3571
Monolithic brick, a single run	0.2690
Bituminous-filled brick, average	0.1560
Bitulithic, average	0.1247
Bituminous macadam, best	0.2998
Bituminous macadam, poorest, average	1.2672
Gravel, typical good, Iowa	0.2668
Gravel, uncrushed chert	0.6526
Gravel, Washington, water-worn, average	0.6250
Macadam, Washington type, best	0.2440
" " " , average	0.5800
" " " , poorest	1.4560

The stone is spread in two courses, each approximately one-half the total thickness. A layer of clay or sandy loam is spread over the base course for a binder. The traffic and trucks hauling stone do the rolling, and a blade grader is frequently run over it to keep the ruts filled. Over this a finer top course is spread, but no binder is used. The surface of the road is left with a layer of sharp, fine, loose material, which adds considerable resistance to the movement of the car and to the wear on the tires.

TABLE 3.—Relative Tire Wear on Various Road Surfaces.

Character of surface.	Wear, in pounds per 1 000 miles.	Index number.
Bitulithic, average of all tests	0.1247	0.945
Concrete, average of all tests	0.1319	1.00
Brick, average of all tests	0.1786	1.36
Bituminous macadam, best	0.2998	2.28

Gravel, typical, Iowa	0.2668	2.02
Macadam, Washington type, best	0.2440	1.85
" " " , average	0.5800	4.40
Gravel, uncrushed, best	0.6526	4.95
Macadam, Washington type, poor	1.4560	11.05
Concrete, average of seven best	0.0657	0.49

Maintenance

The broken stone and gravel roads of Washington are in all stages of maintenance. The surfaces of new roads are loose, just as they are left by the contractor after the top course had been trued up with the blade grader. Under such conditions, automobile tires push the loose gravel or broken stone out to the sides of the road and form ruts, a process destructive to tread rubber and one that forces the car continually to ascend a constant incline.

The same conditions, only in a lesser degree, obtain on roads compacted through use, that have been recently bladed to fill pot-holes and to plane off corrugations. This kind of maintenance leaves a thinner layer of loose material for the traffic to work over and through. Where maintenance is not frequent and regular, the roads soon develop pot-holes and corrugations which greatly reduce riding comfort, shorten the life of the car, and increase the destruction of tread rubber.

For the broken rock and gravel roads here enumerated, it is difficult to describe the condition of the particular road surface under test, and certainly no standard surface conditions can be secured. The surface of any piece of test road will be subject to wide variations. Even on the same road two runs might give a wide variation in gasoline consumed and rubber worn away, depending on whether the car was driven over the well beaten track or on the loose, floating material.

It should be kept in mind that at normal speed and where the road surface is rough, full of pot-holes, or corrugated, tires are not in contact with the surface at all times, or at least the pressure on the road is not constant. When the rear wheels return to the road, the impact kick of the wheels tends further to destroy the road surface and abrade the tread. The tests of the U. S. Bureau of Public Roads have shown that the impact force in some instances has been equivalent to several times the static load. Under such conditions, the tread rubber, being always under tension, in transmitting such added power to the road, is under an additional stress, which adds to the destruction of the tread rubber.

There is generally little uniformity in these broken rock surfaces. Under wear, they range from hard smooth surfaces to loose gravel, corrugations, and pot-holes, and all these conditions may be found on any stretch of sample road.

Corrugations on the broken rock roads examined were about 26 to 27 in. from crest to crest. Consequently, the automobile wheels jump from the crest of one corrugation to the trough of the next, roll up the incline to the succeeding crown, and jump to the next trough. This continuous jumping and back-kicking of the rear wheels, wears down the tread rubber on the tires very much more rapidly than it is worn over pavement, well bound broken rock surface, or graveled road.

In all tests, the comparative roughness of the surface of the road tested and the approximate size of the aggregate material should be considered. As measured by roughness, there are many kinds of broken rock surfaces and many kinds of rocks used in such surfaces. Some kinds of broken rock present sharp edges not found on water-worn gravel.

Some gravel and broken stone roads present well compacted and hard surfaces; on others, the gravel is loose, either from having been recently placed and therefore not well bonded, or from having been recently bladed and left with a floating surface of loose material. The grade of material used, and the degree of "wash-boarding" or corrugation should be noted. Some standard of thickness of the loose floating material on the surface, and of the grade and sharpness of material, should be taken as a criterion, and all roads used in tests should be referred to this standard.

Some samples taken from a broken basalt road a year after the road was built showed the sharp edges practically gone and the fine material very much rounded. It would seem that the crushing and grinding effect of the wheels soon wears away sharp angles, rounds up the stone, and makes an old broken rock surface, when in good order, less destructive to tires than a new one.

Gas Consumption

Professor Agg states* that fuel consumption is not a direct measure of the power developed by a gasoline motor, but it is believed that the results thus obtained are comparative and sufficiently accurate for the purposes of this investigation. If the same car were used with the same carburetor setting, the same kind of gas, and operated by the same driver, the gas consumption curve would likely closely parallel the one for tire wear. Professor Agg states that "until more conclusive information pertaining to the variation of mileage costs other than gasoline is available, it is necessary to assume that all mileage costs vary with the resistance of the road surface in the same manner as does the gasoline cost." The investigations of the U. S. Bureau of Mines show that carburetor adjustments and the use or non-use of the air heater make a marked difference in mileage secured; consequently, if gas consumption is to be a reasonable measure of tire wear, all conditions relative to the car must be made uniform.

Yielding surfaces, due either to moisture or heat, require a greater consumption of fuel; more power is transmitted through the tires to the road, thereby causing a more rapid destruction of the tires.

Spring Action

It has long been known that spring action is a leading factor in the upkeep of a car. It is an important factor in the life of the car and as well as the life of the tires. Efficient springs damp the blows and thereby minimize the work done by the carcass of the tires and by the tread rubber.

Road Material

Theoretically, it would be expected that water-worn gravel would abrade a tire less than crushed rock, as crushed rock offers sharp edges to the tire. This seems to have been proved by the tests in the State of Washington on broken basalt roads and in Kansas, as shown by the tire wear, on crushed chert. The abrading effect of road materials should be studied further so that flinty material breaking with sharp cutting edges might be avoided. With

* *Bulletin 65*, Eng. Experiment Station, Iowa State Coll., Ames, Iowa.

such material, the more it is ground up by use, the more abrading angles it presents to rubber tires.

Tire Wear and Speed

It seems evident that tire wear should be influenced by the speed at which a car is operated. More power is required to drive a car at high speed than at low speed, and the bounding and spinning of wheels due to ruts should be more destructive of tread rubber at the higher speeds.

The few tests of tire wear made thus far at different speeds reveal no consistent relationship between these factors. The tests at different speeds made at the State College of Washington were on broken stone covered with a mulch of finely divided broken stone and under constant maintenance with blade graders. The differences in wear on the several tires of a car were considerable, and the various runs with the same car did not show closely similar tire wear. Plotting tire wear against speed for the cars operated on a single stretch of road produces a wide distribution of points, indicating roughly that tire wear increases with speed.

It seems obvious that high speeds should be very destructive of tires. It is well known that the life of a tire on a racing car is relatively short, although the destruction of such tires may not be due to the factor of tire wear. Of two similar tires, the one used on a car driven at moderate speed should travel many more miles than one on the same car driven at high speed.

Some light on this relation of tire wear and speed may be had from other investigations of closely related factors. The subject of power loss in automobile tires seems to have been first thoroughly investigated in the United States by Professor E. H. Lockwood, and has been continued by Messrs. W. L. Holt and P. L. Wormeley at the U. S. Bureau of Standards.

In a report on "Research on Rubber Tires" to the Advisory Board on Highway Research, Mr. Holt draws the conclusion, that,

> "The power loss [in automobile tires] is very nearly directly proportional to the speed, that is, at 40 miles per hour the loss is approximately twice that at 20 miles per hour. This means that the resistance which a tire offers to rolling, or what will be referred to as the rolling resistance, is very nearly constant and is independent of the speed".

The same result was reached much earlier by Professor Lockwood who reported that "one surprising result of all measurements of rolling resistance at speeds from 20 to 40 miles per hour has been the slight increase of resistance at the higher speed. With some cars the increase of resistance is less than the observation errors. In other cases the increases amount to from 5 to 10 per cent". Considering all tests, Professor Lockwood concluded that the internal rolling resistance of an automobile is practically constant at all speeds up to 40 miles per hour; and from other tests that the tires are responsible for nearly two-thirds of the power loss in the car itself.

Both these tests were made on electrical absorption dynamometers, the essential feature of which is a smooth, flat-faced metal drum on which the tires revolve. Although tests on such apparatus show that the rolling resistance of tires is constant at all speeds, as Professor Lockwood reports,

"the rolling resistance on rough, uneven and soft roads will doubtless increase materially with the speed".

In all tests made on absorption dynamometers the wind resistance is automatically eliminated. This resistance must be overcome by the power of the engine transmitted to the surface of the road through the tires. This wind resistance has been shown by L. E. Conrad, M. Am. Soc. C. E., to be given by the formula, $R = 0.0025\,A\,V^2$, in which, A is the projected area of the car and V is the relative velocity, in miles per hour, of air and car. Since wind resistance causes an increased tractive force to be exerted it seems logical to conclude that tire wear will likewise increase with the speed.

Tire Wear and Temperature

In addition to increased wind resistance, higher speeds increase tire temperatures that may result in increased tire wear through the softening of the rubber, and lessen the mileage life of tires. The generation of heat and the resultant rise of temperature of tires are the result of the work done in overcoming the rolling resistance. This increase of temperature has been computed by Professor Lockwood, and checked almost exactly by a suitably conducted test.

A few tests have been made to determine the effect on tire wear of variations in air temperature, but as yet have not yielded consistent results. The road tests made in 1924 showed that tire wear increases with an increase of air temperature, the other variables of speed—road surface, car, and driver—being kept constant.

The tire wear tests of 1925 show no consistent relationship between tire wear and temperature, probably because the tests on any one road extended over such a limited temperature range.

Laboratory tests by Professor McNown, at the University of Kansas, show that tire wear is increased at higher temperatures. The increased wear at 130° Fahr., as compared to the wear at 70° Fahr., amounted to 13% in one set of tests, and to 81% in another, the results not being entirely conclusive.

It is a popular impression that tires wear out more rapidly at high than at low temperatures. A dealer furnishing tires for a Washington bus line that descends a vertical distance of 2 000 ft. on an average 4.2% grade, ascribes the comparative low mileage (12 000) of the tires used on this run to the heat generated by the brakes on this grade. Tourists across the deserts of Southern Nevada and California describe the landscape as littered with abandoned tires, and believe the heat causes their rapid deterioration.

Considerable trouble is being experienced by auto-bus companies with tires being damaged through heat. A heavy bus traveling on a fast schedule requires frequent application of the brakes, and the heat thereby generated produces destructive temperatures, particularly on the inside tire of a dual mounting. Experience and tests have both demonstrated that brake-drum temperatures of 550° to 600° Fahr. are common. Ordinary operation over heated pavements will produce temperatures of 150° to 160° Fahr. Casings and tubes will withstand these temperatures without trouble, but they will not withstand the much higher temperatures produced by a near-by brake-drum.

Bus companies are in a position to force the dealers to supply tires on a mileage guaranty, and the experience of many dealers has not been a pleasant or profitable one. Notwithstanding the short life of many tires damaged by heat, there is little information showing the exact relationship between the wear of a tire and its temperature.

A leading bus company operating in the State of Washington, has kept tire cost records by months. On one set of buses operated by this company, forty tires were used; on the other line, seventy-four. The buses make the same trip each day; the same number of trips each month; consequently, most of the unknown factors are eliminated. The plotted curve shows a very rapid increase as the season advances to midsummer, and a similar rapid decrease as fall approaches. On one bus line the average cost for November, December, January, and February, was about one-third that for July and August. The distance traveled was 148 104 miles per year. On the other line, the July-August average was more than six times the November-December-January-February average. The distance run was 105 690 miles per year.

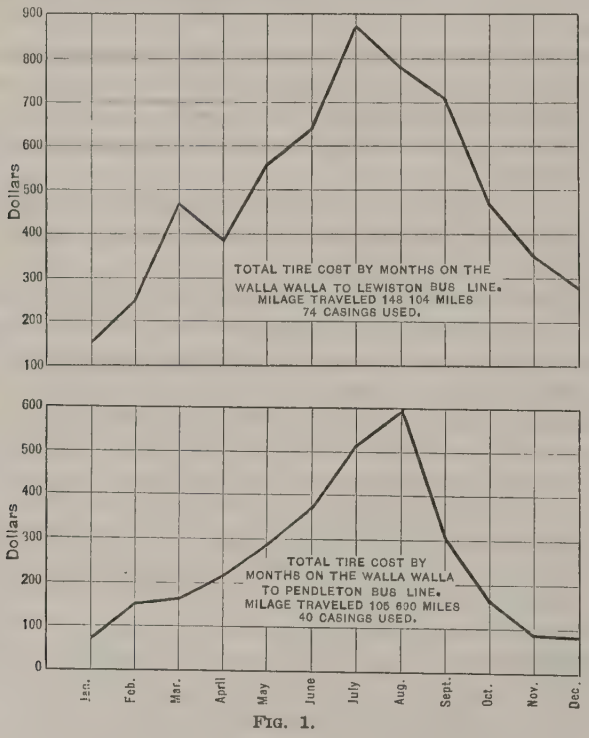

FIG. 1.

The loads may have been heavier and the roads somewhat rougher in the dry summer months than in the winter. This may account in part for the wide variation in tire costs between the summer and winter months. Fig. 1 shows these tire costs by the month.

Relative Tire Wear on Front and Rear Wheels

It is generally believed that tires wear more rapidly on rear than on front wheels. Tests show very erratic results, but averages support the general belief. The tests made at the State College of Washington show average rear tire wear of 140% on macadam, 158% on gravel, and 200% on pavement, as compared to front tire wear. The Kansas tests show smaller differences, the averages being 118% for gravel and 138% for concrete. Professor McNown states that normal front tire wear is 50% that of rear tire wear, but this may not be correct for all road surfaces.

R- 2	136	160	118	Gravel, uncrushed chert.

Professor McNown also states that,

"It is to be expected that rear tire indices would be higher for the rough surfaces due to the bounding and spinning of rear wheels. There is abundant evidence in the above data, however, to indicate that for rough surfaces under the condition of this test the front and rear tire wear is more nearly the same than for well conditioned surfaces".

The tests at the State College of Washington (Table 4) abundantly bear out this statement.

These tests were made on Western type broken stone macadam, which, when well maintained, is covered by a thin mulch of finely broken rock, and when newly constructed or in poor condition, by a considerably thicker layer of ¾-in. rock. On such surfaces the front wheels are being pushed through a layer of loose material, spreading it out and preparing a path for the rear wheels, with the result that tire wear is more nearly equal on front and rear wheels operated over such surfaces. On smooth pavements the front wheels merely roll over the surface, the rear wheels propelling the car. The result should be that on pavements the relative wear of rear tires would be greater than on macadam.

Front tire wear is frequently greatly increased by worn bushing or other parts that throw the front wheels out of alignment. The writer knows of one case where two front tires were entirely ruined by less than 1 000 miles

of travel on account of misalignment of the front wheels. In all the tests quoted, attention was given to front wheel alignment. The extremely erratic nature of the results indicate that many additional data must be secured before dependable conclusions may be reached.

Effect of Weight of Car

Owing to a lack of sufficient data an analysis of tire wear as influenced by the weight of the car is not entirely conclusive. The results (Table 5) seem to show that tire wear per ton of vehicle is either independent of the weight of the vehicle, or increases slightly with an increase in the weight of the vehicle. Averaging all results on concrete pavements, the tire wear per 1 000 miles per ton of car was 9.8% greater on the heaviest car than on the lightest, the increase of weight of car being 153 per cent. Although all four cars were not tested on the same pavement, tire wear increased with increased weight of car for the two pavements tested, and for all four cars tested.

TABLE 5.—Summary of Tire Wear Tests. Effect of Weight of Car.

Car No.	Weight, in pounds.	Average wear, in pounds per 1 000 miles.	Average wear, in pounds per 1 000 miles per ton of car.	Kind of road surface.
1	1 740	0.0477	0.0549	Concrete, Spokane to Coeur d'Alene.

4	4 400	0.1385	0.0603	" " " "
1	1 740	0.349	0.401	Macadam, Pullman to Palouse.
3	3 560	0.628	0.353	" " " "
1	1 740	0.353	0.407	" average of all runs.
2	2 750	0.868	0.628	" " " " "
3	3 560	0.588	0.330	" " " " "
1	.....	.....	0.407	" " " " "
2 and 3	.....	.....	0.479	" " " " "

On broken stone macadam the results are not consistent. Of the two cars tested on the same road between Pullman and Palouse, Wash., the light car had more wear per ton than the heavier. The average of all tests on macadam is erratic, inasmuch as the medium weight car shows the greatest tire wear per ton. This may possibly be accounted for by the fact that this model of car is notoriously known to be very rough riding and hard on tires. The average tire wear on the two heavier vehicles is 18% greater per ton of car than on the lighter one, the increase of weight being 81 per cent.

It is probable, therefore, that tire wear is independent of the weight of car, at least for those cars supplied with the correct size of tire and designed by the same engineering standards. There is some evidence to show that the wear on an overloaded tire is greater than on one carrying a more reasonable load.

Effect of Road Surface on Life of Tires

Although such tests as have been reported yield valuable information on the effect of various road surfaces on tire wear, the real factor desired is the effect of road surfaces on the mileage life of tires. This can be determined only by a long-time test, starting with new tires and operating the car con-

tinuously over the same road surface until the tires are destroyed. Many such tests would be necessary in order to secure dependable averages, and the cost of such testing would be considerable. The mileage of tires is sometimes greatly reduced by such factors as tread cuts, blisters, stone and rail bruises, shimmying, under-inflation, punctures, corrugations, ice, ruts, pot-holes, etc.

Probably the most reliable method of determining the mileage life of tires on various road surfaces, would be to secure the life history of tires from the owners of cars operated exclusively on certain road surfaces. This is difficult, as few owners keep accurate records of their tire mileage and fewer still operate their cars exclusively on one kind of surface. Cars operating exclusively on surfaces with similar wear characteristics are probably mostly owned by taxicab companies and automobile bus lines. A few records from Western bus lines and other sources are given in Table 6. These records were kept as a part of the cost data and presumably are fairly accurate.

In general, these scattered records are in agreement with the tire wear tests, inasmuch as tires operated over pavements have a mileage life at least twice as great as those driven over gravel or macadam.

In addition to a greater tire mileage on pavement, bus companies report other items of expense materially greater when operating on gravel or macadam surfaces. One company reports that there is much more tire trouble on earth, gravel, or macadam surfaces. Tacks and nails are more easily picked up and are more frequently the cause of punctures. Cuts in casings fill quickly with dirt, which soon causes blisters and tread separation.

The life of a tire is generally not determined by external but by internal wear. An interesting confirmation of this fact was obtained from Mr. Lewis A. Corbett, of Walla Walla, Wash., who stated that on the bus line to Lewiston, Idaho, tires were seldom discarded from excessive wear of tread rubber, but generally as a result of internal defects, whereas on the line to Pendleton, Ore., tires frequently lasted 30 000 to 40 000 miles. Mr. W. L. Holt, Mechanical Engineer of the U. S. Bureau of Standards, has stated that:

"Contrary to what seems to be the popular idea, the problem in tire building is not to make a tread which will wear, but to make a tire in which the component parts—the plies, the breaker, the tread, etc.—will stay together, and at the same time distribute the various strains so that the strain will not be excessive at any point. As soon as any of the parts separate, chafing immediately sets in, blisters begin to appear at various places, and the life of the tire is about gone".

Professor McNown, however, has stated that "tire manufacturers are of the opinion that at present the carcass is developed ahead of the tread and that the normal failure of a tire is by tread wear and not by carcass failure". Probably this is true for present-day tires running over improved surfaces, but it may not be true for unimproved surfaces where stresses on the carcass are very much greater.

Tire Operating Costs

Tests of tire wear on various road surfaces will be of value both to the automobile owner and to public officials who build and maintain the highways.

TABLE 6.—TIRE OPERATING DATA FROM BUS COMPANIES.

Owner, or authority.	State.	From:	To:	Kind of bus.	Size of tire, in inches.	Length of run, in miles.	Reported mileage.	Surface.
Red Ball Transportation Company...	Iowa	Mason City	Algona	Fageols Macks	.....	....	28 000 to 30 000	Concrete.
Red Ball Transportation Company...	Iowa	Mason City	Various places	Fageols Macks	.....	....	20 000	Earth and gravel.

Spokane-Lewiston Stage Line	Washington	Spokane	Lewiston, Idaho	.....	34 by 7	115	12 000	102 miles of macadam. 13 miles of concrete.
S. C. Hadden.....	Indiana	Indianapolis	Richmond	2½-Ton. G. M. C.	.....	....	28 000	Concrete.
Mrs. W. I. Coldiron.....	.....	Indianapolis	Bloomington	Studebaker	.....	....	12 000	Gravel.
J. C. Corbett.....	Washington	Walla Walla	Lewiston	White, two-ton trucks	.....	100	11 800	Macadam.
J. C. Corbett.....	Oregon	Walla Walla	Pendleton	White, two-ton trucks	.....	42	16 000	Bitulithic.

The automobile owner is chiefly interested in his tire cost per mile and for the year, whereas the highway engineer is interested in determining the amount he can afford to spend in providing road surfaces that reduce tire wear.

TABLE 7.

Road surface.	Index No.	Computed tire mileage.	Annual tire cost per car for 6000 miles per year.	Cost of tires per vehicle-mile.	Annual cost per mile of road per 100 cars per day.	Tire operating cost, capitalized at 5 per cent.
Concrete, average	1.0	22 750	$31.65	$0.00533	$190	$3 800
Bituhthic	0.95	24 000	30.10	0.00502	180	3 600

Macadam, best	1.9	12 000	60.10	0.01002	361	7 200
Gravel, typical Iowa	2	11 375	63.30	0.01055	380	7 600
Bituminous macadam, best	2.3	10 000	72.80	0.01213	437	8 700
Macadam, average	4.4	5 175	139.40	0.02323	835	16 700
Gravel, uncrushed chert	5.0	4 550	158.25	0.02637	950	19 000
Bituminous macadam, poor	9.6	2 375	302.00	0.05033	1 728	34 600
Macadam, loose	11.0	2 050	316.00	0.05267	2 090	41 800

The following analysis of tire operating costs is based upon the tire wear indexes of Table 3, which are tentative only and subject to change as more data became available. A standard 32 by 4-cord tire will be assumed, with 3 lb. of rubber available for abrasion during its life. The cost of such a tire will be taken as $30, with interest at 5 per cent. Based on these assumptions, Table 7 has been computed.

TABLE 8.—Passenger Automobile Costs.*

* *Bulletin 69*, Eng. Experiment Station, Iowa State Coll., Ames, Iowa.

As a check on the cost of tires per vehicle-mile, Table 8 is presented. This table shows the cost per mile of various items of expense for a composite passenger automobile. The tire expense for this composite car is given as 0.98 cents per mile. This compares with the tire costs of practically 0.01 cent per vehicle-mile of Table 3 for typical Iowa gravel or the best Western type macadam.

The data used in this paper have been largely obtained from the following sources:

(1) *Proceedings,* Third, Fourth, and Fifth Annual Meetings, Highway Research Board, Report of Committee on the Economic Theory of Highway Improvement.

(2) *Bulletins Nos. 16* and *17,* Engineering Experiment Station, State College of Washington, Pullman, Wash.

(3) *Bulletins Nos. 64, 65,* and *69,* Engineering Experiment Station, Iowa State College, Ames, Iowa.

(4) *Technologic Papers No. 213* and *240,* U. S. Bureau of Standards.

(5) *Concrete Highway Magazine,* April, 1926.

(6) Michigan State Highway Department Investigation of Truck Performance on Grades.

(7) *Proceedings,* Tenth Annual Road School, Purdue University.

(9) "Chassis Friction Losses", by E. H. Lockwood, *Transactions,* Society of Automotive Engineers, 1922.

DISCUSSION

TROY CARMICHAEL,* M. AM. SOC. C. E. (by letter).—Since 1919, there seems to have been an ever-growing tendency among engineers to resort to accelerated tests over a short period of time in order to prove the soundness of some new design or theory. In discussing this paper, two main points should be brought to the attention of members: First, the necessity of keeping tests free from the taint of commercialism; and, second, the design of a test to eliminate all variable factors as far as possible.

Engineers have the reputation of being technically trained men striving to inform the public, solely for its own benefit, which of several plans is the best one to adopt. This reputation is valuable, and members of the profession should resent any practice, whether intentional or unintentional, that will give the public reason to believe that they are being influenced by some private interest.

In Table 1, showing results of tests, it is seen that no tests were made on asphaltic types with Cars Nos. 1 and 2, these being the lightest cars; yet in Table 2, showing a summary of the tests, the best results on concrete with Car No. 1 are given the most prominent position on the page. The average of all tests on concrete is shown, and below, the average on all tests on bitulithic—the only higher type of asphaltic construction—is shown. This would naturally lead a casual observer to believe that the tire wear on concrete pavements amounted to 0.0852 lb. per 1 000 miles, and that on a bitulithic pavement the average would be 0.1247 lb. It would take a careful study of this paper to discover that no light cars were used on the asphaltic pavements. This is grossly unfair. An average result of tire wear for two or more cars of different weights means nothing.

In Table 3 the unfairness is even more apparent because the averages of all tests on each type of pavement are shown together. From these figures an index number is determined which is given to the profession without any qualifying statement. It is easy enough to see that the index number for asphaltic pavements would be materially lowered had the tests been truly comparative. The last line in Table 3 gives the average of the seven best tests for concrete, but no attempt is made to give the asphalt pavement the same publicity. Another unfair discrimination in favor of Portland cement concrete is in the fact that these pavements were either new or practically new, long stretches being less than a year old. The bitulithic, while in good condition, was 10 years old. A comparative tire-wear test with this piece of pavement and a Portland cement concrete pavement 10 years old, would be of real interest to the engineers responsible for the design of public highways and streets.

Asphaltic concrete made from coarse aggregate presents the roughest surface to the tire of any mixed asphaltic pavement. Had an asphaltic concrete, fine-aggregate type (so-called Topeka mix) or sheet asphalt been chosen, their linoleum-like surfaces would have given a far smaller index number

* Dist. Engr., Warren Bros. Co., Vancouver, B. C., Canada.

for tire wear than was obtained. Such discrepancies, although they seem trivial, gain importance from the fact that they have been abused by materials companies. Wide propaganda based on these very data has been issued.

These are just a few of the more glaring instances where the authors' methods have allowed their experiment station to become an advertising medium for private interests. Numerous others could be pointed out.

The other main question concerns the design of a test to eliminate all variable factors. A tire-wear test of a few hundred miles here and there with different climatic conditions, types of car, and other "variables" and "personal equations", too numerous to mention, is of no scientific value. Apparently, Professor Waller has arrived at that conclusion. In addition to the doubts in the "Introduction" and concluding pages, practically every section opens with such frank statements as:

"The few tests of tire wear so far made at different speeds reveal no concurrent relationship between these factors."

* * * * * *

"Various runs with the same car did not show closely similar tire wear."

* * * * * *

"Many additional data must be secured before dependable conclusions may be reached."

These statements would seem to indicate that the results obtained from these tests have no real scientific value, and yet the authors have hit on a subject that is of considerable monetary importance to automobile users. The annual tire bill in the United States amounts to approximately $800 000 000, and the difference between the two highest types tested (concrete and asphalt), amounts to $50 000 000 or $60 000 000 per year in favor of asphalt.

Therefore, it appears that this test is important, and that a relative tire-wear index number for the various types of roadways prevalent in this country would be of value to the profession, and certainly very interesting. It would seem that a very reliable figure could be obtained under the following conditions:

(*a*) Testing to destruction instead of by trips of a few hundred miles.
(*b*) Using parallel or adjoining roads as long as available under practically the same climatic, grade, and age conditions.
(*c*) Selecting road surfaces as nearly perfect as possible and five years old or more.
(*d*) Keeping uniform speed as near as possible to 30 miles per hour and 300 miles per calendar day.
(*e*) Making tests simultaneously, so that weather, heat, and moisture conditions are absolutely identical.
(*f*) Starting tests with the same make of new tires and practically new cars of the same make and model.

As Professor Waller suggests, nothing short of such a test will give "accurately, final relative results".

O. L. Waller* and H. E. Phelps,† Members, Am. Soc. C. E. (by letter).—Considerable study has been made by different investigators on the wear of

* Vice-Pres., State Coll. of Washington and Head. Dept. of Civ. Eng., Pullman, Wash.
† Prof., Highway Eng., State Coll. of Washington, Pullman, Wash.

automobile tires due to different types of roads. It was the writers' aim to bring this material together, and to discuss some features of it, but there was no thought of laying down working rules. The writers were not unfair in their use of data, but simply presented the data gathered by others and drew general conclusions therefrom that are believed to be valid although necessarily approximate.

The writers had little to do with the selection of any of the pavements that were tested, but believe that at least the tests made by the State College of Washington were run over pavements fairly representative of the several road surfaces. The lack of sufficient money to make a more extended series of tests does not discredit those that were made. The fact that some types of pavements were not tested at all, is not unfair to those types, nor is it unfair to fail to find a perfect bitulithic pavement. In the Pacific Northwest it is very difficult to find any considerable length of asphaltic pavement in good condition since very little has been constructed on State highways in recent years. The writers are glad to note Mr. Carmichael's statement that the bitulithic pavement tested was in good condition and they believe the index number for average bitulithic, given in Table 3, confirms that fact. This index number is very favorable to bitulithic, and not the reverse, as Mr. Carmichael seems to have found it.

The ideal conditions under which tire wear tests should be conducted were pointed out by the writers, and these conditions are substantially re-stated by Mr. Carmichael, but without any suggestion as to how or where the ideal can be found. It would be interesting to know the location of two parallel or adjoining roads under practically the same climatic, grade, and age conditions, one paved with concrete and one with bitulithic, and both surfaces nearly perfect and at least five years old. The State of Washington has used concrete exclusively for pavement for more than eight years and there are no ideal bituminous pavements in the State highway system, nor is there any long stretch of ideal macadam or broken rock surface road.

Of course, a test in which the tires are run to destruction is better than a short-time test. The experiment should be extensive enough to eliminate the effect of variations in the quality of individual tires. An average of the extreme variations in the condition of each type of road surface should be determined in such a way that the resulting index number would accurately reflect the tire-wearing quality of that surface and the resistance of any particular type of tires manufactured. Such a test would be very expensive. It is believed that the data already secured have been thoroughly studied by careful investigators and that the results secured are reliable.

Paper No. 1675

AERIAL TRAMWAYS*

By F. C. Carstarphen,† M. Am. Soc. C. E.

With Discussion by Messrs. Robert C. Strachan, George Paaswell, Casper D. Meals, and F. C. Carstarphen.

Synopsis

The great industrial expansion which has occurred in the United States during the past decade has placed a premium upon the efficiency of machines and labor.

When properly designed and selected, aerial ropeways are very economical and trustworthy machines. The English bibliography is meager. This paper aims at an outline classification, together with such comments and formulas, that may be of service to engineers in determining the elements of an aerial ropeway for their needs.

These formulas have been derived, checked, and used by the writer, and are believed to be in a correct and convenient form.

It is not the object of this paper to discuss the several structures, or equipment, in detail, but as the loading may be determined by the formulas, the design may be developed in the usual way.

Aerial Tramways

Classification.—The terminology used in describing systems of transportation by means of wire rope is loose and indefinite. The following classification of aerial tramways as distinguished from mine haulages, incline planes, or other forms of surface ropeways, will be found in accordance with the views of the most prominent tramway engineers. Abroad, the tendency is to call the system "aerial ropeways", because of the general application of the word,

* Presented at the meeting of November 2, 1927.

† Cons. Engr., Denver, Colo.

"tramway", to surface-haulage installations. Wire-rope aerial transportation systems may be listed as follows:

A.—Single rope tramways (mono-cables):

(*a*) Grip attached to carriers.
(*b*) Clip attached to carriers.

B.—Stationary cable tramways:

I.—Cableways (cable cranes):

(*a*) Radial cableways.
(*b*) Cable hoist conveyors.
(*c*) Dock hoists.
(*d*) Drag-line conveyors.
(*e*) Cable excavators and conveyors.
(*f*) Movable tower cableways.
(*g*) Balanced tower cableways.

II.—Dumping cradleways:

(*a*) Single-span.
(*b*) Multiple-span.

III.—Single-cable reversible tramways:

(*a*) Aerial dump.
(*b*) Terminal discharge.

IV.—Double-cable reversible tramways:

(*a*) Aerial dump.
(*b*) Terminal discharge.

V.—Double-cable tramways with continuous traction rope:

(*a*) Carriers attached by friction grips.
(*b*) Carriers rigidly attached by clips.

VI.—Automatic tramways.

VII.—Bleichert tramways.

VIII.—Bleichert stacking tramways.

IX.—Storage tramways:

(*a*) Circuitous tramways.

X.—Selective turnout tramways.

Rope Tramways

The development of aerial tramways has been rapid and substantial. To Charles Hodgson is given the credit for promoting both the single-rope and double-rope tramways. His original patent was dated 1868. However, the "Hodgson System" is understood to refer to the single-rope type of tramway. This also applies to the "Hallidie System". Tramway lines constructed of this type are rare in North America, but are being installed abroad. They are favored for the transportation of comparatively light materials, such as coffee, tea, tobacco, charcoal, bananas, copra, cotton, etc. However, by means of careful design, they have been used with success in transporting exceptional tonnages (say, 100 tons per hour) of ore and timber. The economical capacities of such lines are 50 tons per hour, or less. The speed is generally less than 450 ft. per min. As the name implies, this type of tramway has a single rope for the simultaneous support and propulsion of the carriers.

Rope.—The rope must be designed to meet two conditions: (*a*) The wires must be sufficiently large to withstand the wear and abrasion occasioned in passing over the towers and around the driving sheaves; and (*b*) they must be small enough to be flexible and thus reduce the stresses due to bending. Ropes of six strands and seven wire construction and of crucible grade are satisfactory. Nevertheless, the rapid wear of the ropes constitutes the largest item of the maintenance expenses.

Supports.—Cable supports are either of timber or steel construction, built to 6 or 8-ft. gauge of any reasonable height, and are designed to sustain a cap which carries the sheaves supporting the rope. These towers usually consist of a substructure, which is most economically framed with perpendicular posts (Fig. 1), although some manufacturers still favor the batter posts. The tower head is usually standard for any line and can be used interchangeably on any tower. It is desirable that the towers rest on concrete or masonry foundations. However, mudsills or posts set in the ground have been used with success.

Tower Sheaves.—The number of sheaves on either side of the tower may be one, two, three, four, six, or eight, depending on the weight of the load, the radius of curvature desired, and the length of the spans adjoining the tower. When more than one sheave is used, it is customary to carry them in balance by suitable rocker arms. The sheaves are usually 16 to 20 in. in diameter, have shallow rims, rib spokes, and are set-screwed to the shaft, which is carried in babbitted cap bearings.

Carriers.—The load supported by the carriers usually varies from 100 to 1 500 lb., depending on the hourly tonnage to be transported. Loads of 800 lb., or less, are preferable to those of greater weight. If the carrier is equipped with a bucket, the usual volumes are 2 to 10 cu. ft. The bucket is mounted on trunnions supported by swivel castings bolted to U-shaped bails. The trunnions are mounted so that the center of revolution is to one side of the center of gravity. When the bucket latch is tripped, the bucket dumps automatically.

Clips.—A distinguishing feature of single-rope tramways as supplied by different manufacturers is in the method of attaching the hangers to the rope by clips and by friction grips. The Hodgson System provided a saddle fitted with India rubber or wooden friction blocks which came in contact with the rope. The friction developed by the weight of the load was sufficient to transport the carriers up moderate grades. Hallidie inserted a clip in the rope. It consisted of a rod with corrugations that were made to conform with the pitch of the rope and the size of the strands. The bucket hanger was forged into a head, which was drilled to receive a pin, so as to permit oscillation in a direction parallel to the travel of the line. The clip was hinged to provide side sway. This method of attaching the carriers to the rope was positive and was successful on lines having steep gradients.

Other types of clips were developed, which depended on placing a thin sheet of metal around and squeezing the rope by means of bolts. Adolf Bleichert and Company developed a friction grip which seizes the rope automatically

when it leaves the loading terminal and is detached the same way at the discharge terminal. This grip is actuated by the weight of the load and is successful on gradients of more than 30 degrees. Manufacturers of that type of tramway on which the carriers are arranged for detaching from the rope, equip the carriages with two wheels so that the carrier may be moved through the terminals when supported on suspended rails.

Automatic Loaders.—Carriers rigidly attached to the rope must be loaded and unloaded while in motion. This arrangement led to the development of automatic loading devices. The loading terminal is arranged to provide a bin for storing the material to be transported. The bin is equipped with a suitable gate so that a container of the same volume as the bucket may be loaded by the operators at will. This, in turn, is discharged into a traveling hopper which is mounted on wheels and runs on a track parallel with the ropeway. The traveling hopper engages the bucket and travels with it a distance sufficient to dump its contents automatically into the bucket. After this is accomplished, it disengages itself and returns to its former position beneath the stationary hopper. This action trips the gate of the stationary hopper and the loader is again filled, thereby completing the cycle. Various aids, such as sprocket wheels, air cylinders, etc., have been used to assist the loader in keeping pace with the bucket without disturbing the latter's equilibrium. When the bucket reaches the discharge terminal, it is automatically tripped and discharged. Carriers equipped with grips do not need automatic loaders or unloaders. They pass to the point most convenient for loading or discharging because of their greater freedom in the terminals.

Angle Stations.—Angle stations may be installed on single-rope tramways to accommodate any change in their alignment. The deflection is accomplished by horizontal sheaves mounted on supporting structures fitted with guides. The slow speed of the tramway permits the carriers to pass around the sheaves either supported directly by the clips or on curved rails, depending on the type of equipment used.

Drive.—The line is driven by either plain, wood-filled, or grip sheaves. The sheaves are fitted with brake rims and friction brakes so that the motion may be properly controlled.

Approximate Cost.—The equipment for a single-rope tramway of 6-ft. gauge, 6-ton hourly capacity, 1 mile in length, provided with an automatic loader, terminal machinery, gears, automatic dumper, supporting sheaves, stands, guides, woodwork bolts and washers, buckets, hangers, clips, crucible steel wire rope, and splicing tools, would weigh approximately 30 000 lb., and would require 28 000 ft. b.m. of timber, including a 20-ton storage bin.

The total cost for such a line installed would be about $18 000. It costs approximately $2 850 per year to operate for 300 days, and would transport 18 000 tons at a net cost of 15.5 cents per ton.

Stationary Cable Tramways

This is the name given to all systems of aerial transportation that sustain the carrier on a stationary cable as a track and propel it by means of

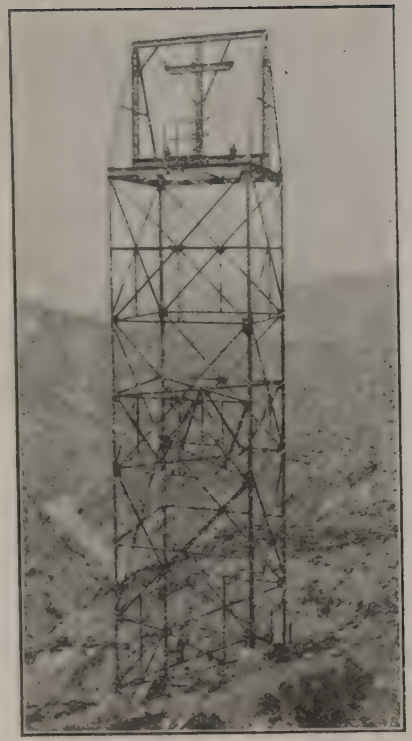

FIG. 1.—STEEL TOWER.

FIG. 2.—DUMPING CRADLEWAYS FOR FILLS.

an independent traction rope. There seems to be a further differentiation among stationary cable tramways, depending on the weight of the unit load handled and the distance through which it is moved. To illustrate, cableways are presumed to handle individual loads weighing from 5 to 10 tons, the translation being usually less than 2 000 ft. On the other hand, double-cable tramways with continuous traction ropes transport loads of 1½ tons, or less, to any distance required. All the other classes are intermediate between these extremes.

Cableways (Cable Cranes).—The cableway is defined as a stationary cable tramway which uses a suspended cable for a track and a carriage that is adapted to both hoisting and conveying, in sequence, or simultaneously. The carriage of a cableway is actuated by a reversing engine, either steam or motor-driven, fitted with an elliptic grooved sheave to accommodate the endless rope which is permanently attached to each end of the carriage and is used in moving it to and fro. The engine has a drum for the hoisting rope. If the span exceeds 300 ft., it becomes necessary to support the hoisting rope; otherwise, the weight of the unsupported rope is sufficient to counterbalance the empty fall-block, and the latter cannot be lowered. To overcome this difficulty, devices called fall-rope carriers have been developed. The difference in the design of these parts is the distinguishing feature of the cableways furnished by different companies. Many patents have been issued for fall-rope carriers and several systems have been proposed to eliminate their use. The method now in general use is to support them on a horn of the carriage so arranged as to hold them in place. A stationary rope is fitted with different sized buttons. As the carriage moves, the buttons engage the fall-rope carriers and they are thus automatically spaced along the track cables. When the direction of travel is reversed, the carriage picks them up. To avoid the hammering of the buttons and the wear of the button rope, the differential fall-rope carriers were designed. This design provides that the individual carriers shall move at different speeds, obtained by a change in the ratio of the diameter of the sheaves in contact with the main cable and the hoisting rope. This difference in the rapidity of travel of the differential fall-rope carriers automatically spaces them along the track cable.

When the difference in the terminal elevations exceeds one-third of the span, and when a three-part fall-block is used, the endless haulage rope may be omitted, for the load can be hoisted until the fall-block reaches the carriage before translation will begin. The carriage is returned to position by gravity and is stopped by a block clamped to the track cable. As soon as the motion of the carriage is arrested, the fall-block is lowered to the ground.

Radial cableways are those in which the tail tower is mounted on a circular track. The movement of this tower is usually confined to a sector of 40° about the head tower as a center. When the carrier moves through the head tower to a boom overhanging a boat, the installation is called a "dock hoist". If the fall-block supports a self-filling bucket, such as drag, slip, orange-peel, or clam-shell, the installation is called a "cable excavator and conveyor"; also, a "drag-line excavator and conveyor". Generally speak-

ing, cableways are not adaptable to sites requiring multiple spans, owing to the inability of the usual carriage to pass intermediate supports. Cableways are built with both towers mounted on rails, and, therefore, can be moved laterally, thus commanding a larger area than is possible with the anchored cable. Cableways for storing coal may also be equipped with terminal masts, which swing in a plane at right angles to the cable. As the mast may function as a radius of a circle, the length of back-stays to anchorage is constant for all mast positions. Cableways have been fitted with steel towers resembling a trestle bent which may oscillate about the base. These towers are controlled by weights, which tend to maintain a constant tension in the rope. Cableways are frequently used for the operation of quarries, placer deposits, tailing dumps, etc.

Dumping Cradleways.—When deep fills are made or excessive dumps are to be accumulated at a rate faster than is obtainable by handling single cars, the dumping cradleway provides a method which eliminates trestles, promotes the speed of handling the train, and insures complete salvage of the equipment when the work is finished. Dumping cradleways (Fig. 2) consist of two stationary cables supported by towers located at the end of the span or spans. Suspended from these cables is a cradle which supports a track. The train is pushed to the edge of the fill and the cars are dumped consecutively, the empty cars passing forward on to the deck of the cradleway. The grade of the fill is controlled by a movable tower which is advanced with the cradle as the fill progresses. The elevation of the supporting cables is thereby kept constant irrespective of the position of the cradle on the span. Hold-down tackle keeps the unloaded cradle in position when the cars are drawn from it.

The Cedar Rapids Manufacturing and Power Company, at Cedars, Que., Canada, successfully used a two-span dumping cradleway to build a 2 000-ft. wing-dam of more than 125 000 cu. yd., across a channel of the St. Lawrence River. The cables were 2½-in., 6 × 37, plow steel. The cradle was 14 ft. wide and 130 ft. long, and had a maximum capacity of ten 6-cu. ft. contractors' cars. The height of the movable tower was 40 ft. The cost of the fill was reported to be less than $1.25 per cu. yd. The depth exceeded 30 ft., the velocity of current about 10 miles per hour, and a limestone bottom made cribbing and piling methods prohibitive and impracticable.

Single-Cable Reversible Tramways.—This type of equipment differs from cableways in that the hoisting feature is eliminated. Accordingly, the endless traction rope is all that is required. These lines are generally short and of small capacity. The direction of travel of the traction rope is reversed at the completion of each trip of the carrier. Such lines are usually equipped with self-dumping buckets, which may be tripped automatically while moving along the cable, or in stations. The speed of such lines is usually 600 ft. per min., but on clear spans they may be operated as fast as 1 000 ft. per min. The capacity, therefore, is directly proportional to the load and velocity, but inversely proportional to the span. The hourly capacity rarely exceeds 20 tons.

Table 1 gives the capacities, in pounds per hour, of single-cable, reversible tramways operating at a speed of 600 ft. per min. The time interval to complete the trip is given in seconds.

TABLE 1.—Capacity, in Pounds per Hour, of Single-Cable Tramway.

Length, in feet.	Time, in seconds.	Bucket Capacity.						
		400.	600.	800.	1 200.	1 500.	2 000.	2 500.
2 000	450	3 200	4 800	6 400	9 600	12 000	16 000	20 000
1 500	348	4 200	6 300	8 400	12 600	15 750	21 000	26 250
1 000	240	6 000	9 000	12 000	18 000	22 500	30 000	37 500
500	144	10 000	15 000	20 000	30 000	37 500	50 000	62 500

Double-Cable Reversible Tramways.—For efficiency it is desirable to operate reversible tramways in balance, in so far as the moving equipment is concerned. Most engineers prefer to use two track cables, thus bringing two single reversible tramways side by side, spaced 6, 8, or 10-ft. gauge, depending on the size of the bucket. Both buckets are moved by the same traction rope, which passes around a sheave at the terminal. Tail ropes are required on lines where power is necessary for their operation. Tramways of this type are operated by gravity when there is sufficient fall between the terminal stations. Like single reversibles, they may be equipped with trippers for aerial dumping of the buckets; otherwise, the bucket dumps automatically over the bins in the discharge terminal. This type of tramway is usually arranged so that all its functions are automatic, except the loading and control of the driving mechanism. One operator is sufficient for either single- or double-cable reversible tramways. The track cables are usually anchored without weight-boxes, and multiple spans are used when necessary. The proper determination of the tension of an empty track cable permits the designer to control the ultimate tension of the cable when carrying a maximum load.

Table 2 gives the capacities, in pounds per hour, of double-cable reversible tramways of different lengths, based on a speed of 600 ft. per min.

TABLE 2.—Capacity, in Pounds per Hour, of Double-Cable Tramways.

Length, in feet.	Time, in seconds.	Bucket Capacity.						
		400.	600.	800.	1 200.	1 500.	2 000.	2 500.
2 000	240	6 000	9 000	12 000	18 000	22 500	30 000	37 500
1 500	192	7 500	11 250	15 000	22 500	28 125	37 500	46 875
1 000	144	10 000	15 000	20 000	30 000	37 500	50 000	62 500
500	90	16 000	24 000	32 000	48 000	60 000	80 000	100 000

The Consolidation Coal Company has used this type of tramway for handling mine waste. At Mine 206, a three-span, double-cable, reversible tram-

way is installed. It is equipped with 27-cu. ft., bottom-dump buckets which hold approximately 2 000 lb. of slate, and which dump automatically into bins supplying a larry system of distribution. The difference in elevation between the loading and discharge terminals is 427 ft., and the horizontal length is 789 ft. The tramway is operated by a reversing slip-ring motor fitted with a drum controller and resistance grids capable of 50% speed regulation.

Double-Cable Tramways with Continuous Traction Ropes.—Although Messrs. Hodgson and Carrington first considered the arrangement used in double-cable tramways, it remained for Messrs. Adolf Bleichert, J. Pohlig, and T. Otto, of Germany, Cerretti and Tanfini, of Italy, and the Trenton Iron Company, Leschen and Sons, Roebling, The American Steel and Wire Company, Broderick and Bascomb, Riblett, and others, in America to demonstrate the practicability and perfection of this type of aerial tramway. Two-track cables are used to support the carriers. The usual practice is to increase the diameter of the cable carrying the loaded buckets over that used on the empty side. The traction rope is of the well-known Lang lay construction, is spliced endless, and is controlled by suitable terminal mechanism. The positive attachment of the carrier to the traction rope promotes the development of the highest efficiency possible in any system of transportation.

Tramways built on favorable gradients of 2 to 3% eliminate, owing to gravity, the friction developed by tower rollers, terminal sheaves, carriages, and other moving parts. The power developed or required in the operation of double-cable tramways is then an exact function of the load transported. This is not true for any self-propelled vehicle depending on wheel friction for tractive effort. There is no permanent ratio between the horse power of the prime mover and the load moved. On grades of 12%, the locomotive fails as a tractor under its own weight. Not so with aerial tramways which use, in a modified way, the most efficient system known of transmitting power, for example, by wire rope.

Transportation Costs.—Transportation costs are usually expressed in terms of the ton-mile. This factor is reasonable enough when the haul is of sufficient length for the grades to compensate, thereby presenting costs equivalent to hauling the loads on the level projection of the track. However, with aerial tramways of moderate length—5 miles or less—there is no material increase in operating charges over those experienced on short lines. In other words, the cost of transporting material by aerial tramways is not proportional to the length. The greater part of the expense of operation is for labor in the terminals, so that on equal tonnage lines, one being ½ mile long and the other 2 miles long, the former will show about 400% greater cost per ton-mile than the latter.

Aerial tramways of equal hourly capacity transport the same weight of material per unit of time and the capacity is independent of the length. Hence, generally speaking, the distance of the haul has no effect on aerial tramway transportation costs, as is the case in surface-haulage systems. It is noted that an aerial tramway on a level gradient, and having a capacity of 50 tons per hour, can successfully compete with surface railways less than 17 miles in length. If the topography of the site is rough and broken, double-

cable tramways with continuous traction ropes are supreme. They are especially adapted to the transportation of any substance that can be readily loaded into buckets, 40 cu. ft., or less, in volume, and that produces a net weight of load of 3 500 lb., or less.

Automatic Tramways.—Double-cable tramways with continuous traction ropes, like single-rope tramways, have been developed so that one system attaches the carriers to the traction rope by means of buttons or clips—the so-called automatic system—whereas the other plan is to attach the carriers automatically to the moving traction rope by means of friction grips. The latter type is known as the Bleichert System. The Leschen Special Automatic System is probably the best known type of the button-attached buckets, whereas in the Lawson System, the carriers are attached by clips to the traction rope. This tends to localize the bending stresses in the traction rope, thereby greatly shortening its life, as compared with lines using friction grips. This latter method is favorable because it is not probable that successive grips will seize continuously the rope at exactly the same points.

The filling of the buckets is accomplished with the aid of an automatic loader, which consists of a hopper having approximately the same volume as the bucket. This hopper is mounted on rails and is movable. It is filled when the operator manipulates the gates of the storage bin. The loader engages a lug on the hanger of the carrier and moves forward in unison with it until the contents have passed to the bucket. The loader then returns to its initial position and, when refilled, completes the cycle of operation. Air pistons, chains, counterweights, and other accessories are used to control the motion of this device. Self-dumping buckets are used, so that when the latch is tripped the bucket revolves on its trunnions, thus discharging its contents. All these operations take place while the carrier is in motion.

In the Lawson or Interstate System parallel track cables are used, which support the carriers, the axes of which are approximately in the horizontal plane. These carriers are dumped when passing over a tail-drum, which reverses their direction of motion, and they return on twin track cables supported on the same structures, but below the cables carrying the loaded buckets. The track cables of both the empty and loaded sizes are sometimes arranged in the same plane, rather than one above the other.

The Leschen System uses carriers hanging in the vertical plane. As a typical automatic double-cable tramway, may be mentioned the "International Line" across the Rio Grande River, which was designed by Leschen and Sons for the Del Carmen Mining Company, of San Antonio, Tex. Its length was 31 500 ft.; its maximum capacity was 10 tons per hour, with a speed of 300 ft. per min. It was equipped with buckets holding 600 lb., which ran on 1-in. and $\frac{3}{4}$-in. track cables of flattened strand construction, cast-steel grade. The traction rope was driven by a 45-h.p. gas engine, which operated a 10-ft. grip sheave. Water carriers used on the line were equipped with hand-attached friction grips, so that they could be removed from the line at will.

Bleichert Tramways.—The Bleichert System and similar systems have carriers equipped with friction grips, which are automatically attached and detached to and from the moving traction rope. The freedom of motion

attained by the carriers in the stations is of prime importance. It permits increasing the speed of these lines to 600 ft. per min. The detaching of the carriers allows their ready control in stations where, of necessity, the rail curves must have short radii. The high speed permits the development of lines of great capacity, such as 275 tons per hour. They have, however, an economical equipment of carriers and track cables. Table 3 gives the elements of Bleichert tramways, in tons per hour; also, the average number of men required on lines of 3 miles, or less. The speed of the line is assumed at 500 ft. per min.

A Bleichert tramway of very large hourly capacity was in service for several years at the mines of the Spring Canyon Coal Company, at Storrs, Utah. It was 3 050 ft. long, with a difference in elevation between the loading and discharge terminals of 330 ft. The capacity was 285 tons per hour. It was equipped with 40-cu. ft. buckets, designed to be transferred from the trucks of the mine haulage system to the hangers of the tramway carriers by a special device called a "tilting table". The empty buckets were placed on the trucks and again entered the mine, thus completing the circuit. The speed of the tramway was 520 ft. per min. Locked-coil steel track cables, in sizes of 1⅝ in. and 1¼ in., were used. The traction rope was of ⅞-in., Lang lay, crucible cast steel. The towers were equipped with compensating saddles on the loaded side, reducing the bending stresses in the cable. The line was under the continuous control of a sentinel brake. A speed-indicating alarm sounded a warning if the velocity of the line increased 5% above normal. The traction rope passed around an 8-ft. grip sheave equipped with differential, hand-operated brakes. When in operation the line developed 65 h.p. A 75-h.p., 3-phase induction motor could be connected to the drive by means of a friction clutch. The motor was not used except when the line was being stripped of its carriers.

Bleichert Stacking Tramways.—The Bleichert stacking tramways consist of a trussed framework, having bents securely cross-braced and designed so as to be capable of extension by the addition of one or more bents. The tip consists of an independent structure telescoped into the trussed framework. It is mounted on rollers and may be moved outward by screws or hydraulic-jacks. This tip carries a terminal sheave of ample diameter, so that the carriers which ascend the supporting double-headed tramway rail of the framework, pass around it, and are automatically dumped. As the pile grows, the tip is pushed outward. When sufficient space has accumulated, another bent is added to the structure. Piles 250 to 300 ft. in height are not unusual. When the pile has reached a sufficient height, the alignment of the framework is changed to the horizontal plane, and the pile may be extended indefinitely. A sufficient length of travel is provided for the traction-rope tension mechanism so that it is not necessary to splice in additional pieces of traction rope for every extension of the line.

Tramways of this design have been installed at the Brakepan Mines, Limited, of Johannesburg, South Africa, the Boulder Proprietary Gold Mines, Limited, of Kalgoorlie, West Australia, and elsewhere. These installations move as much as 200 tons of waste per hour.

NOTES.—Weight of ore taken as 100 lb. per cu. ft.; neutral line; lines requiring power, add for automatic reversing prevention ratchet, 455 lb., $176; lines developing power, add for speed-indicating alarm, 150 lb., $120; power-operated instead of hand-operated chutes, add for each, 2 550 lb., $275; sentinel brake and control mechanism, add 6 200 lb., $530. The data given in the table do not include costs of structures or installation expenses.

* Locked-coil track cables; Lang lay, crucible cast-steel traction rope, standard carriers, equipped with grips, tower saddles, rollers and bolts, telephones and line equipment; that is, all parts affected by change in length.

† Terminal equipment: Sheaves, shafts, pulleys, clutch, tension mechanism, rails, hoods, attachers, detachers, chutes, spacing gong, and tools; that is, all parts not affected by change in length.

‡ Tension station mechanism: Rail, sheaves, rollers, chain, bolts, hoods, etc. Add one station for every mile of line.

Storage Tramways.—These are double-cable, continuous, traction-rope lines equipped with trippers attached to the track cables to trip the latches of the self-dumping buckets. The discharged material accumulates in a pile beneath the tripper. When the pile has reached a height sufficient to interfere with the dumping of the buckets, the tripper is moved farther along the cable. This permits of the accumulation of a pile of relatively narrow width, but of considerable length, in a direction parallel to the tramway. Since the natural slope of such piles is rarely greater than 34°, it is found desirable to increase the gauge of the tramway so as to cover square or circular plots rather than rectangular spaces of great length. This demand has resulted in the development of the circuitous type of storage tramway. Installations of this kind may be provided with overhead grip carriages, or underhung grips, which are capable of passing around curves of 6-ft. radius without being detached from the traction rope. When 12-ft. guide sheaves are used, the speed of the tramway should not exceed 350 ft. per min.; with sheaves, 20 ft. in diameter, 450 ft. per min. The angular throw of the bucket due to centrifugal force can be readily controlled by curved guides when the velocity is within the limits mentioned. Tramways of this type, therefore, consist of towers supporting single-track cables and the traction rope as well as angle stations, equipped with guide sheaves of large diameter. The line follows the perimeter of figures which approach the square or rhomboid in shape. The carriers are always equipped with self-dumping buckets, and it is preferable to use those having the self-righting feature as well.

Bucket trippers may be small pendant clamps, attached to the track cables, or they may be mounted in tripping frames. Tripping frames are of two classes; those that are positively attached to the cable, and, like the clips, can only be moved by sending a member of the tramway crew out on the span to loosen the frame's attachment to the cable. This procedure is more or less dangerous, and, in addition, causes considerable delay in shifting the tripper. The ambulating tripping frame consists of a hood supported on the track cables by rollers. The frame is held in position by four ground lines fitted with proper tackle. The selective ambulating tripping frame carries a toothed bar so that it may be adjusted at will by a line reaching to the ground. The buckets used on tramways equipped with selective ambulating tripping frames are provided with adjustable latch-bars which can be set in the loading terminal according to the material in the bucket. This arrangement permits the handling of various ores simultaneously and storing them in their separate piles or combining them in any proportion desired.

The Tacoma Smelting and Refining Company, of Tacoma, Wash., had such a storage tramway. This line handled zinc and copper ore, or other classes as received, and stored them simultaneously in separate or in bed piles, as the metallurgists decided. The capacity of the line was 100 tons per hour and its length, 3 000 ft. The traction rope was §-in. Lang lay. The track cables were 1§-in. special locked-coil. The line was equipped with 16-cu. ft. buckets, selective ambulating tripping frames, and pneumatic power chutes. A 25-h.p. vertical motor equipped with drum controller and resistance grids for 50% speed regulation, was used.

Selective Turnout Tramways.—This tramway is used where the material transported is to be delivered at several different points, and for the sake of economy the labor required to throw the switches and detachers is eliminated by the substitution of automatic machinery. The carriers are fitted with a shoe attached to a selector bar which has as many notches as there are turnout stations. The buckets are filled at the loading terminal in the usual way, and the operator sets the selector bar in the notch representing the desired turnout station.

When the carrier arrives at this point, the shoe engages the throttle of an air-valve, which actuates the pistons of two cylinders controlling the swinging detacher and the turnout switch. The carrier automatically releases the traction rope, enters the siding, and coasts to the proper point under its own momentum. As it leaves the station, the shoe encounters a release valve, which restores the mechanism to its original position. Any carrier with the selector bar set for another station passes by this switch, because the shoe on its carriage does not engage the air mechanism.

Economic Design.—The structures of an aerial tramway are grouped into the terminal stations, which are usually independent of the length of the line and, for a given tonnage, represent a fixed cost. Tension and other intermediate structures are required only occasionally along the tramway and may be also regarded as additional cost factors. Towers for any given line will be of standard design, and, therefore, the criterion to apply in choosing the capacity of the carriers and the size of cable for economy of design is to select them so that the cost per foot of cable multiplied by the bucket spacing plus the cost of a carrier shall be a minimum, or as near thereto as the time interval will permit.

Track Cables.—The track cables are an essential part of all systems of aerial tramways. Four styles of cable have been used for this purpose. They are locked-wire, locked-coil, smooth-coil track strand, and patent flattened strand. The first three are shown in Fig. 3.

Locked-wire cable is so named from the fact that the outer wires have a Z-shape so that they interlock one with the other and thus present a smooth surface on the exterior, resulting in a uniform distribution of wear of the wires, which cannot be attained by the use of any other cable. Experience has shown that no other track cable gives as great a tonnage life as locked-wire and locked-coil cable. Table 4 gives the properties of locked-wire cables.

Locked-coil track cable is very similar to locked-wire cable, except that the core and key wires are of larger cross-section, so that the cost of manufacture is reduced and likewise the price to the trade. Fig. 4 shows a test specimen of this cable. (Note the holding power of the zinc sockets.) It is satisfactory for use as a track cable for aerial tramways carrying net loads of 5 000 lb., or less, whereas locked-wire cable is greatly favored for use on cableways where the weight of the moving load is approximately 8 to 10 tons. Table 5 gives the characteristics of locked-coil cable.

TABLE 4.—Properties of Locked-Wire Cable.

1¼	0.040	3.80	62
1⅛	0.858	3.15	50
1	0.680	2.50	40

When a cheaper track cable is desired, smooth-coil track strand is used. This cable is composed of a number of comparatively large round wires laid about a core wire. The number of wires and their size vary according to the size of the cable, 19, 37, and 55 being the usual construction for cables of the size used on most tramways. Should a wire break, it uncoils rapidly to the points of support of the span. With locked-coil cable, it is necessary for two or more adjacent wires to break before the wires can run. Smooth-coil track strand is superior to all other track cables except the locked-wire and locked-coil types. The use of cables, such as patent flattened strand, or of the ordinary type of wire ropes, on permanent installations, is not good practice, for the life of such cables is frequently extremely short, due to the breakage of the small wires which must be used in their construction. Table 6 gives the characteristics of smooth-coil track strand.

TABLE 5.—Locked-Coil Cable.

1	0.70	2.35	40
⅞	0.50	1.80	30

The modulus of elasticity of track cables in both bending and direct tension varies with the stress imposed. When a load, such as a moving carrier, passes along the track cable, bending stresses are developed in the cable. The relationship between the weight of the loaded carrier and the size of the track cable is based on the criterion that the combined bending and direct stresses in the outermost wires must be a minimum. The weight of a carrier that may be safely sustained by a track cable varies with the tension between limits of 300 to 700 times the weight per foot of the cable.

Tramway track cables show, when properly tested, several interesting phenomena which explain their behavior in service. The elongation of a specimen of locked-coil cable is not the same for equal values of progressive and retrogressive loading. If elongations are plotted as ordinates and the loads as abscissas, a frictional hysteresis graph is developed, and is capable of being interpreted in the same manner as the well-known engine indicator diagrams. The area bounded represents work. As the rate of application of the loading is very slow, the heat generated is small. Hence, the work shown is a measure of the internal friction developed among the wires. This force is comparable with the effect of cohesion in homogeneous bodies. As the internal friction is a function of the tension, so is the modulus of elasticity. The cable specimen does not follow Hooke's law until the tension is well advanced. Because of these properties the tonnage life of track cables is profoundly influenced by the manner of their support, the weight of the moving carrier, the amount and the method of applying the tension, and the lubrication and care received.

Radius of Saddle.—In aerial tramway designing, the ratio of load to tension should be taken as less than 0.05. As the wheel base of the carriage is known, the radius of curvature of the cable between the carriage wheels can be approximated. This value, or a greater one, should be used for the radius of the track cable saddles, so that the bending stresses in the cable at the supports will be of the same order as those developed under the carriage. If the wheel base of the carriage is 1.2 ft., the radius of curvature of the cable should be about 25 ft. Fig. 5 shows a rocking saddle.

Anchored Spans.—As track cables under high tension show properties similar to homogeneous bars, it is well to bear in mind that heavy boxes promote the development of great internal friction; in other words, there is no relief to the constituent wires from the stresses imposed by the passing carriers. These stresses are not reduced by stopping the tramway. This continuous loading results in reduced tonnage service and engineers have given their attention to the merits possessed by anchored spans.

If a loaded carrier traverses a cable span, the ends of which are firmly anchored, and the cable is assumed to be non-elastic, the only stress effect

observed is an increase in the tension as the carrier moves from the support toward the center; when passed, the tension declines to that of the empty span as the carrier passes the support. As the erection tension of the empty cable is less than that required to develop an internal friction sufficient for the cable to show an elongation proportional to the stress, it follows that the continual change in the tension due to the passing carrier results in a mutual adjustment of the wires with regard to the applied stresses. The result is that broken wires are less frequent, and the usefulness of the cable is enhanced. The objection of tramway designers to the use of anchored spans is due to the difficulty of computing the erection tension of the cable so as not to exceed, when loaded, a pre-determined amount. By the use of formulas developed from the principles of the elastic theory, this objection has been overcome.

Lubrication.—In order to keep the internal friction at a minimum and protect cables from the elements, the aerial tramway track cables and traction ropes should be thoroughly lubricated with a non-acid oil. Tramway manufacturers can supply track-cable oilers which are equipped with tanks and oil pumps (some are operated by compressed air) belted to the carriage wheels and, when they are in motion, the pumps deliver a constant stream of oil to the cable. Traction-rope oilers are maintained in the terminals, and consist of tank, sheave, and wiping brushes. The sheave runs in oil and thus lubricates the rope. To insure uniform wear on the exterior surface of a track cable, experience has shown that it may be turned so as to present a different surface to the carriage wheels. If cables are turned, the operation must be done methodically. It will not do to operate a cable for a long time in one position and thereby allow the wires to assume a permanent set, due to the development of large internal adhesive forces, and then turn it, for the cable will then show broken wires very quickly. If a tramway has a capacity of 50 tons per hour and the cables are given a one-quarter turn for every 12 000 tons transported, and the other conditions of support, tension, and lubrication are favorable, the tonnage life will be increased. It has been recorded that more than 2 000 000 tons traversed a $1\frac{1}{4}$-in. locked-coil cable before complete replacement. Large sized track cables have not as yet developed a tonnage life equal to that secured from small cables, but by using the proper principles of design, the tonnage life is being greatly augmented.

Couplings.—Locked-coil and smooth-coil track cables cannot be spliced in the usual acceptance of the term. They are joined by a special device called a coupling, which consists of three pieces: Two sockets of nickel steel which are joined by a central plug having right and left-hand threads, the unscrewing of the several parts being prevented by dowel pins. The ends of the cable are introduced into the tapered sockets and are flared by thimbles driven between the several layers of core, key, and lock wires. The wires are gathered into groups by means of wedges driven lightly between them. Fig. 6 shows three lock-coil cable couplings that proved to be 92%, 80%, and 60%, respectively, as strong as the cable. The photograph also shows the nature of the failures resulting from improper driving of the thimbles.

FIG. 5.—ROCKING SADDLES.

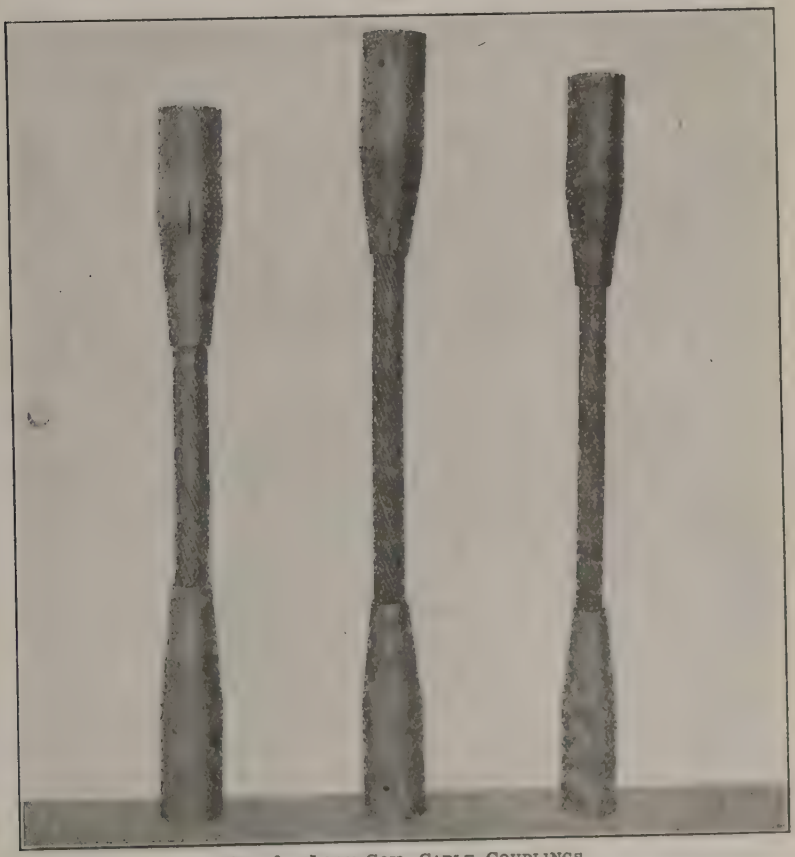

FIG. 6.—LOCK-COIL CABLE COUPLINGS.

This system of joining cables is very satisfactory, as the coupling frequently develops 90% of the ultimate strength of the cable. The sockets are made from nickel steel, and should be specially heat-treated so as best to stand the bursting pressure imposed on the tapered shell. Track cables do not fail simultaneously at all points along the line. Broken wires appear and are either welded by the oxy-acetylene blow-pipe torch, or a section of the cable is removed and a new piece coupled in, which is a very simple operation.

Traction Rope.—Practically all double-cable tramways are equipped with traction ropes made of six strands of seven wires coiled about a hemp center in a manner known as Lang lay. Steel of a grade higher than extra strong crucible is seldom used because of the hardness of the wires and the consequent tendency to rupture. Lang lay rope has the wires approximately

TABLE 7.—Crucible Steel Tramway Traction Rope, Lang Lay.

parallel in adjoining strands, which increases the flexibility and gives a greater surface of wear. Traction ropes should be lubricated regularly if satisfactory service is to be obtained. Table 7 gives the properties of Lang lay traction ropes.

Carriers.—The ordinary carrier in general use consists of a carriage that traverses the track cable. The carriage supports a trussed hanger by means of a hanger pin, which slips into a suitable receptacle in the carriage and thus permits the oscillation required by various grades on the line. The hanger holds the bucket by its trunnions and a latch. It is also provided with the necessary parts to sustain a friction grip, which may be one of several types. The carriage, hanger, and grip should be designed in accordance with the weight of the load. Table 8 gives the weight of standard empty

carriers of different volume. Self-dumping buckets and odd designs weigh more. These data are of great importance in calculating deflections, horsepower, and traction-rope tensions.

Grips.—Friction grips are divided into two classes: (1) Constant closure grips, arranged so that the movement of the jaw is fixed, as long as the adjustments remain constant; and (2) compensating grips, in which the movement of the jaw is dependent on the diameter of the rope.

Grips are further sub-divided as to style, into side-opening, top-opening, and bottom-opening, depending on whether the traction rope enters the grip from the side, top, or from below.

Constant closure grips are satisfactory because the position of the closing lever is under perfect control. They are of great utility on lines having only one section of traction rope. The compensating grips, on the other hand, should be used on multi-section lines, because traction ropes, irrespective of equal stress, do not wear so as to maintain equal diameters. The Webber grip is an example of the constant closure side-opening type, the closure of the jaws being self-locking under a positive pressure, the amount depending on the position of the adjusting screws. This is classed as an underhung grip, meaning that it is mounted on the hanger below the track cable. In traversing long spans, under conditions where the traction rope has a severe tension, underhung grips show a tendency to lift from the cable. The Bleichert grip may be either overhead or underhung and is one of the best known top-opening grips. It depends on the weight of the load acting through proper leverage on the grip jaw for its holding power. It will easily handle ropes of $\frac{3}{8}$-in. difference in diameter. The Pohlig grip is of simple design and has a bolt carrying a coarse and fine thread. The coarse thread insures rapid movement of the jaws for a limited throw of the closing lever. The finer thread acts as a differential, imposing great pressure on the rope for the final movement of the closing lever. The position of the lever, when the grip is closed, is not constant, but varies with the wear of the parts and the traction rope. It, therefore, requires constant adjustment to prevent serious accident due to the closing lever under-running the detacher. The "Wico" compensating grip is regarded by many as the best friction grip yet developed. All styles of grips for satisfactory service should develop a resistance to slipping of 1 500 lb., or more, when properly closed on the traction rope.

Buckets.—Manufacturers of tramways will supply any style of bucket desired, such as self-dumping, self-dumping and self-righting, bottom dump, etc. When buckets are not required, special receptacles are used, depending on the nature of the material to be transported.

Supports.—These may be of wood or steel and cover three classes of structures, namely, towers, rail structures, and bent supports. Towers are of two general types (*a*) those in which the track cables may be mounted without threading them through the tower; and (*b*) those with closed heads. Towers of the first type are very satisfactory for loads up to 1 500 lb. Those of the second class are battered on a slope of 10 on 1 in a direction at right angles to the center line of the tramway. Tramways are usually designed

with 6, 8, or 10-ft. gauges, depending on the size of the receptacles, transition being made between 6 and 8-cu. ft. buckets for the 6-ft. gauge, and 30 to 35-cu. ft. buckets for the 8 and 10-ft. gauges, respectively. Table 9 gives the quantities of timber in both types of supports of various heights for both 6 and 8-ft. gauges.

* For permanent construction, increase these weights 50 per cent.

When the tramway survey crosses a crest or summit of such height that a vertical curve of small radius is developed, tramway engineers specify rail structures composed of successive bents that support the carriers on tramway rails overhanging the cables, and thus accommodate the required curvature. These structures relieve the track cables of the severe stresses due to bending.

When the rate of change of the vertical curve for a chord length (determined by the spacing of the bents) is sufficiently moderate so that the cable can be used for the support of the carriers, the structure is called a bent-support. It is seldom that these structures have more than four bents, and they are not as desirable as rail structures when the slight difference in cost is neglected.

Tension Structures.—On tramway lines exceeding 1 mile in length, it is frequently necessary to use tension structures for the purpose of supporting weight-boxes which are connected to the track cables. This obviates the necessity of attempting to maintain a uniform tension in a cable passing over a great number of tower saddles. Tension structures are equipped with tramway rails so that the carriers pass from one section of cable to the next without difficulty. The traction rope is continuous and is supported by rollers. If the cables of one section are anchored and the other section is controlled by weights, the structure is known as an anchorage and tension structure. There are also double anchorage and double tension structures, depending on whether the four cables are anchored or weighted.

Guard Nets and Bridges.—In crossing public highways or railroads, it is sometimes necessary to provide protection against the premature discharge of the bucket, or its derailment. Such guards may be steel structures or suspended nets. Accidents, however, are of very rare occurrence, and unless the traffic is considerable, guard nets are installed for safety. Most railroads require an overhead clearance to the under side of the guard screens of more than 22 ft. Fig. 7 illustrates the use of guard screens.

Terminals.—This is the name given to the stations at the ends of the tramway. They are designed and equipped so as to make the operation of the tramway as nearly automatic as possible. On lines of ordinary length, the loading and discharge terminals only are required. In the former, the buckets are loaded (see Fig. 8), and, in the latter, they are discharged. Hence, the names, loading and discharge terminals.

Lines of considerable length, and especially those having a great difference in elevation between the loading and discharge terminals, must be divided into sections so as to relieve the stress in the traction rope. This requires the use of intermediate control stations. Also, if angles are desired, they may be installed at intermediate control stations or by the use of angle towers. The judicious utilization of angle towers frees the designer of aerial tramways from the limitation that they must be built in straight lines between stations.

The terminals are equipped with rails so that the carriers may run freely to the loading and discharging points. In these stations are located the

FIG. 7.—T-RAILS USED FOR GUARD-SCREEN FLOOR.

FIG. 8.—LOADING TERMINAL FOR MINE WASTE AT TIPPLE.

attachers and detachers, which automatically close and release the levers of the carrier grips.

When the velocity of the traction rope is 500 ft. per min., or more, angle stations are not desirable. However, when the velocity of the line is 400 ft. per min., or less, angle stations with continuous traction ropes may be used, and the direction of the carrier is changed by passing it around guide sheaves of large diameter. In this case, the carriers are frequently equipped with grips of the overhead type, designed so that the jaws will pass freely between the traction rope and the sheave, irrespective of the direction of travel of the carriers. In properly designed angle stations underhung grips may be used and the large diameter deflecting sheaves omitted.

Bins.—As usually installed, aerial tramways load from, and discharge into, bins. Storage facilities at the loading and discharge terminals permit freedom in operation, for production delays do not immediately stop the tramway; and, similarly, the tramway delays do not stop the operation of the plant. As bins of large capacity are built of a number of cells, Table 11 will be found of service in estimating the dimensions of square cross-section bins with bottoms sloping 45 degrees. These dimensions are computed so as to give a maximum volume with a minimum surface for the style of bin shown. The volume is stated in cubic feet and also in tons for material weighing 100 lb. per cu. ft. The dimensions apply to the inside of the bin and the framing should be arranged accordingly.

TABLE 11.

Volume, in cubic feet.	Capacity, in tons at 100 lb. per cu. ft.	Sides of square cross-section, in feet.	Center depth, in feet.	Depth of front face of bin, in feet.	Depth of back face of bin, in feet.

2 000	100	14.16	9.97	17.05	2.89

Controllers.—Tramways having considerable difference in elevation between the loading and discharge terminals, operate by gravity, and, if not controlled, tend to accelerate until the line is wrecked by "running away". Such installations are equipped with efficient differential hand-brakes and with sentinel brakes. The sentinel brake consists of revolving cone-shaped vanes attached to hinged arms so that the radius of the path of travel changes, and hence the power absorbed varies with the cube of the speed. The sentinel brake is easily adapted to absorbing from 10 to 100 h.p. Properly selected multi-vane fans may be used, also, for tramway control.

It was formerly the custom to use hydraulic controllers, which were designed on the principle of the cycloidal pump. A valve was provided, which

controlled the discharge pressure of the fluid and thus varied the resistance of the regulator. Owing to the excessive wear of the moving parts of this device, the high fluid pressure, and the danger of freezing in cold weather, it has been generally abandoned.

Tramways have been designed wherein the buckets served both as bodies of mine cars and receptacles for the aerial tramway, the transfer being effected in the loading terminal by suitable mechanism. This arrangement is not altogether desirable, for the reason that aerial tramways and mine haulages are decidedly different in principles of operation, and the class of equipment which is ideally adapted for use as mine cars is not completely satisfactory for tramway buckets.

Tramways are often equipped with elevators for raising and lowering either the empty or loaded carriers from one level to another. This usually happens when the returning carriers are loaded with back freight, which is discharged on the upper floor commanding a warehouse, and the buckets are then dropped to the lower floor, which is convenient to the loading bin.

Scales should be located in a section of the tramway rail, so that the weight of every carrier can be ascertained. These scales are equipped with type-registering beams or plain beams as required. Counters may also be installed so that the exact number of carriers passing a given point can be ascertained at any time.

Speed-indicating alarms show the velocity of the tramway at any instant. Should it exceed the predetermined speed by 5%, an electric gong sounds, which calls the operator's attention to this dangerous condition, and he may apply the brakes before disaster occurs. Special gongs are used to sound a signal for dispatching the carriers, thus insuring their uniform spacing. Electrical dispatching and loading control systems that are available reduce the toil of terminal labor to a minimum.

Reverse preventers, installed on the driving machinery of tramways, would reverse their direction due to the action of gravity on the loaded buckets. This condition always exists when the discharge terminal is at a higher elevation than the loading terminal.

Solenoid brakes have been proposed for use on aerial tramways that are motor-controlled. Alternating current is usually available, especially in the mining district. Induction motors, therefore, are used to drive or brake the tramway. Such motors "run away" when the power circuit is interrupted. The solenoid brakes operate when the circuit is broken. However, care must be utilized in choosing the size of brake so as to prevent wrecking the line due to its sudden stoppage. The speed of tramways having electrical drives is most conveniently varied by the use of drum controllers, resistance grids, and slip-ring type of motors; 50% speed regulation is easily obtained by this method.

Chutes.—A great variety of gates are used to control the flow of material from the loading bins to the tramway buckets.

Tramway Profile.—The tramway profile should be made by a competent surveyor and should have an accuracy of at least 1 to 1 500. The profile should

show the topography 25 ft. each side of the center line joining the loading and discharge terminals, and the plan should show all the control points at the loading and discharge terminals. Particular detail should be given of railroad tracks, intervening structures, the shaft, or adit, as the case may be. The topography on 2-ft. contours should be given of the sites of the loading and discharge terminals, as well as of the intermediate structures. The slope of the ground surface at right angles to the line should be indicated in degrees. It is always understood that the initial station of a tramway survey is located at the loading terminal. Accordingly, slopes may be indicated to the right or left of the line without confusion.

In crossing summits the elevations should be carefully noted, for the reason that the tramway will probably require a rail structure at such points. In crossing valleys where the depth is greater than one-tenth the span, it is not necessary to carry the line to the bottom, but it should be carried well down the slopes. This is particularly true for the ends of spans which have different elevations. If the length of the line is in excess of 5 000 ft., it should be plotted 100 ft. to the inch, the horizontal distances and elevations being drawn to the same scale. On shorter lines, a scale of 40 ft. to the inch is preferable. However, profiles when analyzed mathematically may be drawn to convenient scales, as 1 in. = 500 ft. horizontally, with 1 in = 200 ft. vertically.

Stadia surveys, carefully made, are satisfactory, but the accuracy of the work is put to the final test when the track cables are stretched from terminal to terminal like a giant tape measure. Errors in elevations appear when the cable fails to rest properly on the saddles of the supports. The position of track cables when empty and loaded can be computed with such accuracy that it is not necessary to raise or lower the towers except when errors exist in the survey. The tramway designer sometimes adds to the purchaser's expense the cost of shifting supports, because of negligence or unwillingness to analyze accurately the characteristics of the cables at the point of support and thus determine the proper elevation of the saddles so as to develop proper cable pressures.

The profile should also state the horizontal length of the proposed line; the difference in elevation of the terminal points; the capacity of the tramway, in tons per hour; the weight of the material per cubic foot when broken to the size that will be delivered to the buckets; and the nature and location of the power; also, all railroad crossings, power lines, roads, buildings, snow, grazing or cultivation clearances, or other obstacles, which the tramway must cross. The minimum clearance between the ridge of a building and the track cable is 10 ft. Most railroad companies specify a minimum clearance of 22 ft. between the bottom of the tramway bucket and the top of rail.

These points should be well considered by the engineer who makes the survey. If the work is carefully done, it is not necessary to supply the tramway manufacturer with field notes other than the data shown on the profile. The elevations and station numbers should be carefully noted.

Tables 12 and 13 are given as aids in approximating the size and timber content of the several structures used on tramways. They show the name of the station, its volume, in cubic feet, the number of feet board measure, the ratio of board feet per unit volume, and the length, width, height, and capacity.

TABLE 12.—Timber Contents of Tramway Structures.

Name.	Volume, in cubic feet.	Feet board measure.	Feet board measure, volume.	Length, in feet.	Width, in feet.	Height, in feet.	Tons per hour.	Average of
Loading terminal	18 260	15 000	0.85	67	22	15	37.5	24

Tail tower	8 790	7 450	1.01	18	16	34	15	5

Cost of Erection.—Most tramway manufacturers supply the metal parts of the tramway in accordance with the usual terms of a material contract. The customer undertakes the erection and operation of the line, and he, therefore, finds it convenient to estimate the cost of erecting and installing the tramway. Tables 14 and 15 will be of service in this regard. It will be noted that the timber required is about 20% of the cost of the installation. Tables 9 and 12 indicate the timber contents of towers and stations, from which data the cost of the installation can be approximated.

TABLE 13.—Average Weights of Steel Tramway Structures.

Name.	Volume, in cubic feet.	Length, in feet.	Width, in feet.	Height, in feet.	Weight, in pounds.	Weight, in cubic feet per pound.
Loading terminal	18 260	67	22	15	37 000	2

Formulas Used in Designing Cable Structures

Notation.—The following list of symbols has been used by the writer:

a = carrier spacing.

A = area of cross-section of cable.

$b = \dfrac{n\,(n-1)}{2}$

B = distance between points of tangency of carriage wheels on cable.

$c = \dfrac{p\,(p-1)}{2}$

d = ratio of distance from support to first carrier to span $= \dfrac{m}{s} = d.$

e = base of natural system of logarithms.
E = modulus of elasticity.
f = coefficient of friction.
F = amount of friction in terminals.
g = weight of empty carrier.
G = weight of empty carrier plus load plus weight of traction rope of length, a.
h = difference in height of span supports.

J = change in length of cable for a unit load $= \dfrac{L}{A\,E}.$

l = length of cable in empty span.
L = length of cable in loaded span.
m = distance from support to first carrier.
n = total number of loads on span.
P = net load of the carrier.
p = number of loads to left of Point $x\ y$.
Q = capacity of tramway, in tons per hour.

q = ratio of carrier spacing to span $= \dfrac{a}{s} = q.$

R = radius of curvature.

r = ratio of distance to Point $x\ y$ to span $= \dfrac{x}{s} = r.$

s = horizontal length of span.
t = horizontal component of cable tension (empty spans).
T = horizontal component of cable tension (loaded spans).
tr = Traction rope tension, empty bucket side.
Tr = Traction rope tension, loaded bucket side.
v = velocity of traction rope, in units per minute.
w = weight of cable per unit of length.
W = weight of weight-box.
x = horizontal distance from Y-axis to point under investigation.
y = distance from X-axis to point under investigation.
α = angle of slope from horizontal of chord joining supports of span.
β = angle of tangent from horizontal to curve at any point.

λ = elongation for cable for length and load $= \lambda = \dfrac{T\,L}{A\,E}.$

δ = time-spacing of carriers.
Δ = angle formed by intersecting tangents.
θ = angle of slope of tramway sections.
ϕ = angular change from end to end of catenary corresponds to Δ of parabolic formulas.

Using this notation, a number of formulas will be given, which will be found most useful in designing cable structures.

Empty Horizontal Span.—For a catenary with the origin at the left support (Fig. 9):

$$y = \frac{t}{w}\left[\sinh\frac{w\,x}{t}\sinh\frac{w\,s}{2\,t} - \cosh\frac{w\,s}{2\,t}\left(\cosh\frac{w\,x}{t} - 1\right)\right] \ldots\ldots (1)$$

For deflection at center of span:

$$y = \frac{t}{w}\left(\cosh\frac{w\,s}{2\,t} - 1\right) \quad \ldots\ldots (2)$$

Example.—Let $s = 1\,000$ ft.; $t = 10\,000$ lb.; $w = 3.6$ ft-lb.; and $x = 500$ ft.; $y = ?$

$$\frac{t}{w} = 2\,777.7778;\ \cosh\frac{w\,s}{2\,t} = 1.0162$$

$$y = 2\,777.7778 \times 1.0162 = 2\,822.7778 - 2\,777.7778 = 45.0 \text{ ft.}$$

Inclined Span.—Use plus (+) for down, and minus (—) for up, slopes:

$$y = \frac{t}{w}\left[\sinh\frac{w\,x}{t}\sinh\frac{w\,s}{2\,t} - \cosh\frac{w\,s}{2\,t}\left(\cosh\frac{w\,x}{t} - 1\right)\right]\sec\alpha \pm x\tan\alpha. \quad (3)$$

Example.—As in Equation (2), with $\tan\alpha = 0.1$; $\sec\alpha = 1.005$:

$$\begin{aligned} y &= 45 \times 1.005 = 45.225 \\ &\quad 500 \times 0.1 = 50.000 \\ &\qquad\qquad 95.225 \text{ ft.} \end{aligned}$$

Tangent.—

$$\frac{d\,y}{d\,x} = \left(\cosh\frac{w\,x}{t}\sinh\frac{w\,s}{2\,t} - \cosh\frac{w\,s}{2\,t}\sinh\frac{w\,x}{t}\right)\sec\alpha \pm \tan\alpha \quad \ldots\ldots (4)$$

Example.—$\tan\beta = ?$ in Equation (3).

At left support:

$$\tan\beta = \left(\sinh\frac{w\,s}{2\,t}\right)\sec\alpha \pm \tan\alpha \quad \ldots\ldots (5)$$

$$\sinh\frac{3.6 \times 1\,000}{20\,000}\ \sinh 0.18 = 0.1810$$

$$0.181\ \sec\alpha = 0.181 \times 1.005 = 0.1819$$

$$0.1819 + \tan\alpha = 0.2819 = 15°\ 44'\ \text{below horizontal.}$$

At right support:

$$0.1819 - 0.1 = 0.0819 = 4°\ 41'\ \text{below horizontal.}$$

Length of Span.—

$$l = \frac{t}{w}\tan\phi \quad \ldots\ldots (6)$$

in which, $\tan\phi$ = angular change, end to end of span.

Example.—In Equation (6), $\tan\phi = 0.2819 + 0.0819$, or 2×0.1819:

$$l = 2\,777.78 \times 0.3638 = 1\,010.556 \text{ ft.}$$

If

$$l = \frac{t}{w}\tan\phi = \frac{2\,t}{w}\left(\sinh\frac{w\,s}{2\,t}\right)$$

$\sec\alpha$ is written with the expansion of $\sinh\frac{w\,s}{2\,t}$, then,

$$l = s + \frac{w^2\,s^3}{24\,t^2}\sec\alpha \quad \ldots\ldots (7)$$

$$l = 1\,000.00 + (5.40 \times 1.005) = 1\,010.427 \text{ ft.}$$

This compares with the parabolic formula,

$$l = s + \frac{w^2 s^3}{24 t^2} + \frac{h^2}{2 s} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

$$\begin{aligned} s \quad + &= 1\,000.00 \\ \frac{w^2 s^3}{24 t^2} + &= \quad 5.40 \\ \frac{h^2}{2 s} \quad &= \quad 5.00 \\ l \quad &= 1\,010.40 \text{ ft.} \end{aligned}$$

Simple Spans (Parabola).—Caution: If $\alpha >$ than 6°, multiply the right-hand side of the equation by sec α.

The deflection at any point of a simple inclined span (see Fig. 9):

$$y = \frac{w x}{2 t} (s - x) \pm x \tan \alpha \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

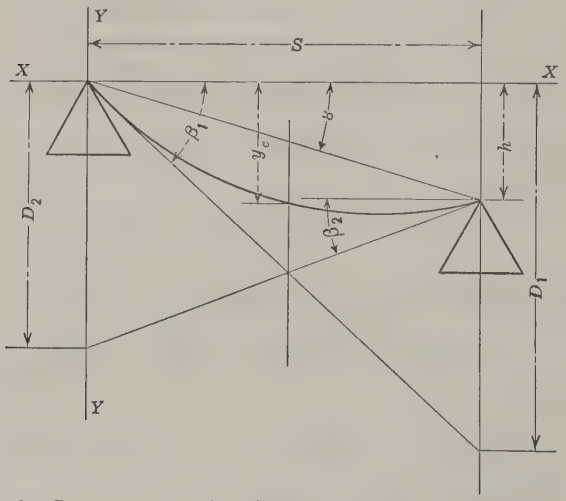

FIG. 9.—DEFLECTION OF ANY POINT OF A SINGLE INCLINED SPAN.

With the origin at either support, plus (+) indicates down slopes and minus (—), up slopes.

Example.—Let $s = 1\,000$ ft.; $w = 3.6$ lb.; $t = 10\,000$ lb.; $h = 100$ ft.; and $x = 500$ ft.

$$y = \frac{3.6 \times 500}{20\,000} (1\,000 - 500) + 500 \times \frac{100}{1\,000} = 45 + 50 = 95 \text{ ft.}$$

below the left-hand support.

Level Spans.—If the span is level, $h = 0$, and,

$$y = \frac{w x}{2 t} (s - x) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

or 45 ft. in the previous example.

Note that with a center deflection of $\frac{1}{22.2}$ of the span, the catenary (Equation (2)) and parabola equations still give equal values.

Center of Span.—If $x = \frac{s}{2}$, then,

$$y = \frac{w\,s^2}{8\,t} \pm \frac{h}{2}$$

Note that $\frac{w\,s^2}{8\,t}$ is the vertical distance below the chord, and $\frac{h}{2}$ is the distance between the chord and the x-axis through the support.

If w equals the weight of a foot of cable, 1 sq. in. in cross-section, t equals pounds per square inch, and s equals hundreds of feet, then these simple equations for center deflection of empty spans result. (See Table 16.)

TABLE 16.—Center Deflection of Empty Spans.

t, in pounds per square inch.	Deflection at center of span.	Example. 1 000-ft. span with 100-ft. difference in terminal elevation.
10 000	$y = 0.45s^2 + \frac{h}{2}$	$y\,c = 0.45 \times 10^2 + 50 = 95$ ft.
20 000	$y = 0.225s^2 + \frac{h}{2}$	$y\,c = 0.225 \times 10^2 + 50 = 72.5$ ft.
30 000	$y = 0.15s^2 + \frac{h}{2}$	$y\,c = 0.15 \times 10^2 + 50 = 65.0$ ft.
40 000	$y = 0.1125s^2 + \frac{h}{2}$	$y\,c = 0.1125 \times 10^2 + 50 = 61.25$ ft.
50 000	$y = 0.09s^2 + \frac{h}{2}$	$y\,c = 0.09 \times 10^2 + 50 = 59.0$ ft.

Deflection Formulas for Plotting Curve of Empty Cable.—If $y = \frac{w\,x}{2\,t}(s - x) + x \tan \alpha$ be stated as,

$$y = \frac{w\,s^2}{2\,t}\,r\,(1 - r) + r\,h \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

formulas of the type of Equation (11) may be written for different points along the span, as in Table 17.

Any other tension in pounds per square inch can be used by (inverse) proportion.

Example.—If $t = 10\,000$ lb. per sq. in.; $s = 1\,000$; $x = 300$; $y = ?$ In Table 17, at $x = 0.30$,

$$y = 9.45 + r\,h$$

The inverse ratio of tensions $= \frac{40\,000}{10\,000} = 4$; therefore, at 10 000,

$$y = 4 \times 9.45 = 37.80 + r\,h$$

Tangent of Simple Spans.—(See Fig. 9):

$$\tan \beta = \frac{d\,y}{d\,x} = \frac{w}{t}\left(\frac{s}{2} - x\right) \pm \tan \alpha$$

TABLE 17.—Curve of Empty Cable.

(Deflections with $t = 40\,000$ lb. per sq. in.; $y = 0.45s^2r\ (l - r)$; s given in hundreds of feet.)

$\frac{x}{s} = r.$	y at $t = 40\,000$ lb. per sq. in.	$\frac{x}{s} = r.$	y at $t = 40\,000$ lb. per sq. in.
0.02, or 0.98	$0.00882\ s^2 + r\,h$	0.26, or 0.74	$0.08658\ s^2 + r\,h$
0.04, or 0.96	$0.01728\ s^2 + r\,h$	0.28, or 0.72	$0.09072\ s^2 + r\,h$
0.05, or 0.95	$0.021375\ s^2 + r\,h$	0.30, or 0.70	$0.09450\ s^2 + r\,h$
0.06, or 0.94	$0.02538\ s^2 + r\,h$	0.32, or 0.68	$0.09792\ s^2 + r\,h$
0.08, or 0.92	$0.03312\ s^2 + r\,h$	0.34, or 0.66	$0.10098\ s^2 + r\,h$
0.10, or 0.90	$0.0405\ s^2 + r\,h$	0.35, or 0.65	$0.102375\ s^2 + r\,h$
0.12, or 0.88	$0.04752\ s^2 + r\,h$	0.36, or 0.64	$0.10368\ s^2 + r\,h$
0.14, or 0.86	$0.05418\ s^2 + r\,h$	0.38, or 0.62	$0.10602\ s^2 + r\,h$
0.15, or 0.85	$0.057375\ s^2 + r\,h$	0.40, or 0.60	$0.10800\ s^2 + r\,h$
0.16, or 0.84	$0.06048\ s^2 + r\,h$	0.42, or 0.58	$0.10962\ s^2 + r\,h$
0.18, or 0.82	$0.06642\ s^2 + r\,h$	0.44, or 0.56	$0.11088\ s^2 + r\,h$
0.20, or 0.80	$0.07200\ s^2 + r\,h$	0.45, or 0.55	$0.111375\ s^2 + r\,h$
0.22, or 0.78	$0.07722\ s^2 + r\,h$	0.46, or 0.54	$0.11178\ s^2 + r\,h$
0.24, or 0.76	$0.08208\ s^2 + r\,h$	0.48, or 0.52	$0.11232\ s^2 + r\,h$
0.25, or 0.75	$0.084375\ s^2 + r\,h$	0.50, or 0.50	$0.11250\ s^2 + r\,h$

Example.—If $s = 1\,000$ ft.; $t = 40\,000$ lb.; $w = 3.6$ lb.; $\tan \alpha = 0.1$; $x = 300$ ft.; $\tan \beta = ?$

$\tan \beta = 0.00009 \times 200 + 0.1 = 0.1180$; $\beta = 6° 44'$ below horizontal axis

Tangent at Supports.—Left, $x = 0$; right, $x = s$:

Left:

$$\tan \beta_1 = \frac{w\,s}{2\,t} \pm \tan \alpha\ (+ \text{ when } \alpha \text{ is below horizontal axis})$$

Example.—If $s = 1\,000$; $t = 40\,000$ lb.; $w = 3.6$ lb.; $\tan \alpha = 0.1$:

$\tan \beta_1 = 0.00009 \times 500 + 0.1 = 0.1450$; $\beta_1 = 8° 15'$ below horizontal axis

Right:

$$\tan \beta_2 = \frac{w\,s}{2\,t} \pm \tan \alpha\ (+ \text{ when } \alpha \text{ is above horizontal axis})$$

Example.—As before:

$\tan \beta_2 = -0.00009 \times 500 + 0.1 = 0.055 = 3° 09'$ above horizontal axis

The tangent formula is of a type that is easily adapted to any span; thus, if $t = 40\,000$ lb. per sq. in., $w = 3.6$ lb., and s is in feet, there results:

$$\frac{w\,s}{2\,t} \pm \tan \alpha = 0.000045\,s \pm \tan \alpha$$

TABLE 18.—Values of $0.000045\,s$ for Tens of Feet.

Span, in feet.	10	20	30	40	50	60	70	80	90
$\frac{w\,s}{2\,t}$	0.00045	0.00090	0.00135	0.0018	0.00225	0.0027	0.00315	0.0036	0.00405

A table, such as Table 18, may be used, by addition, for finding the tangent at the support of any simple span. Thus, let $s = 545$ ft.; $t = 40\,000$ lb. per sq. in.; and $\tan \alpha = 0.1$:

$\tan \beta_1 = 0.0225$

$0.0018 = 0.0245 + 0.1 = 0.1245$; $\beta_1 = 7° 06'$ below the horizontal axis

0.0002

If t was 20 000 lb. per sq. in., then,

$$\beta_1 = \frac{40\ 000}{20\ 000} \times 0.0245 + 0.1 = 0.149\,; \quad \beta_1 = 8° 29'$$

Maximum Span for Limiting Value of $\tan \beta_1$.—As it is often found advisable to limit the angle over the supports of a span, the length of such a span may be found by a reverse process. Thus, let $\tan \beta = 0.25$ and $t = 40\,000$ lb. per sq. in. Taking from Table 18, the successive spans corresponding to the nearest smaller values of $\frac{w\,s}{2\,t}$, the total horizontal span may be found as follows:

$$\text{For } \frac{w\,s}{2\,t} = 0.225, \text{ span} = 5\ 000 \text{ ft.}$$

$$\text{For } \frac{w\,s}{2\,t} = 0.0225, \text{ span} = 500 \text{ ft.}$$

$$\text{For } \frac{w\,s}{2\,t} = 0.00225, \text{ span} = 50 \text{ ft.}$$

$$\text{For } \frac{w\,s}{2\,t} = 0.000225, \text{ span} = 5 \text{ ft.}$$

$$\text{For } \frac{w\,s}{2\,t} = 0.249975, \text{ span} = 5\ 555 \text{ ft.}$$

By the formula, for the horizontal axis,

$$s = \tan \beta_1 \times \frac{2\,t}{w} \qquad (12)$$

$$= 0.25 \times 22\ 222.22 = 5\ 555.5 \text{ ft.}$$

By the formula, for the inclined axis,

$$s = \frac{t}{w} \tan \beta_1 \pm \frac{1}{w} \sqrt{t^2 \tan^2 \beta_1 - 2\,w\,h\,t} \qquad (13)$$

Example.—In these data, let $h = 100$ ft.; then,

$$s = 0.25 \times 11\ 111.11 + 0.2778 \sqrt{100\ 000\ 000 - 28\ 800\ 000}$$

$$= 2\ 778 + 2\ 344 = 5\ 122 \text{ ft.}$$

This may be proven by correcting the value of $\tan \beta_1$ by $\tan \alpha_1$ and solving as a horizontal span. Thus, as before,

$$\tan \alpha = \frac{100}{5\ 122} = 0.0195$$

$$\tan \beta_1 = 0.25 - 0.0195 = 0.2305$$

$$s = 0.2305 \times 22\ 222.22 = 5\ 122$$

Lowest Point of a Simple Span.—(See Fig. 9):

If $\tan \beta = 0$,

$$x = \frac{s}{2} + \frac{t}{w} \tan \alpha \quad \ldots\ldots (14)$$

If $\tan \beta = \tan \alpha$,

$$x = \frac{s}{2} \quad \ldots\ldots (15)$$

Example.—If $s = 1\,000$; $w = 3.6$; $t = 40\,000$ lb.; and $\tan \alpha = 0.0100$; how far from the left support is the lowest point of the cable?

$$x = 500 + 111.11 = 611.11 \text{ ft.}$$

If the ground surface is level, the minimum clearance will be found at this point. If x is greater than the span, the right-hand support is the lowest point.

Rate of Curvature.—

$$\frac{d^2 y}{d x^2} = -\frac{w}{t} \quad \ldots\ldots (16)$$

If, $w = 3.6$ lb. and $t = 40\,000$ lb.,

$$\frac{w}{t} = 0.00009 = \text{tan of angle per foot of span}$$

For 100 ft., $0.009 = 0° 31'$ as the total angular change for a 100-ft. span. If horizontal, this angle is equally divided between β_1 and β_2; that is, the slope of the tangent at the left support is altered 15.5′ for every 100 ft. of span for a cable, $w = 3.6$ lb. and $t = 40\,000$ lb. This permits computing the value of β_1 by direct multiplication. Thus, a 1 000-ft. span $= 10 \times 15.5' = 2° 35' = \beta_1$, if $t = 40\,000$ lb., or $10 \times 20.7' = 3° 27' = \beta_1$, if $t = 30\,000$ lb.

The Tangent Intercept.—Simple Spans.—(See Fig. 9):

$$D_1 = s \times \tan \beta_1 = \frac{w\, s^2}{2\, t} + h \quad \ldots\ldots (17)$$

But, $\frac{w\, s^2}{2\, t} = 4 \times$ the deflection of the center of a horizontal span.

Example.—If $s = 1\,000$ ft.; $t = 40\,000$ lb. per sq. ft.; $h = 100$ ft.; $D_1 = ?$ From Table 16 (deflections at 40 000 lb. per sq. ft.),

$$yc = (11.25 \times 4) + 100 = D_1$$

$$D_2 = h + s \tan \beta_2 = h + s \left(\frac{w\, s}{2\, t} - \tan \alpha\right) = \frac{w\, s^2}{2\, t} \quad \ldots\ldots (18)$$

Point of Intersection.—The equations of Line (1) and Line (2) (Fig. 9) may be written:

$$y = x \left(\frac{w\, s}{2\, t} + \tan \alpha\right) \quad \ldots\ldots (19)$$

$$y = + \frac{w\, s^2}{2\, t} - x \left(\frac{w\, s}{2\, t} - \tan \alpha\right) \quad \ldots\ldots (20)$$

Subtracting Equation (20) from Equation (19),

$$0 = \frac{w\,s\,x}{2\,t} + x \tan \alpha - \frac{w\,s^2}{2\,t} + \frac{w\,s\,x}{2\,t} - x \tan \alpha \ldots\ldots\ldots (21)$$

or,

$$\frac{2\,w\,s\,x}{2\,t} = \frac{w\,s^2}{2\,t}; \; x = \frac{s}{2} \ldots\ldots\ldots (22)$$

Therefore, the tangent rays always intersect $x = \frac{s}{2}$.

The distance below the left support is,

$$\frac{s}{2} \tan \beta_1 = \frac{s}{2}\left(\frac{w\,s}{2\,t} + \tan \alpha\right) = \frac{w\,s^2}{4\,t} + \frac{h}{2} \ldots\ldots\ldots (23)$$

Note that $\frac{w\,s^2}{4\,t}$ equals twice the center deflection of a horizontal span. Since the point of intersection and the tangent intercepts are so readily determined, the tangents to the curve at its supports are easily drawn or computed.

Radius of Curvature.—The well-known formula for radius of curvature is,

$$R = \frac{\left[1 + \left(\frac{d\,y}{d\,x}\right)^2\right]^{\frac{3}{2}}}{\frac{d^2\,y}{d\,x^2}} \ldots\ldots\ldots (24)$$

For a horizontal span, with $x = \frac{s}{2}$ and $\frac{d\,y}{d\,x} = 0$,

$$R = \frac{1}{-\frac{w}{t}} = -\frac{t}{w} \ldots\ldots\ldots (25)$$

This permits the use of circular arcs to represent cable curves. Thus, let the profile be plotted on a scale of 1 in. = 100 ft., what radius curve should be used for a cable, $w = 3.6$ lb. and $t = 40\,000$ lb.?

$$R = -\frac{t}{w} = 11\,111.11 \text{ ft.}$$

But 1 in. = 100 ft. Therefore, the proper curve is $R = 111.1$ in., if $t = 30\,000$ lb.; $\frac{t}{w} = 8\,333.3$ ft.; and $R = 83.33$ in.

Length of Simple Spans.—(See Fig. 9):

$$l = s + \frac{w^2\,s^3}{24\,t^2} + \frac{h^2}{2\,s} \ldots\ldots\ldots (26)$$

Example.—If $s = 1\,000$ ft.; $w = 3.6$ lb.; $h = 100$ ft.; and $t = 40\,000$ lb.; $l = ?$

$$s = 1\,000 \text{ ft.}$$

$$\frac{w^2\,s^3}{24\,t^2} = 0.338$$

$$\frac{h^2}{2\,s} = 5.00$$

Then,

$$l = 1\,005.338$$

Carrier Spacing, in Feet.—

Given P = the net load of a carrier.

Q = capacity, in tons.

V = velocity, in feet per minute.

$$a = \frac{0.03\ P\ V}{Q} \quad \ldots\ldots (27)$$

Carrier Spacing, in Seconds.—

$$\phi = \frac{a}{V}\ 60 = \frac{1.8\ P}{Q} \quad \ldots\ldots (28)$$

Example.—$P = 1\,000$ lb.; $Q = 20$ tons per hour; and $V = 500$ ft. per min.:

$$a = \frac{15 \times 1\,000}{20} = 750 \text{ ft.}$$

$$\phi = \frac{1.8 \times 1\,000}{20} = 90 \text{ sec.}$$

Cable Spans Supporting Carriers.—Span Carrying a Single Load.—Note that a cable supporting loads does not present a continuous curve, but rather $(n + 1)$ parabolas which intersect with an angle, $\Delta = \tan^{-1} \frac{G}{t}$, beneath each load. (See Fig. 10.) The curve of the path of any load is continuous and may be treated accordingly.

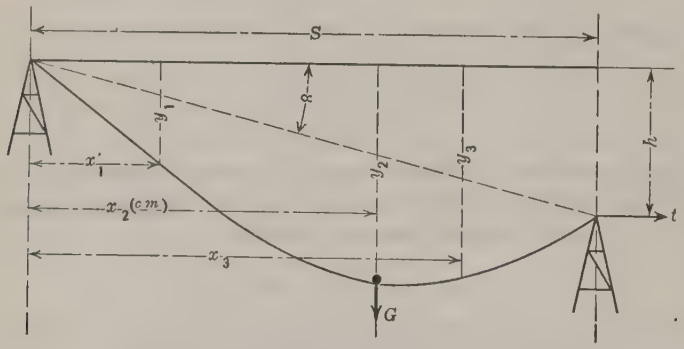

FIG. 10.—SPAN CARRYING A SINGLE LOAD.

Case I.—$m > x < s$ = equation of parabola adjoining left support:

$$y_1 = \frac{G\ (s - m)\ x_1}{s\ t} + \frac{w\ x_1}{2\ t}\ (s - x_1) + x_1 \tan \alpha \quad \ldots\ldots (29)$$

Case II.—$m = x < s$ = equation for path of load:

$$y_2 = \frac{G\ x_2\ (s - x_2)}{s\ t} + \frac{w\ x_2\ (s - x_2)}{2\ t} + x_2 \tan \alpha \quad \ldots\ldots (30)$$

Case III.—$m < x < s$ = equation of parabola adjoining right support:

$$y_3 = \frac{G\ m\ (s - x_3)}{s\ t} + \frac{w\ x_3\ (s - x_3)}{2\ t} + x_3 \tan \alpha \quad \ldots\ldots (31)$$

When $x = m = \frac{s}{2}$, Equations (29), (30), and (31) become,

$$y = \frac{G\ s}{4\ t} + \frac{w\ s^2}{8\ t} + \frac{h}{2} \quad \ldots\ldots (32)$$

Example.—Let $s = 1\,000$ ft.; $m = 500$ ft.; $x_1 = 200$ ft.; $x_2 = 500$ ft.; $x_3 = 800$ ft.; $t = 75\,000$ lb.; $w = 10$ lb. per ft.; $h = 100$ ft.; and $G = 10\,000$ lb.; y_1, y_2, and y_3 = ?

$$y_1 = \frac{10\,000 \times 500 \times 200}{1\,000 \times 75\,000} + \frac{10 \times 200 \times 800}{150\,000} + 200 \times \frac{100}{1\,000} =$$

$$13.33 + 10.67 + 20 = 44 \text{ ft. below left support.}$$

$$y_2 = \frac{10\,000 \times 500 \times 500}{1\,000 \times 75\,000} + \frac{10 \times 500 \times 500}{150\,000} + \frac{500 \times 100}{1\,000} =$$

$$33.333 + 16.667 + 50 = 100 \text{ ft. below left support.}$$

$$y_3 = \frac{10\,000 \times 500 \times 200}{1\,000 \times 75\,000} + \frac{10 \times 800 \times 200}{150\,000} + \frac{800 \times 100}{1\,000} =$$

$$13.33 + 10.67 + 80 = 104 \text{ ft. below left support.}$$

Tangents to Span Supporting One Load.—(See Fig. 10):

Case I.—

$$\tan \beta = \frac{d\,y}{d\,x} = \frac{w\,s}{2\,t} - \frac{w\,x}{t} + \frac{G}{s\,t}(s - m) + \tan \alpha \ldots\ldots\ldots (33)$$

If $x_1 = 0$, $m = 0$,

$$\tan \beta_1 = \frac{w\,s}{2\,t} + \frac{G}{t} + \tan \alpha = \text{tangent with load at left support} \ldots\ldots (34)$$

Case II.—

$$\tan \beta = \frac{w\,s}{2\,t} - \frac{w\,x_2}{t} + \frac{G}{t} - \frac{2\,G\,x_2}{s\,t} \pm \tan \alpha \ldots\ldots\ldots\ldots (35)$$

If $x_2 = 0$, $m = 0$,

$$\tan \beta_1 = \frac{w\,s}{2\,t} + \frac{G}{t} \pm \tan \alpha \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

If $x_2 = s$, $m = s$,

$$\tan \beta_2 = \frac{w\,s}{2\,t} + \frac{G}{t} \mp \tan \alpha \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

Case III.—

$$\tan \beta = \frac{w\,s}{2\,t} - \frac{w\,x_3}{t} - \frac{G\,m}{s\,t} \mp \tan \alpha \ldots\ldots\ldots\ldots\ldots (38)$$

If $x_3 = s$, $m = s$,

$$\tan \beta_2 = -\frac{w\,s}{2\,t} - \frac{G}{t} \mp \tan \alpha = \frac{w\,s}{2\,t} + \frac{G}{t} \mp \tan \alpha \ldots\ldots\ldots (39)$$

Example.—If $s = 1\,000$ ft.; $m = 500$ ft.; $x_1 = 200$ ft.; $x_2 = 500$ ft.; $x_3 = 800$ ft.; $t = 75\,000$ lb.; $w = 10$ lb. per ft.; $h = 100$ ft.; and $G = 10\,000$ lb.; $\tan \beta$ = ?

$$\tan \beta_1 = \frac{10 \times 1\,000}{2 \times 75\,000} - \frac{10 \times 200}{75\,000} + \frac{10\,000}{1\,000 \times 75\,000}(500) + 0.1$$

$$= 0.0667 - 0.0267 + 0.0667 + 0.1 = 0.2067$$

Therefore, the tangent to the cable 200 ft. from the left support makes an angle of 11° 41′ with the horizontal.

$$\tan \beta_1 \text{ at support} = 0.0667 + 0.1333 + 0.1 = 0.3000 = 16° 42'$$

$$\tan \beta_2 = -0.0667 - 0.0667 + 0.1333 + 0.1 = 0.1000 = 5° 43'$$

$$\tan \beta_3 = 0.0667 - 0.1067 - 0.1066 + 0.1 = -0.0466 = -2° 40'$$

It is understood that when using Equations (33) to (39) the minus signs indicate below horizontal, and the plus signs, above horizontal.

Spans Supporting More Than One Load.—(See Fig. 11 and Table 19):

$$y = \frac{G}{t}\left\{x\,(n-p) - m\left[\frac{x\,n}{s} - p\right] - a\left[\frac{b\,x}{s} - c\right]\right\} + \frac{w\,x}{2\,t}(s-x) \pm x \tan \alpha \quad \ldots\ldots (40)$$

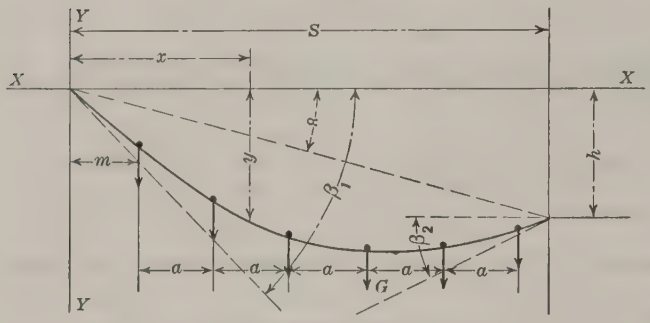

FIG. 11.—SPAN SUPPORTING MORE THAN ONE LOAD.

This may be written in the form,

$$y = \frac{G\,s}{t}\left\{(n-p)\,r - d\,(n\,r-p) - q\,(r\,b-c)\right\} + \frac{w\,s^2}{2\,t}(l-r)\,r \pm r\,h \quad \ldots\ldots (41)$$

Example.—Let $s = 1\,000$ ft.; $h = 100$ ft.; $G = 1\,000$ lb.; $w = 3.6$ lb.; $t = 40\,000$ lb.; $n = 4$; $a = 300$ ft.; $m = 50$ ft.; and $x = 500$ ft.; $y = ?$

$$r = \frac{500}{1\,000} = 0.5;\ d = \frac{50}{1\,000} = 0.05;\ q = \frac{300}{1\,000} = 0.3$$

$$y = 25\left\{2 \times 0.5 - 0.05\,(4 \times 0.5 - 2) - 0.3\,(0.5 \times 6 - 1)\right\} + \frac{3.6 \times 1\,000^2}{80\,000}\,0.5 \times 0.5 + 0.5 \times 100$$

$$y = 10 + 11.25 + 50 = 71.25 \text{ ft. below left support}$$

Tangent to Span Supporting Multiple Loads.—(See Fig. 11):

$$\tan \beta = \frac{d\,y}{d\,x} = \frac{G}{t}\left\{(n-p) - \frac{n\,m + b\,a}{s}\right\} + \frac{w}{t}\left(\frac{s}{2} - x\right) \pm \tan \alpha$$

which may be written,

$$\tan \beta = \frac{G}{t}\left[(n-p) - d\,n - q\,b\right] + \frac{w\,s}{t}\left(\frac{1}{2} - r\right) \pm \tan \alpha \quad \ldots\ldots (42)$$

Example.—Data as in previous example.

At the left support:

$$\tan \beta_1 = 0.025\,[4 - 0.20 - 1.8] + 0.027 + 0.1$$
$$= 0.050 + 0.027 + 0.1 = 0.177 = 10^\circ\ 02'$$

At the center:

$$\tan \beta_3 = 0.025\,[2 - 0.20 - 1.8] + 0 + 0.1 = 0.1 = 5^\circ\ 43'$$

At the right support:

$$\tan \beta_2 = 0.025\,[0 - 0.2 - 1.8] - 0.027 + 0.1 = 0.023$$
$$= 1^\circ\ 19'\ \text{below horizontal axis.}$$

TABLE 19.—Deflection at Center of Spans Supporting Multiple Loads, Symmetrically Placed.

No. of loads.	Deflection of loads.	+ of cable.	$+\frac{h}{2}$
1	$\frac{G\,s}{4\,t}$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$
2	$\frac{G\,s}{4\,t}(2 - 2\,q)$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$
3	$\frac{G\,s}{4\,t}(3 - 4\,q)$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$
4	$\frac{G\,s}{4\,t}(4 - 8\,q)$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$
5	$\frac{G\,s}{4\,t}(5 - 12\,q)$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$
6	$\frac{G\,s}{4\,t}(6 - 18\,q)$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$
7	$\frac{G\,s}{4\,t}(7 - 24\,q)$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$
8	$\frac{G\,s}{4\,t}(8 - 32\,q)$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$
9	$\frac{G\,s}{4\,t}(9 - 40\,q)$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$
10	$\frac{G\,s}{4\,t}(10 - 50\,q)$	$\frac{w\,s^2}{8\,t}$	$+\frac{h}{2}$

With an even number of loads, the deflection under load to right of center is,

$$\frac{G\,s}{4\,t}\left[N - \frac{N^2}{2}\,q\right] + \frac{w\,s^2}{8\,t}(1 - q^2) \pm r\,h \qquad (43)$$

With an odd number of loads, the deflection under the center load is,

$$\frac{G\,s}{4\,t}\left[N - \frac{N^2 - 1}{2}\,q\right] + \frac{w\,s^2}{8\,t} \pm \frac{h}{2} \qquad (44)$$

Example.—Let $s = 1\,000$ ft.; $h = 100$ ft.; $G = 1\,000$ lb.; $w = 3.6$ lb.; $n = 4$; $t = 40\,000$ lb.; and $a = 300$ ft.; y at center = ?

$$q = \frac{300}{1\,000} = 0.3\,;\ m = 50\ \text{ft.}$$

$$y = \frac{1\,000 \times 1\,000}{4 \times 40\,000}[4 - 8 \times 0.3] + \frac{3.6 \times 1\,000^2}{8 \times 40\,000} + 50$$
$$= 6.25 \times 1.6 + 11.25 + 50 = 71.25\ \text{ft.}$$
below left support.

Note that with n equal to an odd number, the middle load is at the center of the span.

Tangents Due to Loads Only on Saddle of Adjoining Multiple-Loaded Spans.—In Fig. 12 let the loads be arranged so that one is at the support, B.

Also, $q = \frac{a}{s}$, q_1 = Span $A\ B$, and q_2 = Span $B\ C$ (Table 20).

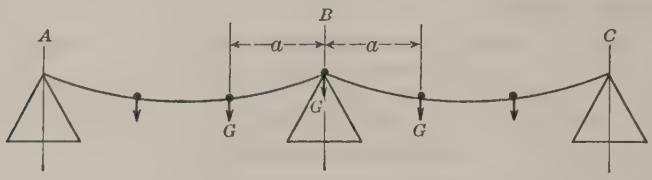

FIG. 12.—MULTIPLE-LOADED SPANS.

TABLE 20.

Span $A\ B$.	No. of loads.	Span $B\ C$.
$\frac{G}{t}(1 - q_1)$	1	$\frac{G}{t}(1)$
$\frac{2\ G}{t}(1 - \frac{3}{2}\ q_1)$	2	$\frac{2\ G}{t}(1 - 0.5\ q_2)$
$\frac{3\ G}{t}(1 - 2\ q_1)$	3	$\frac{3\ G}{t}(1 - q_2)$
$\frac{4\ G}{t}(1 - 2.5\ q_1)$	4	$\frac{4\ G}{t}(1 - 1.5\ q_2)$
$\frac{5\ G}{t}(1 - 3\ q_1)$	5	$\frac{5\ G}{t}(1 - 2\ q_2)$
$\frac{6\ G}{t}(1 - 3.5\ q_1)$	6	$\frac{6\ G}{t}(1 - 2.5\ q_2)$
$\frac{7\ G}{t}(1 - 4\ q_1)$	7	$\frac{7\ G}{t}(1 - 3\ q_2)$
$\frac{8\ G}{t}(1 - 4.5\ q_1)$	8	$\frac{8\ G}{t}(1 - 3.5\ q_2)$
$\frac{9\ G}{t}(1 - 5\ q_1)$	9	$\frac{9\ G}{t}(1 - 4\ q_2)$
$\frac{10\ G}{t}(1 - 5.5\ q_1)$	10	$\frac{10\ G}{t}(1 - 4.5\ q_2)$

Example.—If Span $A\ B$ = 900 ft. and Span $B\ C$ = 1 000 ft., a = 300 ft.; G = 1 000 lb.; and t = 40 000 lb., the maximum angle over Support B due to loads only, can be found, as follows:

Span $A\ B$ = 3 loads = $3 \times 0.025\ (1 - 0.667) = 0.025 = 1°\ 26'$
Span $B\ C$ = 4 loads = $4 \times 0.025\ (1 - 0.45) = 0.055 = 3°\ 09'$

Maximum angle over Support B $= 4°\ 35'$

Catenary.—The deflection of a loaded cable when treated as a catenary is:

$$y = \frac{G\ s}{t}[(n - p)\ r - d\ (n\ r - p) - q\ (b\ r - c)] + \frac{t}{w}\left[\sinh\frac{w\ x}{t}\sinh\frac{w\ s}{2\ t} - \cosh\frac{w\ s}{2\ t}\left(\cosh\frac{w\ x}{t} - 1\right)\right]\sec\alpha \pm r\ h \quad \ldots\ldots\ldots\ldots (45)$$

At the center of span:

$$y = \frac{G\,s}{4\,t}\left[n - \frac{n^2-1}{2}\,q\right] + \frac{t}{w}\left[\cosh\frac{w\,s}{2\,t} - 1\right]\sec\alpha \pm \frac{h}{2} \quad \ldots\ldots(46)$$

At the tangent:

$$\frac{d\,y}{d\,x} = \tan\beta = \frac{G}{t}\left[(n-p) - d\,n - q\,b\right] + \left(\cosh\frac{w\,x}{t}\sinh\frac{w\,s}{2\,t} - \cosh\frac{w\,s}{2\,t}\sinh\frac{w\,x}{t}\right)\sec\alpha \pm \tan\alpha \quad \ldots\ldots(47)$$

The deflections of a cable span, when loaded symmetrically, can be computed rapidly, by the method of differences.* Use is made of the fact that all the second differences of the deflections are equal to $-\frac{a}{t}(G + w\,a)$. Further, if the number of loads on the span is odd, the first differences are numerically equal to one-half the second. If the number is even, then the first differences are equal to the second. The slope correction is constant, and is to be added or subtracted from the first differences as indicated by the direction of the slope of the chord. In using this method it is necessary only to compute one deflection (which may be for any load, but preferably a center one), because of the simplicity of the calculation, and find the others by addition, thus: Let $s = 1\,000$ ft.; $h = 100$ ft.; $G = 1\,000$ lb.; $w = 3.6$ lb.; $t = 40\,000$ lb.; $a = 300$ ft.; and $m = 50$ ft.; $y = ?$

Compute the deflection of load nearest the left support:

$$y = \frac{G\,s\,r}{t}\left[n\,(1-d) - q\,b\right] + \frac{w\,s^2\,r}{2\,t}(1-r) \pm r\,h \quad \ldots\ldots(48)$$

$$\frac{1\,000 \times 1\,000 \times 0.05}{40\,000}\left[4\,(1-0.05) - \frac{0.3 \times 4 \times 3}{2}\right]$$

$$+ \frac{3.6 \times 1\,000^2 \times 0.05 \times 0.95}{80\,000} + 0.05 \times 100 = 2.50 + 2.14 + 5 = 9.64 \text{ ft.}$$

The second difference is:

$$-\frac{300}{40\,000} \times (1\,000 + 1\,080) = -15.6 \text{ ft.}$$

The first difference is:

$$15.6 + 0.3 \times 100 = 45.6 \text{ ft.}$$

Construct Table 21, writing the deflection found for Load 1; then add the first difference to it for the next load; then correct the first difference by subtracting the second difference and the new first difference is obtained; which, added to the deflection of the second load gives the third, etc.

TABLE 21.

Load No.	1	2	3	4
Deflection	9.64	55.24	85.21	99.64
First difference		45.6	30	14.40
Second difference		−15.6	−15.6	

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 1383.

The deflections of loaded spans may also be quickly ascertained by the use of Figs. 13, 14, and 15 for: (1) the slope factor; (2) the deflection of empty cable; and (3) the deflection due to load. Their use may be illustrated by the following example: Let, $s = 1\,000$ ft.; $h = 200$ ft.; $g = 2\,800$ lb.; $t = 60\,000$ lb.; $w = 5.5$ lb.; $X = 100$ ft.; and $M = 300$ ft.; find y.

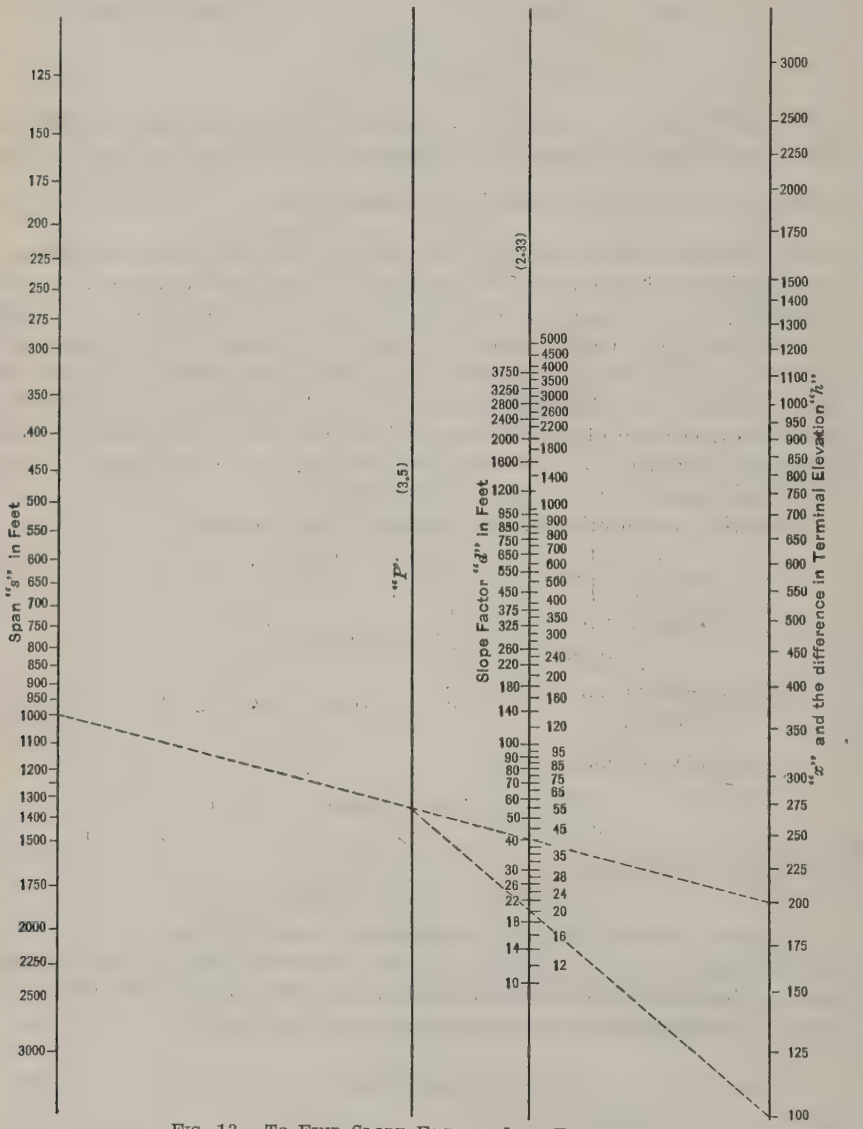

FIG. 13.—TO FIND SLOPE FACTOR, d, IN EQUATION (49).

(*a*) Refer to Fig. 13 and solve for the slope factor:

$$d = \frac{x}{s} h \qquad \text{.....(49)}$$

First, place the straight-edge from s to h and mark P. Then place the straight-edge from P to x and read the intercept, d.

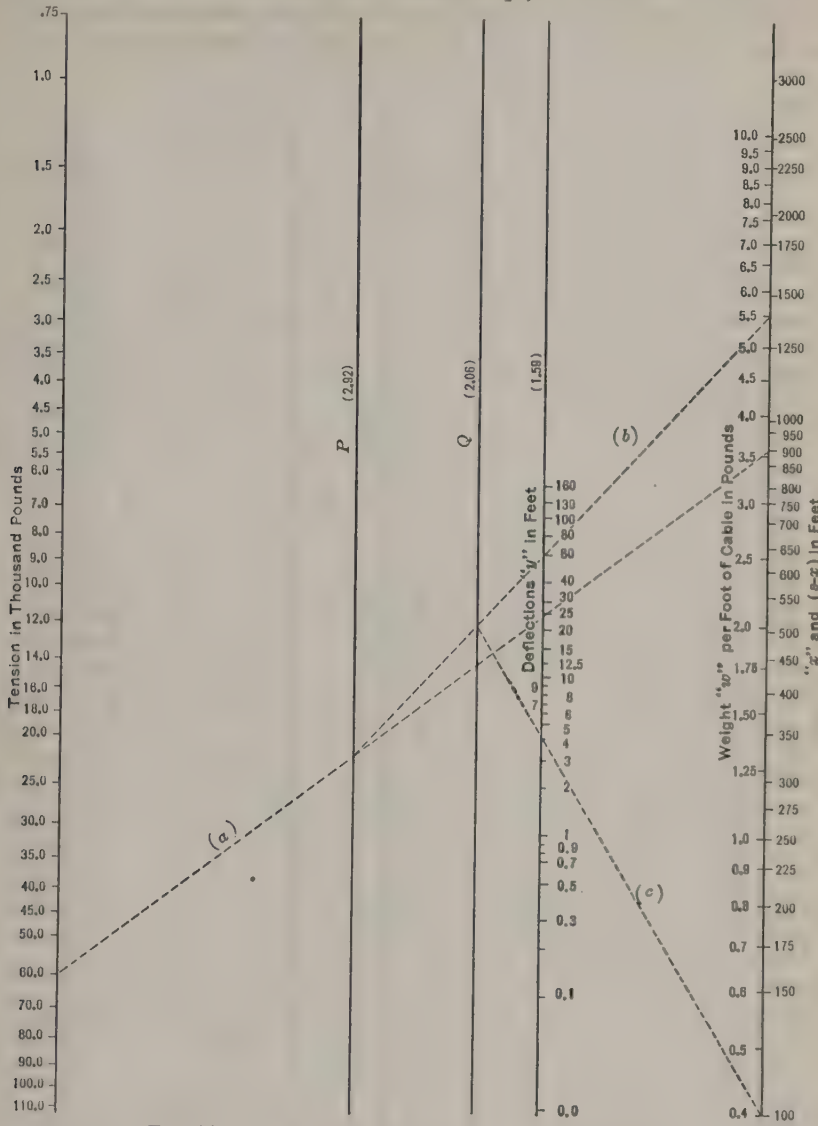

FIG. 14.—TO FIND DEFLECTION, y, IN EQUATION (50).

Thus,

$$d = \frac{100 \times 200}{1\,000} = 20 \text{ ft.}$$

(*b*) Refer to Fig. 14 and solve for,

$$y = \frac{w\,x\,(s - x)}{2\,t} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (50)$$

First, place the straight-edge on the given tension and on x, or $(5\,x)$ and note the intersection on P. Next, place the straight-edge from this point to the weight, w, and note the intersection on Q. Finally, place the straight-edge from this point (on Q) to $(s - x)$, or x, and read the deflection on y.

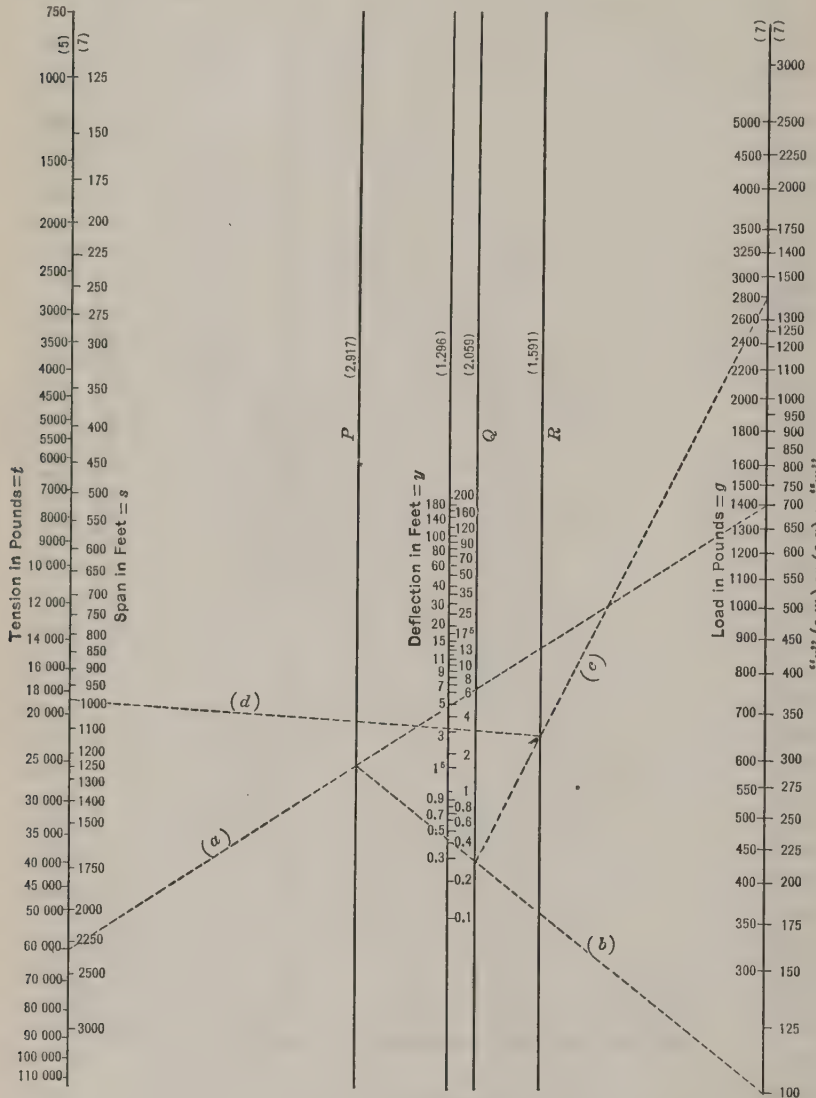

FIG. 15.—TO FIND THE DEFLECTION, y, FOR LOAD.

Thus,

$$y = \frac{5.5 \times 100 \times 900}{2 \times 60\,000} = 4.1 \text{ ft.}$$

The load part of Equations (29), (30), and (31) becomes:

$$y = \frac{g\,x\,(s - m)}{s\,t} \qquad (51)$$

when the point, xy, is between the left support and g,

$$y = \frac{g\,x\,(s - x)}{s\,t} \qquad (52)$$

when the point, xy, is under the load, g; and

$$y = \frac{g\,m\,(s - x)}{s\,t} \qquad (53)$$

when the point, xy, is between g and the right support. These may be solved by the use of Fig. 15.

First, place the straight-edge on the tension scale and $(s—m)$ and mark the intercept on P.

Next, place the straight-edge from P to x and mark Q. Then, place the straight-edge from Q to g and mark R. Finally, placing the straight-edge from R to s, read the answer on y.

Thus,

$$y = \frac{2\,800 \times 100 \times 700}{1\,000 \times 60\,000} = 3.30 \text{ ft.}$$

The total deflection below the left-hand support is:

$$20 + 4.1 + 3.3 = 27.4 \text{ ft.}$$

The diagrams may also be used to find the deflection at a point, $x\,y$, for multi-loaded spans, thus (Fig. 16); let $w = 3.5$ lb.; $t = 30\,000$ lb.; $g = 1\,800$ lb.; $a = 450$ ft.; and $m = 150$ ft.

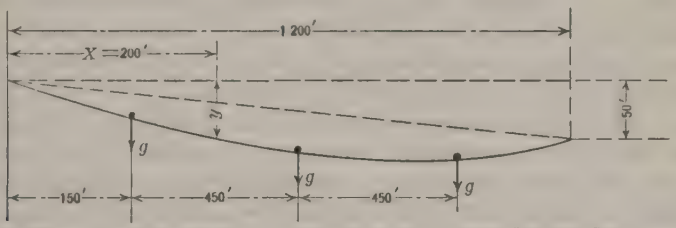

Fig. 16.—Deflection at Any Point on a Multi-Loaded Span.

(*a*) The slope factor is found from Fig. 13:

$$d = \frac{200 \times 50}{1\,200} = 8.3$$

Note since 50 does not appear on Fig. 13, use 500, but point off one place in the answer.

(*b*) The deflection of the cable is (Fig. 14):

$$y = \frac{3.5 \times 200 \times 1\,000}{2 \times 30\,000} = 11.7 \text{ ft.}$$

(*c*) To find the deflections for loads treat each one as if it were separate. As the first load is to the left of xy, the following equations result (Fig. 15):

By Equation (53):

$$y_1 = \frac{1\,800 \times 150 \times 1\,000}{1\,200 \times 30\,000} = 7.5$$

by Equation (52):

$$y_2 = \frac{1\,800 \times 200 \times 600}{1\,200 \times 30\,000} = 6.0;\ m = 150 + 450 = 600$$

by Equation (51):

$$y_3 = \frac{1\,800 \times 200 \times 150}{1\,200 \times 30\,000} = 1.5\ ;\ m = 150 + 450 + 450 = 1\,050$$

$$y_1 + y_2 + y_3 = 15.0$$

The diagrams may be used to find any of the unknown factors if the others are given. Thus, let $s = 1\,200$ ft.; $w = 3.5$ lb.; and $y = 12.5$ ft. at $x = \frac{s}{2}$; what is t (Fig. 14)?

Place the straight-edge on $y = 12.5$ to $x = 600$, and mark Q; place it on Q to $w = 3.5$, and mark P; and place it on P to $s - x = 600$, and read $t = 50\,500$ lb.

Anchored Spans.—A suspended cable hangs as a moment curve. The moment is the product of the deflection and tension. When weight-boxes are used the tension factor is made constant, and the deflection varies with the loading. It is often desirable to keep deflections within limits and have the tension vary with the loading. Such cases arise in the design of suspension bridges, cableways, and the long spans of aerial tramways. The ends of the cables of such spans are fastened to immovable anchorages; hence the term, anchored spans. To avoid injuring the cable, the loaded tension, T, is taken as the criterion for design. As it is not often practicable to erect the cable under load, the problem is to compute the empty cable erection tension, so that when loaded the tension developed in the cable will not exceed, but will be of approximately the magnitude of, the tension, T.

Cables, when placed under tension, increase in length. A part of this increment remains as permanent stretch, the remainder being due to the elastic properties of the cable. After several applications of the highest working tension, the permanent stretch becomes constant, and the elastic properties of the cable are not masked by it within this limit of tension. Therefore, anchored spans are calculated on the assumption that the cables will be erected and brought to a tension somewhat higher than the full working tension and then slackened to the empty tension.

For a span supporting a single load, such as a cableway, for instance, the loaded length, L, is given for every position of the load, by the formula,

$$L = s + \frac{G\,m}{2\,s\,T^2}(G + w\,s)(s - m) + \frac{w^2\,s^3}{24\,T^2} + \frac{h^2}{2\,s} \quad \ldots\ldots\ldots (54)$$

The maximum tension occurs when the load is at the middle of the span. The length of the empty span is,

$$l = s + \frac{w^2\,s^3}{24\,t^2} + \frac{h^2}{2\,s} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (55)$$

The change in tension, $T - t$, however, causes a shortening of the cable (ΔL). Then,

$$\Delta L = \frac{(T - t)\, L}{A\, E} = (T - t)\, J \ldots\ldots\ldots\ldots\ldots\ldots (56)$$

Therefore,

$$L - \Delta L = l, \text{ or } L = (T - t)\, J + s + \frac{w^2\, s^3}{24\, t^2} + \frac{h^2}{2\, s} \ldots\ldots\ldots\ldots (57)$$

$$J\, t + L - \left(T\, J + s + \frac{h^2}{2\, s}\right) = \frac{w^2\, s^3}{24\, t^2} \ldots\ldots\ldots\ldots\ldots\ldots (58)$$

a cubic equation having one real root.

Example.—Let $s = 1\,000$ ft.; $G = 2\,000$ lb.; $w = 4$ lb.; $T_{\max.} = 40\,000$ lb.; $h = 100$ ft.; $E = 20\,000\,000$ lb.; and $A = 1.1$ sq. in.; $t = ?$

$$L = 1\,000 + \frac{2\,000 \times 1\,000}{8 \times 40\,000^2}(2\,000 + 4\,000) + \frac{4^2 \times 1\,000^3}{24 \times 40\,000^2}$$

$$+ \frac{100^2}{2 \times 1\,000} = 1\,000 + 0.9375 + 0.4167 + 5 = 1\,006.354 \text{ ft.}$$

$$\frac{L}{A\, E} = \frac{1\,006.354}{1.1 \times 2 \times 10^7} = 0.0000457 = J$$

$$T\, J = 40\,000 \times 0.0000457 = 1.828.$$

$$L - \left(T\, J + s + \frac{h^2}{2\, s}\right) = 1\,006.354 - (1.828 + 1\,000 + 5) - 0.474$$

$$\frac{w^2\, s^3}{24} = \frac{4^2 \times 1\,000^3}{24} = 666\,666\,667$$

Then,

$$0.0000457\, t - 0.474 = \frac{666\,666\,667}{t^2}$$

Table 22 results from slide-rule computations, showing a succession of assumed values of t until the equation is satisfied (the values in the last two columns are equal).

TABLE 22.—Computations to Find Value of t.

Values of t.	$0.0000457\, t$.	-0.474	$\frac{666\,666\,667}{t^2}$
30 000 lb.	1.371	0.897	0.741
29 000 "	1.325	0.851	0.794
28 000 "	1.280	0.806	0.852
28 400 "	1.308	0.834	0.830

The erection tension is, therefore, 28 400 lb. The center deflections of this span are:

Loaded = 75 ft. below left support.
Empty = 67.6 " " " "

Difference = 7.4 ft.

If the cables were non-elastic, this difference in deflection would be very much smaller than indicated.

Conversely: To find T if a load, G, is placed on the mid-point of an empty span:

$$l - \left(J\,t + s + \frac{h^2}{2\,s}\right) = \frac{G\,s\,(G + w\,s)}{8\,T^2} + \frac{w^2\,s^3}{24\,T^2} - J\,T \ldots\ldots (59)$$

Example.— $s = 1\,000$ ft.; $G = 2\,000$ lb.; $w = 4$ lb.; $t = 28\,400$ lb.; $h = 100$ ft.; $E = 2 \times 10^7$; and $A = 1.10$ sq. in.; $T = ?$

$$l = 1\,000 + 0.827 + 5 = 1\,005.827 \text{ ft.}$$

$$J = 0.0000457$$

$$J\,t = 1.298$$

$$l - \left(J\,t + s + \frac{h^2}{2\,s}\right) = 1\,005.827 - 1\,006.298 = -0.471$$

$$\frac{G\,s\,(G + w\,s)}{8} = \frac{2\,000 \times 1\,000 \times 6\,000}{8} = 1\,500\,000\,000$$

$$\frac{w^2\,s^3}{24} = \frac{4^2 \times 1\,000^3}{24} = \frac{666\,670\,000}{2\,166\,700\,000}$$

$$0.0000457\,T - 0.471 = \frac{2\,166\,700\,000}{T^2}$$

TABLE 23.—Computations to Find Values of T.

Values of T.	$0.0000457\,T$	-0.471	$\frac{2\,166\,700\,000}{T^2}$
40 000	1.830	1.359	1.355

Therefore, the loaded tension will be 40 000 lb.

Aerial Dumping.—Cableways and aerial tramways are often used to accumulate stock or waste piles, in which case aerial dumping is required. To prevent the carrier leaving the cable, the weight of the load dumped should not exceed twice the weight of the empty carrier plus the weight of the cable of the span. In practice, it is best to make these weights equal, if unwelcome oscillations of the span are to be avoided.

If the load is not released instantly, then the minimum time interval for dumping it should exceed, in seconds, one-fourth the square root of the difference in deflection of the span before and after discharging the load. Thus, if the difference in deflection of the span when supporting the loaded and empty carrier is 4.82 ft., the time of dumping must exceed $\frac{1}{4}\sqrt{4.82}$, or 0.55 sec.

To protect roads, railways, or other points of danger, guard screens (see Fig. 17), suspended from anchored cables, are often installed. In order to design the structure properly, it becomes necessary to compute the instantaneous deflection of the screen due to the falling carrier.

The following solution of the problem is presented for the case of single spans with weighted or anchored cables.

Theory of Guard Screens.

Let the normal position of the guard screen be as shown in Fig. 17. The notation used in computing the formulas for guard screens is, as follows:

s = horizontal length of span.
h = difference in terminal elevation.
W = virtual weight of the span per foot. W is to be increased by sec α when $\alpha > 10°$.
y_0 = normal deflection below the chord.
y_1 = normal deflection increased 1 ft.
y = deflection at any instant.
x = increase in normal deflection at any instant.
t_0 = tension for normal deflection.
t_1 = tension for y_1 deflection.
T = tension for y deflection.
P_0 = resistance of screen to 1 ft. deflection.
P = resistance of screen to any deflection.
L_0 = length of cable (normal).
H = fall of carrier.
$G_0 = \dfrac{\text{weight of loaded carrier}}{\text{number of cables}}$.
G_1 = hypothetical load on screen for 1 ft. deflection.
G = hypothetical load on screen for any deflection.
$d\,t_1 = t_1 - t_0$.
$d\,t = T - t_0$.

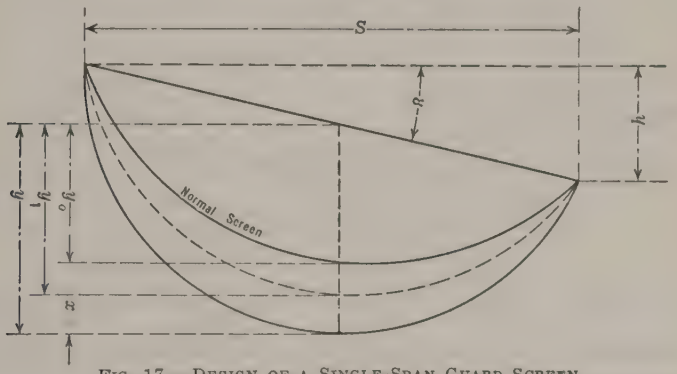

Fig. 17.—Design of a Single-Span Guard Screen.

$$y_0 = \frac{W s^2}{8 t_0} \qquad (60)$$

$$y_1 = \frac{W s^2 + 2 G_1 s}{8 (t_0 + d t_1)} = \frac{P_0 s}{8 t_1} \qquad (61)$$

$$y = \frac{W s^2 + 2 G s}{8 T} = \frac{P s}{8 (t_0 + d t)} \qquad (62)$$

$$y : y_1 = \frac{P s}{8 (t_0 + d t)} : \frac{P_0 s}{8 (t_0 + d t_1)} \qquad (63)$$

But, $y = y_0 + x$:

$$P = \frac{P_0\, y\,(t_0 + d\,t)}{y_1\,(t_0 + d\,t_1)} = \frac{P_0\,(y_0 + x)(t_0 + d\,t)}{y_1\,(t_0 + d\,t_1)} = \frac{P_0\,(y_0\,t_0 + y_0\,d\,t + t_0\,x + x\,d\,t}{y_1\,(t_0 + d\,t_1)} \quad (64)$$

$$L_0 = s + \frac{8\,y_0^2}{3\,s}\,,\quad L = s + \frac{8\,y^2}{3\,s} \quad (65)$$

$$\lambda = L - L_0 = \frac{8\,(y^2 - y_0^2)}{3\,s} \quad (66)$$

$$d\,t = \frac{\lambda\,A\,E}{L_0} = \frac{8\,(2\,y_0\,x + x^2)\,A\,E}{3\,s\,L_0} = K\,(2\,y_0\,x + x^2) \quad (67)$$

Substitute in Equation (64):

$$P = \frac{P_0\,(y_0\,t_0 + 2\,K\,y_0^2\,x + K\,y_0\,x^2 + t_0\,x + 2\,K\,y_0\,x^2 + K\,x^3)}{y_1\,(t_0 + d\,t_1)} \quad (68)$$

$$v\,d\,v = p\,d\,x \quad (69)$$

Since the carrier falls a distance, H, it has a velocity C ft. per sec. when it strikes the screen. This velocity is brought to zero in the distance, x. To state acceleration, p,

$$p = (G_0 - P)\,\frac{g}{G_0} \quad (70)$$

$$\frac{1}{g}\,v\,d\,v = d\,x - \frac{P}{G_0}\,d\,x$$

Considering the downward direction as positive and integrating:

$$\frac{1}{g}\int_c^0 v\,d\,v = \int_0^x d\,x - \frac{P_0}{G_0\,y_1\,t_1}\int_0^x (y_0\,t_0 + 2\,K\,y_0^2\,x + K\,y_0\,x^2 + t_0\,x + 2\,K\,y_0\,x^2 + K\,x^3) \quad (71)$$

Let $\frac{P_0}{G_0\,y_1\,t_1} = B$:

$$+ H = -x + B\,y_0\,t_0\,x + B\,K\,y_0^2\,x^2 + \frac{B\,K\,y_0\,x^3}{3} + \frac{B\,t_0\,x^2}{2} + \frac{2\,B\,K\,y_0\,x^3}{3} + \frac{B\,K\,x^4}{4} \quad (72)$$

$$x^4 + 4\,y_0\,x^3 + 2\left[2\,y_0^2 + \frac{t_0}{K}\right]x^2 - \frac{4\,[B\,y_0\,t_0 - 1]}{K\,B}\,x - \frac{4\,H}{K\,B} = 0 \quad (73)$$

Weighted Span.—The resistance of the screen is proportional to its deflection. Tension is constant. (See Fig. 18.)

$$y_0 = \frac{W\,s^2}{8\,t} \quad (74)$$

$$y_1 = \frac{W\,s^2 + 2\,G_1\,s}{8\,t} = \frac{P_0\,s}{8\,t} \quad (75)$$

$$y = \frac{W\,s^2 + 2\,G\,s}{8\,t} = \frac{P\,s}{8\,t} \quad (76)$$

$$y : y_1 = \frac{P\,s}{8\,t} : \frac{P_0\,s}{8\,t}$$

But $y = y_0 + x$:

$$P = \frac{P_0\, y}{y_1}\ ;\ d\,t = 0$$

Substitute in $v\,d\,v = p\,d\,x$:

$$v\,d\,v = \frac{(G - p)\,g}{G}\,d\,x \qquad (77)$$

or,

$$\frac{v\,d\,v}{g} = d\,x - \frac{P}{G}\,d\,x$$

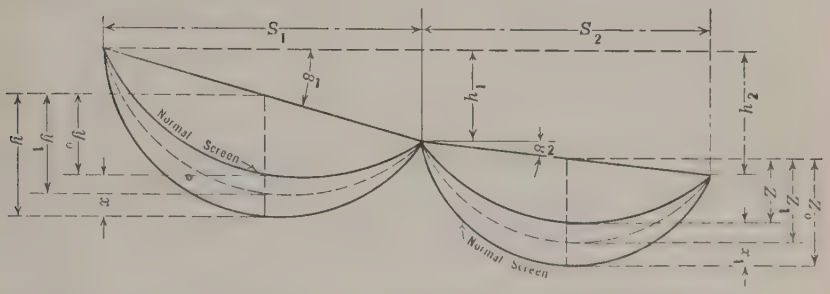

Fig. 18.—Design of Guard Screens on Adjoining Spans.

Integrating,

$$\frac{1}{g}\int_c^0 v\,d\,v = \int_0^x d\,x - \frac{P_0}{G\,y_0}\int x\,d\,x \qquad (78)$$

$$\frac{1}{g}\left[0 - \frac{C^2}{2}\right] = (x - 0) - \frac{P_0}{G\,y_0}\left[\frac{x^2}{2} - 0\right] \qquad (79)$$

$$-H = x - \frac{P_0}{G\,y_0}\cdot\frac{x^2}{2} \qquad (80)$$

$$x = \frac{G\,y_0}{P_0} \pm \frac{1}{2}\sqrt{\left(\frac{2\,G\,y_0}{P_0}\right)^2 + \frac{8\,H\,G\,y_0}{P_0}} \qquad (81)$$

Adjoining Spans.—(See Fig. 18):

$$y_0 = \frac{W_1\,s_1^2}{8\,t_0}\ ,\ Z_0 = \frac{W_2\,s_2^2}{8\,t_0}\ ;\ y_1 - y_0 = 1\text{ ft} \qquad (82)$$

$$y_1 = \frac{W_1\,s_1^2 + 2\,G_1\,s_1}{8\,(t_0 + d\,t_1)}\ ;\ Z_1 = \frac{W_2\,s_2^2}{8\,(t_0 + d\,t)} \qquad (83)$$

$$L_{y_1} = \frac{8\,y_1^2}{3\,s_1}\ ;\ L_{Z_1} = \frac{8\,Z_1^2}{3\,s_2} \qquad (84)$$

Let b = length of back-stays. Then, the normal length is $L_{y_0} + L_{Z_0} + b = L_0$. $L_0\,\lambda = B$.

$$L_{y_1} + L_{Z_1} + b = L_{y_0} + L_{Z_0} + b + d\,L_1 \qquad (85)$$

$$(L_{y_1} - L_{y_0}) = C\ ;\ \ (L_{Z_1} - L_{Z_0}) = d = \frac{W_2^{\,2}\,s_2^{\,3}}{24\,(t^2 - t_0^2)} \qquad (86)$$

therefore,

$$C + d - d\,L_1 = 0\,; \quad d\,L_1 = \lambda\,(L_{y_0} + L_{Z_0} + b)\,(t - t_0)$$

$$C + \frac{W_2^{\,2}\,s_2^{\,3}}{24\,(t^2 - t_0^{\,2})} - B\,(t - t_0) = 0 \ldots\ldots\ldots\ldots\ldots (87)$$

This gives the solution for t, from which G_1 and P_0 can be computed.

$$d\,L = L - L_0 = \frac{8}{3\,s_1}\,(y^2 - y_0^{\,2}) + \frac{8}{3\,s_2}\,(Z^2 - Z_0^{\,2}) \ldots\ldots\ldots (88)$$

But,

$$y = y_0 + x\,; \; Z = Z_0 - x_1$$

$$d\,t = \frac{d\,L\,A\,E}{L_0} = \frac{8}{3}\,\frac{(2\,y_0\,x + x^2)\,A\,E}{L_0} + \frac{8}{3}\,\frac{(-2\,Z_0\,x_1 + x_1^{\,2})\,A\,E}{L_0} \ldots (89)$$

But,

$$x_1 = \frac{W_2\,s_2}{W_1\,s_1}\,x = J\,x$$

$$d\,t = K\,[2\,(y_0 + Z_0\,J)\,x + (1 + J^2)\,x^2] \ldots\ldots\ldots\ldots (90)$$

$$P = \frac{P_0\,(y_0\,t_0 + y_0\,K\,[2\,(y_0 + Z_0\,J)\,x + (1 + J^2)\,x^2] + t_0\,x + x\,K\,[2\,(y_0 + Z_0\,J)\,x + (1 + J^2)\,x^2]}{y_1\,(t_0 + d\,t_1)} \ldots\ldots (91)$$

$$v\,d\,v = p\,d\,x$$

Since the velocity of the falling carrier is brought to zero in the distance, x, to state acceleration, p,

$$p = (G_0 - P)\,\frac{g}{G_0} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (92)$$

$$\frac{1}{g}\,v\,d\,v = d\,x - \frac{P}{G_0}\,d\,x$$

Considering the downward direction as positive and integrating,

$$\frac{1}{g}\int_c^0 v\,d\,v = \int_0^t d\,x - \frac{P_0}{G_0\,y_1\,t_1}\int_0^x \{y_0\,t_0 + y_0\,K\,[2\,(y_0 + Z_0\,J)\,x + (1 + J^2)\,x^2] + t_0\,x + x\,K\,[2\,(y_0 + Z_0\,J)\,x + (1 + J^2)\,x^2]\} \ldots (93)$$

Let $\frac{P_0}{G_0\,y_1\,t_1} = B$,

$$+ H = -x + B\,y_0\,t_0\,x + B\left[\frac{t_0}{2} + y_0\,K\,(y_0 + Z_0\,J)\right]x^2 + \frac{B\,K\,[y_0 + y_0\,J^2 + 2y_0 + 2\,Z_0\,J]\,x^3}{3} + \frac{B\,K\,[1 + J^2]\,x^4}{4} \ldots\ldots (94)$$

$$x^4 + \frac{4\,y_0\,[3 + J^2 - 2\,Z_0\,J]}{3\,[1 + J^2]}\,x^3 + \frac{4\left[\frac{t_0}{2} + y_0\,K\,(y_0 + Z_0\,J)\right]}{K\,[1 + J^2]}\,x^2 + \frac{4\,[B\,y_0\,t_0 - 1]}{B\,K\,[1 + J^2]}\,x - \frac{4\,H}{B\,K\,[1 + J^2]} = 0 \ldots\ldots\ldots (95)$$

Anchored Cables.—

Example.—Let $W = 10$ lb. per ft.; $t_0 = 5\,000$ lb.; $y_0 = 10$ ft.; $G_0 = 1\,000$ lb.; $H = 12$ ft.; $s = 200$ ft.; $A = 1.1$ sq. in.; and $E = 20 \times 10^6$. Then:

$$L_0 = 200 + \frac{8 \times 10^2}{3 \times 200} = 201.33 \text{ ft.}; \quad L_1 = 200 + \frac{8 \times 11^2}{3 \times 200} = 201.61 \text{ ft.}$$

$$\lambda = 201.61 - 201.33 = 0.28 \text{ ft.}$$

$$d\,t_1 = \frac{0.28 \times 1.1 \times 20 \times 10^6}{201.33} = 30\,600 \text{ lb.}$$

$$t_1 = 30\,600 + 5\,000 = 35\,600 \text{ lb.}$$

$$K = \frac{8 \times 1.1 \times 20 \times 10^6}{3 \times 200 \times 201.33} = 1\,460$$

$$P_0 = \frac{11 \times 8 \times 35\,600}{200} = 15\,700 \text{ lb.}$$

$$B = \frac{15\,700}{1\,000 \times 11 \times 35\,600} = 0.00004$$

$$x^4 + 40\,x^3 + 406.86\,x^2 - 68.4\,x - 825 = 0$$

$$x = 1.41 \text{ ft.}; \quad \lambda = 0.41 \text{ ft.}; \quad T = 49\,675 \text{ lb.}$$

Weighted Cables.—

$$t = \frac{10 \times 200^2}{8 \times 10} = 5\,000 \text{ lb.}$$

$$P_0 = \frac{40\,000 \times 11}{200} = 2\,200 \text{ lb.}$$

$$x = \frac{1\,000 \times 10}{2\,200} + \frac{1}{2}\sqrt{\left(\frac{2 \times 1\,000 \times 10}{2\,200}\right)^2 + \frac{8 \times 12 \times 1\,000 \times 10}{2\,200}}$$

$$= 4.53 + 11.39 = 15.92 \text{ ft.}$$

Friction.—The coefficient of friction, k, of tramway carriages moving at speeds less than 700 ft. per min. were determined to be as shown in Table 24.

TABLE 24.—Coefficient of Friction of Tramway Carriages.

Load, in pounds.	Wheel-base, in inches.	Journals.*	Coefficient of friction, k.
5 525	21.5	Ball-bearings	0.0045
1 535	21.5	" "	0.0031
2 525	13.75	Cast-steel wheels on bronze pins	0.0192
2 500	13.75	Babbitt bushings on steel pins	0.0158
2 500	13.75	Bronze bushings on steel pins	0.0163
535	13.75	Bronze bushings on steel pins	0.0122
1 240	11.875	Cast-steel wheels on bronze pins	0.0160
1 245	11.875	Ball-bearing	0.0108
255	11.875	Cast-steel wheels on bronze pins	0.0073
260	11.875	Ball-bearing	0.0083

* For roller bearings, multiply values for ball bearings by 1.5.

Coasting Distance.—It is often necessary to determine the coasting distance of a detached carrier.

Let,

$\frac{G}{32.2}$ = mass of tramway carrier; G = weight, in pounds.

p = acceleration, plus or minus.

F = friction.

$\frac{F}{G} = k$ = coefficient of friction.

S = distance traveled.

V = velocity.

H = velocity head.

T = time, in seconds.

Then,

$$F = \frac{G}{32.3}p;\ p = 32.2\,k;\ S = \frac{V_1^2 - V_0^2}{2\,p} = \frac{0.0155\,(V_1^2 - V_0^2)}{k} \quad \ldots\ (96)$$

To coast to rest,

$$S = \frac{0.0155\,V^2}{k}, \text{ or } S = \frac{H}{k}.$$

Example.—If a carrier, running free upon a level rail, has an initial velocity of 8.33 ft. per sec. ($k = 0.0155$), how far will it coast?

$$S = \frac{0.0155 \times 8.33^2}{0.0155} = 69 \text{ ft.}$$

If the rail is not level, but has a slope equal to tan θ:

$$S = \frac{0.0155\,V^2}{k \pm \tan\theta} \quad \ldots\ (97)$$

Thus, in the previous example, if the rail grade is 1% upward:

$$S = \frac{0.0155 \times 8.33^2}{0.0155 + 0.01} = 41.9 \text{ ft.}$$

Example.—What upward grade should a rail have to stop a free running carrier moving 8.33 ft. per sec. ($k = 0.0155$), in a distance of 10 ft.?

$$\tan\theta = \frac{0.0155\,V}{S} - k = \frac{0.0155 \times 8.33^2}{10} - 0.0155 = 9.2\%$$

and the difference in elevation of the points on the rail 10 ft. apart is 0.92 ft. Should the time required to bring the carrier to rest be desired:

$$T = 0.25\sqrt{\frac{S}{k \pm \tan\theta}} \quad \ldots\ (98)$$

$$= 0.25\sqrt{\frac{10}{0.0155 + 0.092}} = 2.41 \text{ sec.}$$

Tension in Traction Rope.—Let A, B, and C, Fig. 19, be loading, discharge, and curve rail stations, respectively, of an aerial tramway. It is desired to determine the traction rope tensions at Stations A and C, friction included. Motion is impending from Station A to Station B, loaded side. Let $T\,r$ = ten-

sion loaded side and $t\,r$ = tension empty side. The tensions at Station C for loaded and empty sides are, as follows:

$$T\,r = N_2\,G\,(\sin\theta_2 - k) + \frac{W}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (99)$$

$$t\,r = N_2\,g\,(\sin\theta_2 + k) + \frac{W}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (100)$$

in which, W is the weight of the traction rope weight-box, and k is the coefficient of friction.

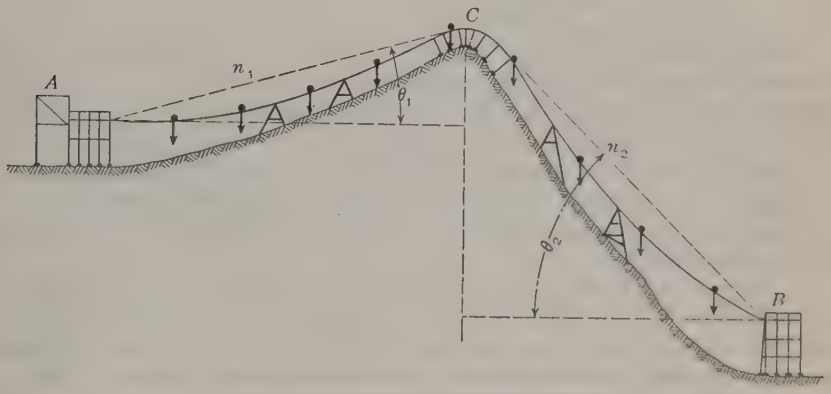

FIG. 19.—TENSION IN TRACTION ROPE.

The tension at Station A will be that at Station C increased or reduced by the loading of the Section A-C, depending on the elevation of Station A as compared with that of Station C. If Station A is lower than Station C, then,

$$T\,r = G\,[N_2\,(\sin\theta_2 - k) - N_1\,(\sin\theta_1 + k)] + \frac{W}{2} \quad \ldots\ldots\ldots (101)$$

$$t\,r = g\,[N_2\,(\sin\theta_2 + k) - N_1\,(\sin\theta_1 - k)] + \frac{W}{2} \quad \ldots\ldots\ldots (102)$$

$$\pm\,(T\,r - t\,r) = (G - g)\,(N_2 \sin\theta_2 - N_1 \sin\theta_1) - (G + g)\,(N_2\,k + N_1\,k) \quad \ldots\ldots\ldots\ldots\ldots (103)$$

As the relative values of $T\,r$ and $t\,r$ are not known, their difference may be plus or minus. Let this difference equal $\pm\,D$, then the horse power, $H\,P$, of the tramway may be estimated:

$$H\,P = \frac{\pm\,D\,V}{33\,000} - 2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (104)$$

When the sign is plus, power is developed; when it is minus, power is required. The number, 2, represents the terminal friction reduced to horse power, and will be found sufficient for all stations of usual design.

To prevent the traction rope from slipping, $T\,r$ must have a proper value, $2\,T\,r_1$, which is,

$$2\,T\,r_1 = D\,(1 + K)$$

in which,

$$K = \frac{e^{f\pi n} + 1}{e^{f\pi n} - 1}$$

in which, f is the coefficient of friction of the rope on the sheave, and n is the number of half laps of the rope on the sheave.

For $n = 1$, K has the following values:

Greasy rope on an iron sheave	9.13
" " " a wood-filled sheave	4.62
" " " a rubber and leather-filled sheave	3.21
" " " a grip sheave	2.00

Traction Rope Weight-Box.—Let $W = 2\ (T\ r_1 - T\ r)$ be positive; then W equals the weight of the traction rope tension mechanism. If W is zero or negative, the adhesion to the driving sheave is sufficient, and the weight-box will be of such size only as may be required to maintain a proper tension in the traction rope at the attacher. This tension is usually about 1 000 lb., so that the minimum weight of the tension mechanism is about 2 000 lb.

The use of these formulas is illustrated in the mathematical analysis of the tramway profile.

Size of Track Cables.—The selection of a track cable for a carrier of known weight is one of the important problems of aerial tramway engineering. Track cables are to the tramway what rails are to a railway; they must be sturdy enough to give reasonable tonnage capacities, but not so large as to involve excessive first cost. The choice of track cables may be left to the results of experience, or immersed in the fog of theoretical speculation which surrounds the question of the bending stress in wire ropes. It is presumed that the determination of the bending stress in the wires of a rope has for its purpose the discovery of the reduction in strength of a wire rope due to bending. Those who have had occasion to make practical use of wire ropes by bending them around the small sheaves of wire-rope blocks, know that the loss in strength is an insignificant part of the amount it should be according to published tables based on bending stress. For instance, a 6 × 19 ¾-in. plow steel rope is reduced about 8% in strength when bent around a sheave 6 in. in diameter.

The velocity of the rope in passing around sheaves has a profound influence on its life and, for the same rope, sheaves of different diameters are required for equal service at different speeds. As aerial tramway velocities are usually less than 600 ft. per min., velocity factors may be eliminated from this discussion.

If the validity of the theory of flexure when applied to wire ropes is granted, it is easy to derive an expression for the curve of a track cable between the points of contact of the carriage wheels:

$$y = \frac{G}{t}\left[x - \frac{\sinh\sqrt{\frac{t}{E\ I}}\,x}{\sqrt{\frac{t}{E\ I}}\cosh\sqrt{\frac{t}{E\ I}}\,L}\right] \qquad (105)$$

and,

$$\frac{dy}{dx} = \frac{G}{2t}\left[1 - \frac{\cosh\sqrt{\frac{t}{EI}}x}{\cosh\sqrt{\frac{t}{EI}}L}\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (106)$$

Where the origin is at the point of wheel contact and L is one-half the distance between wheel contacts, I is the moment of inertia of the rope. Therefore, the curve of cable bending is a function of the load, tension, wheel base, wheels, and the construction, as well as the metal of the cable. It is noted, from an examination of the data of lock-coil cable tests, that the modulus of elasticity is a function of the tension, which influences the amount of internal friction, and thus determines the behavior of the cable when loaded. Fig. 20 illustrates three complete cycles of progressive and retrogressive loading of a 1-in. lock-coil cable. It is apparent that the stress-strain curve of restitution does not coincide with the curve of deformation. After the permanent stretch has been eliminated, a closed foot-pound diagram results, from which the magnitude of the internal friction can be estimated in a manner similar to the mean effective pressure from an engine indicator card. Table 25 gives the internal friction of several lock-coil cables under sufficient tension to follow Hooke's law.

TABLE 25.—Internal Friction of Lock-Coil Cables.

Diameter, in inches.	Internal friction, in pounds.
⅞	4 900
1	7 700
1⅛	8 800
1¼	9 700
1⅜	13 100
1⅝	14 800

Since the internal friction is due to the pressure exerted by the helical windings, and varies with the tension, it is clear that the cable resistance to bending increases with the tension until it takes on the semblance of a homogeneous bar, although it is noted that the modulus of elasticity does not reach the values of bars. Table 26 gives the value of the modulus of elasticity of various ropes under tensions equal to one-fourth the ultimate strength.

TABLE 26.—Modulus of Elasticity of Various Ropes.

Kind.	Size, in inches.	Values of E, in pounds.
Lock-coil, lock-wire, and smooth coil	1¼ and smaller	23 000 000
Lock-coil, lock-wire, and smooth coil, larger than	1¼	20 000 000
6 × 7 crucible	⅝	12 000 000
6 × 19 "	¾	10 000 000
6 × 37 "	"	10 000 000
8 × 19 "	"	6 000 000
6 × 37 plow	2¼	15 000 000

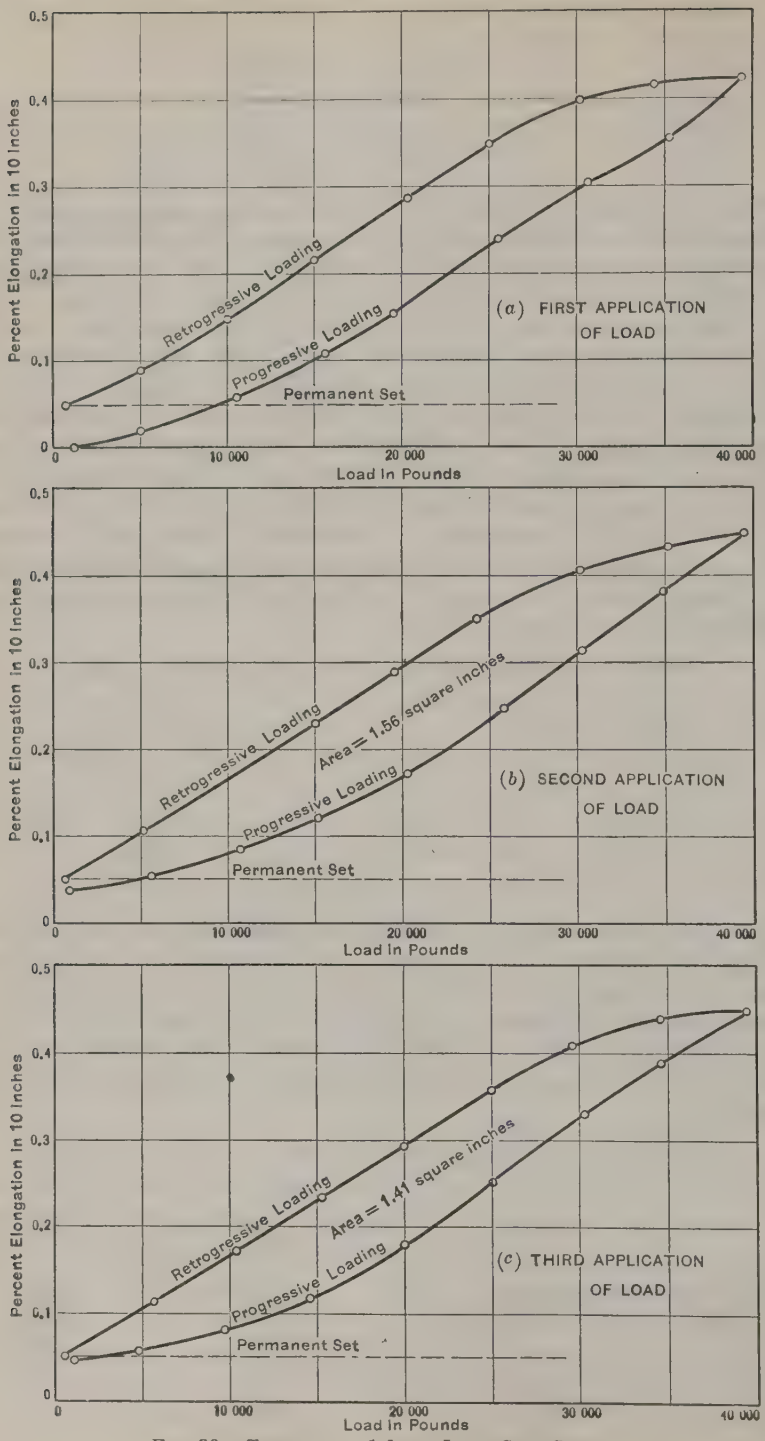

FIG. 20.—TESTS ON A 1-INCH LOCK-COIL CABLE.

For tensions less than one-quarter the ultimate, the following values of E (Table 27) are given for a 1-in. lock-coil cable.

TABLE 27.—Modulus of Elasticity for Lock-Coil Cable.

Tension, in pounds.	Values of E, in pounds.
0	1 500 000
5 000	2 400 000
7 500	3 400 000
10 000	5 000 000
12 500	7 750 000
15 000	9 250 000
17 500	12 000 000
20 000	15 300 000
25 000	23 000 000

Having ascertained the value of the modulus of elasticity with regard to tension, the value of the stress set up in the outermost wire of the cable due to bending, may be computed approximately. It can be shown that the curve of the bent track cable does not differ greatly from a circular arc, and if the intersection angle of the tangents is Δ, the radius of curvature, R," will be,

$$R'' = \frac{W}{2 \times \sin \frac{\Delta}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (107)$$

Table 28 gives the value of R for various chords and intersection angles for a 1-in. lock-coil cable.

TABLE 28.—Values of R for Various Chords and Intersection Angles.

Δ, in degrees.	$\frac{G}{t}$	Chord, in inches.	Radius, in feet.	Remarks.
1	0.0175	11.96	57	
2	0.0349	12.04	28.7	
3	0.0524	12.12	19.2	
4	0.0700	12.20	14.50	Wheel base, $W = 11.875$ in.
5	0.0875	12.28	11.7	Diameter of wheel = 8.25 in.
6	0.1051	12.36	9.9	
7	0.1228	12.44	8.5	
8	0.1405	12.52	7.5	

Having the radius, the bending stress, B, may be computed from the formula,

$$B = \frac{E\,d}{2\,R} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (108)$$

in which, d is the diameter of the rope or cable, and R is the radius of the cable curve, in inches.

Tables 29 to 37 give the computed bending and direct stresses for several different sizes of lock-coil track cables. It will be noted that the sum of these stresses changes rapidly with the tension. This leads to the conclusion that their sum is a minimum for a given load and a variable

TABLE 29.—STRESSES IN $\frac{7}{8}$-INCH LOCK-COIL CABLE, OX CARRIAGE.*

2	9.4	2.60	78 000	4 700

For cableways, and similar designs, in which the carrier does not pass the supports, moderate tensions may be used to advantage. For aerial tramways in which the cable angles over the tower saddles are small, the higher cable tensions are preferable. Considering these results in the light of experience, Table 38, of loads for lock-coil cable, is presented.

Profiles.—The calculation of aerial tramway profiles is as follows: Let Table 39 be a record of the survey of the center line, the initial station at the proposed loading terminal, topography being omitted.

TABLE 39.—Record of Survey of Center Line for Aerial Tramways.

Station.	Elevation.	Station.	Elevation.
0	6 180	15	5 660
1	6 118	Deep gorge	
2	6 077	29	5 525
3	6 058	30	5 570
4	6 062	31	5 605
5	6 015	32	5 630
6	5 948	33	5 590
7	5 920	34	5 538
8	5 898	35	5 460
9	5 868	36	5 380
10	5 855	37	5 325
11	5 835	38	5 278
12	5 807	39	5 245
13	5 752	40	5 225
14	5 715	41	5 215
15	.....	42	5 210
..	.....	43	5 200

The stations have been plotted, and are shown in Fig. 22. By using a horizontal scale of 1 in. = 500 ft. and a vertical scale of 1 in. = 200 ft., the diagram becomes of a size convenient for analysis.

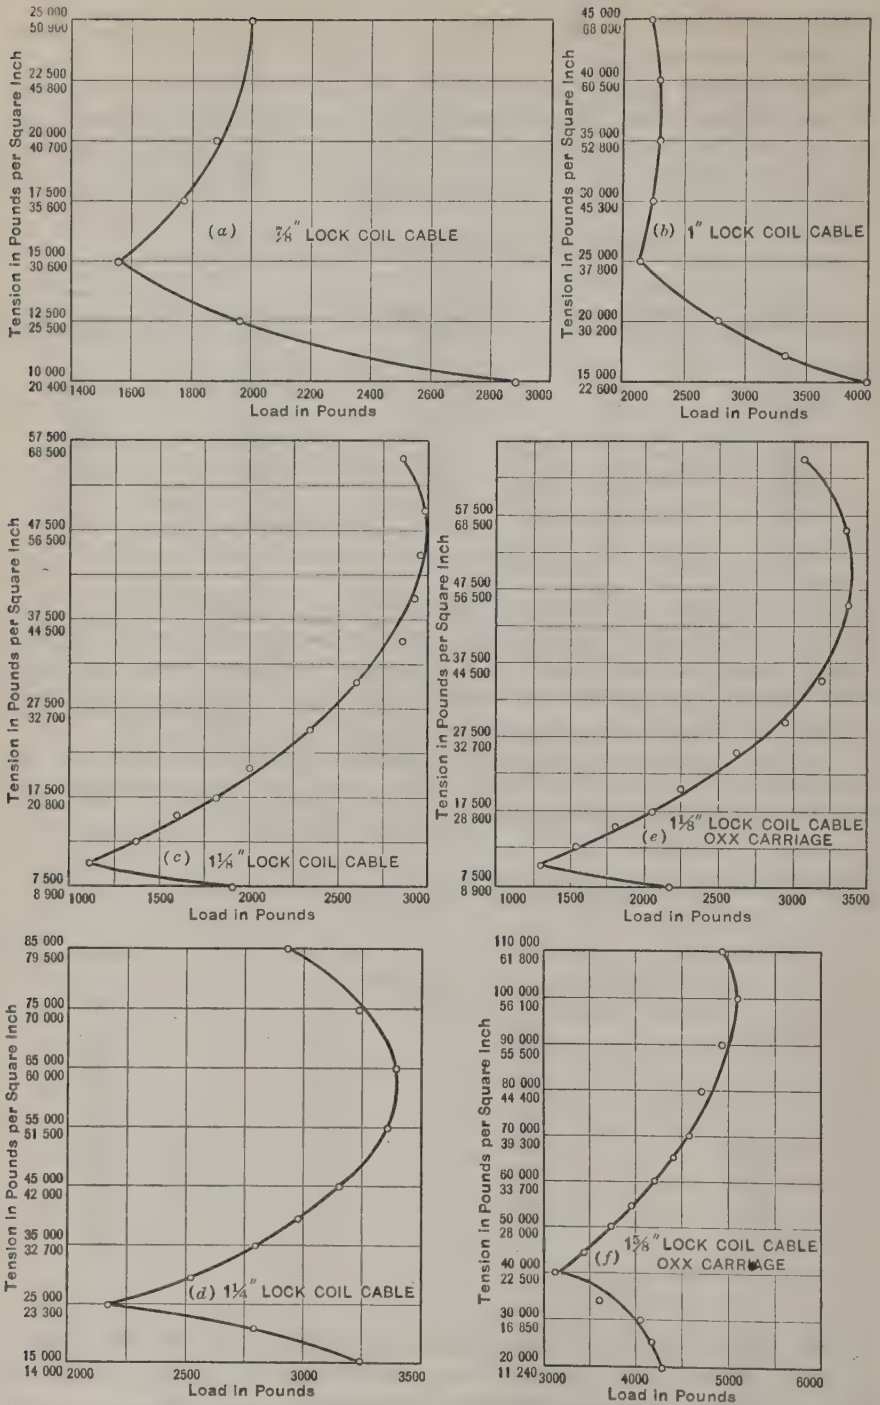

FIG. 21.—LOAD CAPACITY OF LOCK-COIL CABLES FOR DIFFERENT TENSIONS, STRESS IN OUTERMOST WIRE, 115 000 POUNDS PER SQUARE INCH.

The capacity of the tramway is 72 tons per hour of ore weighing (in buckets) 100 lb. per cu. ft., with a velocity 500 ft. per min. The bucket spacing is best determined by the criterion that the cost of the carrier is equal to the cost of the track cable between carriers. Thus, if the cost of a 12-cu. ft.

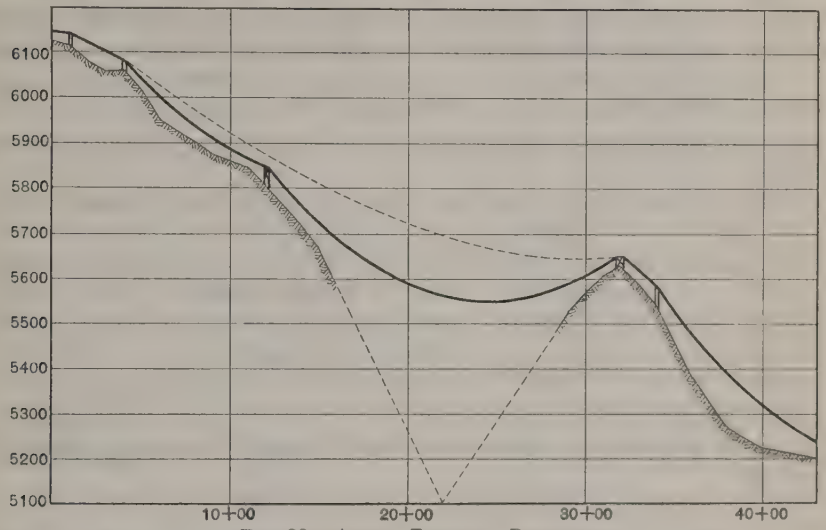

FIG. 22.—AERIAL TRAMWAY PROFILE.

carrier is \$150.00 and 1¼-in. locked-coil cable costs \$0.60 per ft., the spacing should be about 250 ft. As the carriers hold 1 200 lb., the spacing is calculated as follows:

$$\frac{0.03 \times 1\,200 \times 500}{72} = 250 \text{ ft.}$$

Therefore, the spacing of carriers based on velocity and tonnage agrees with the cost criterion. A study of the bending stress of lock-coil cables under tension and of their frictional hysteresis, and personal experience, lead to the following conclusion: The weight of the loaded carrier plus the weight of a traction rope of a length equal to the spacing should not exceed $500\,w$ or $525\,w$ (w = weight per foot of cable) for track cables under tensions of 30 000 lb., or 40 000 lb., per sq. in., respectively.

The weight of an empty 12-cu. ft. carrier may be taken as 450 lb., that of ore as 1 200 lb., and 250 ft. of traction rope as 220 lb., a total of 1 870 lb. This sum, divided by 500, indicates a track cable weighing 3.8 lb. per ft., or 1¼ in. in diameter, when under 30 000 lb. per sq. in.

Assuming a snow clearance of 10 ft. for structures along the line, this profile may be divided in two sections as follows:

Section I:

Loading terminal....	Station	0	....	Elev.	6 145
Curve rail	"	31 + 80	....	"	5 650
		3 180 ft.			495 ft.

Section II:

Curve rail	Station 32 + 20	....Elev.	5 645
Discharge terminal ..	" 43 + 00	.... "	5 235
	1 080 ft.		410 ft.

These data give chord slopes of 8° 51′ and 20° 46′ for Sections I and II, respectively. Multiplying the carrier spacing by the cosine of these angles results in horizontal spacings of 247 ft. and 234 ft. The number of carriers on Section I is $\frac{3\,180}{247} + 1 = 14$; and on Section II, $\frac{1\,080}{234} + 1 = 5$. The coefficient of friction, $k = 0.0141$; therefore, the traction rope tension may be computed:

$$T\,r = 1\,870\,[14\,(\sin 8° 51' - 0.0141) + 5\,(\sin 20° 46' - 0.0141)]$$

$$1\,870\,[1.95 + 1.71] = 6\,860 \text{ lb.}$$

$$T\,r - t\,r = (G - g)\,[14 \sin 8° 51' + 5 \sin 20° 46'] - (G + g) \times 19 \times 0.0141)$$

$$1\,200\,[2.155 + 1.775] - 2\,540 \times 0.268$$

$$4\,716 - 681 = 4\,035 \text{ lb.}$$

$$\text{Horse power} = \frac{4\,035 \times 500}{33\,000} = \frac{4\,035}{66} = 61$$

Therefore, 61 — 2 = 59 h. p. developed.

Using a grip sheave, the traction rope tension (to prevent slipping) should be:

$$2\,T\,r = D\,(1 + K) = 4\,035 \times 3 = 12\,105 \text{ lb.}$$

in which, $T\,r = 6\,055$ lb. This, compared with the load tension of 6 860 lb., indicates that a nominal weight for the tension mechanism may be chosen, say, 3 000 lb.

The total tension in the traction rope is then 6 860 + 1 500 = 8 360 lb. Since the stress due to bending a traction rope around a grip sheave 8 ft. in diameter is inconsequential, the size of traction rope may be tested by multiplying 8 360 lb. by a factor of safety of 4 = 33 440 lb. A 6 × 19, ¾-in. crucible steel, Lang lay traction rope has a listed strength of 17.5 tons; therefore, the traction rope weight used in these calculations is correct.

In order to locate, approximately, the position of the important structures on the profile, the empty and loaded cable curves should be drawn. If templates are not available they may be easily prepared. Referring to the table of coefficients (Table 17) of deflections at points located at multiples of 2% of the span under 40 000 lb. tension, the corresponding coefficients for 30 000 lb. may be found by multiplying the tabular values by $\frac{4}{3}$, and a curve plotted for the empty cable, say, on a span of 5 000 ft. The loaded curve is prepared on the assumption that the weight of the carrier may be distributed along the track cable for a distance equal to the carrier spacing. In this case:

1 200 + 450 = 1 650 lb. ÷ 250 ft.	=	6.60 lb per ft.
Track cable	=	4.00 " " "
Traction rope	=	0.90 " " "
Total	=	11.50 lb. per ft.

Since a track cable with a cross-section of 1 sq. in. weighs 3.6 lb. per ft., the cable will hang as if the tension were $\frac{3.6}{11.50} \times 30\,000$ lb., or 9 425 lb. In other words, the deflections are $\frac{11.50}{3.6} = 3.19$ greater than those of the empty cable. From these data the two curves are plotted and templates are prepared for the scales used on the diagram. If the diagram had been plotted with the same scale for vertical and horizontal measurements, say, 1 in. = 100 ft., the radius of circular arcs could be determined from the $\frac{t}{w}$-relationship. The radius for the empty cable is $\frac{30\,000}{3.6} = 8\,333$ ft. Divide by the scale chosen and the radius of the circular arc is 83.33 in. The loaded curve is approximated in a similar manner, namely, $\frac{30\,000}{11.50} = \frac{2\,609}{100}$ results in a radius of 26.1 in.

The curves enable the computer to locate quickly the critical points of the profile. By referring to Fig. 14, it will be noted that the empty cable has an approximate center deflection of 60 ft. and 191 ft. when loaded, or a change of more than 130 ft. If weights are to be used to maintain a constant tension, space must be provided in the station for a travel of,

$$\frac{8}{3 \times 2\,000}(191^2 - 60^2) = 44 \text{ ft.}$$

resulting in a lofty and expensive structure. The change in the cable slopes at the ends of the span are as follows:

$$\tan \beta = 0.0006 \times 2\,000, \text{ or } 6^\circ\ 50' \text{ empty cable.}$$
$$3.19 \times 6^\circ\ 50' \quad , \text{“ } 21^\circ\ 00 \text{ loaded “}$$

or a difference, say, of 14 degrees.

The station hoods for transferring carriers from cable to rail cannot accommodate so great a change in slope, not to mention the many other difficulties of design and operation that will be encountered if the change in cable slopes is not limited to reasonable values. This may be done by anchoring both ends of the track cables.

When the line is in operation, the tension of the traction rope of the long span exceeds 3 200 lb., an amount sufficiently great to carry a part of the carrier weight; that is, the equivalent weight per foot of track cable is reduced from 11.50 lb. to 11.00 lb. per ft. Therefore, care must be used in stripping the line to remove alternate carriers and avoid fouling of the track cable and traction rope. Also, the track cable supporting the empty carriers must be placed under such a tension that winds will not blow it into the loaded side.

By the proper use of the templates and the deflection charts (Figs. 13, 14, and 15), structures have been located and elevations adopted for checking by calculation. It is desirable to record these data in a simple manner and to arrange them so that the calculations follow in sequence. Such a form is shown in Table 40. For convenience the elements of design have been recapitulated.

TABLE 40.—Calculations of Profile.

(Data as follows: Capacity, 72 tons per hour; weight of material in buckets, 100 lb. per cu. ft.; velocity, 500 ft. per min.; spacing, 250 ft.; weight of loaded carrier on the line, 1 870 lb., and of empty carrier, 670 lb.; traction rope, $\frac{3}{4}$-in. crucible steel at 0.89 lb. per ft.; track cables, $1\frac{1}{4}$-in. and $\frac{7}{8}$-in. lock coil for loaded and light sides, respectively; cross-sectional areas, 1.1 and 0.5 sq. in.; at 30 000 lb. per sq. in., the tensions are 33 000 lb., and 15 000 lb. in the horizontal components of the track cables; $\frac{G}{t} = 0.0567$, or 3° 15′; the slope angle at support for empty cable is 20.7′ of arc per 100 ft.)

Explanation of Table 40.—Column (1) indicates the type of structure, such as loading terminal, two-bent support, curve rail, and double-anchorage structure, tower, discharge terminal, etc. Column (2) indicates the survey station and the horizontal distance between. Column (3) gives the elevations of the saddles and the differences in height between them. Column (4) gives the tangents, and Column (5), the slope angles of the chords. Column (6) records the intersection angle of the chords. Plus (+) indicates downward pressure; minus (—), uplift. This angle may be changed at will by shifting the elevations of the adjoining saddles. Column (7) has the slope angle of

the tangent to the empty cable at the saddle. This angle is easily computed from the fact that cables of constant cross-section have a definite curvature per foot; for instance, a track cable weighing 3.6 lb. per ft., under a tension of 30 000 lb., curves 41.4′ of arc per 100 ft. of span, hence the slope of the tangent is 20.7′ per 100 ft. The angle of the empty cable on the saddle is the algebraic sum of the intersection and cable angles, as shown in Column (8). The former may be negative; the latter is always positive. Column (9) gives the angular increase due to the loads. These are quickly determined from the table for load tangents (Table 20). Column (10) gives the sum of the load angles at the support. Column (11) gives the result of the calculation, namely, the total angle of the loaded cable over the saddle. It is the usual aim of profile designers to impose equal cable angles on adjacent saddles. When the slope angles of cables entering or leaving structures are known, the loads imposed, and the radius of rail curvature, can be readily computed. Column (12) gives the radius of the curve tangent to the cable slopes. Experience indicates that the curvature of track cables of small diameter over saddles should be less than 9°; and less than 6° for cables 1⅜ in., or larger.

To determine the position of the empty cable on the long span, the erection tension must be computed. The simplicity of the calculation, by the method of second differences, is shown in Table 41.

Anchored Span.—The data used in computing the anchored span are as follows: Locked-coil cable, 1¼ in. in diameter, weighing 4 lb. per ft.; maximum horizontal tension, 33 000 lb.; horizontal span, 1 958 ft.; difference in terminal elevations, 184.0 ft.; weight of loaded carrier, 1 870 lb.; spacing of loads, 250 ft.; slope of chord, 5° 22′; horizontal spacing, 250 cos 5° 22′=248.91 ft.; number of loads, 8; distance from support to first load, 107.83 ft.; and deflection of fourth load from left support:

$$y = \frac{1\,870 \times 1\,958}{4 \times 33\,000}\left[8 - \frac{64 \times 248.91}{2 \times 1\,958}\right] + \frac{4 \times 1\,958^2}{8 \times 33\,000}\left[1 - \left(\frac{248.91}{1\,958}\right)^2\right] + \frac{854.55}{1\,958} \times 184.0$$

$$= 109.062 + 57.143 + 80.305 = 246.51 \text{ ft.}$$

In this case the first and second differences are equal:

$$-\frac{248.91}{33\,000}[1\,870 + 4 \times 248.91] = 21.607 \text{ ft.}$$

$$\text{Slope factor} = \frac{248.91}{1\,958} \times 184 = \underline{23.386}$$

$$\text{Total} = 44.993 \text{ ft.}$$

TABLE 41.—Deflections of Anchored Span by First and Second Differences.

Load No.	0.	1.	2.	3.	4.	5.	6.	7.	8.	9.
Deflection	5 831.29	5 784.58	5 696.37	5 629.77	5 584.78	5 561.39	5 559.62	5 579.44	5 620.88	5 647.29
First difference		46.71	88.207	66.60	44.993	23.386	1.779	19.828	41.435	26.41
Second difference		21.607	21.607	21.607	21.607	21.607	21.607	21.607	21.607	

To check Table 41, compute the deflection of the load nearest the support:

$$y = \frac{1\,870 \times 1\,958 \times 0.05507}{33\,000}\,[8\,(1 - 0.05507) - 0.1271 \times 28]$$

$$+ \frac{4 \times 1\,958 \times 0.05933 \times 0.05507 \times 0.94593}{2} + 0.05507 \times 184.0$$

$$= 24.460 + 12.114 + 10.133 = 46.707 \text{ ft.}$$

Therefore, the deflections given in Table 41 are correct.

The length of the loaded span is:

$$1\,958 + \frac{46.71^2 \times 26.41^2}{2 \times 107.83}$$

$$+ \frac{88.207^2 + 66.60^2 + 44.993^2 + 23.386^2 + 1.779^2 + 19.828^2 + 41.435^2}{497.82}$$

$$= 1\,958 + 13.35 + 33.95 = 2\,005.30 \text{ ft.}$$

The length of the empty span, when loaded, is increased to 2 005.30 ft., that is,

$$2\,005.30 = 1\,958 + \frac{4^2 \times 1\,958^3}{24\,t^2} + \frac{184^2}{3\,916} + \frac{0.000041 \times 1\,954}{1\,000}\,(33\,000 - t)$$

or,

$$t + \frac{5\,005\,000\,000}{t^2} = 36.01 + 0.00008\,t$$

Solving by slide-rule for $t = 11\,650$,

$$\frac{5\,005\,000\,000}{t^2} = 37.00$$

Similarly,

$$36.01 + 0.00008\,t = 36.95$$

Therefore, erect at a tension of 11 650 lb.

Conclusion

In conclusion, it may be stated that the foregoing remarks only hint at the magnitude and scope of aerial tramway systems of transportation. It should be emphasized that the highest degree of engineering skill and advanced mathematical analysis are required to design properly and erect a successful and economical aerial tramway. It is recalled that multi-loaded spans are not continuous functions, but a series of arcs which intersect under each carrier with an angle the tangent of which is equal to the weight of the load divided by the horizontal component of the tension. Because of this, the determinations of deflections, tangent slopes, and other properties of the cable spans have developed a system of mathematical analysis, which is as distinctive as that used in railroad location, or any other engineering specialty. In other words, aerial tramways are best designed by those who are fitted by experience and training to undertake this type of construction.

The advance in freight rates in this country makes it imperative to supply a system of transportation for industrial plants, mines, and quarries, which is safe, free from meteoric conditions, and economical, and aerial tramways meet these specifications in a most practical and satisfactory manner.

DISCUSSION

ROBERT C. STRACHAN,* M. AM. SOC. C. E. (by letter).—Without questioning the correctness of the author's formulas relating to unloaded spans, it appears that the inherent complexity of the equations, when the origin is taken at one support, might well be avoided; more especially since the operations in problems of the catenary, even under the most favorable assumptions, are as a rule not simple.

Let the origin for the curve shown in Fig. 9 be taken at the lower extremity of the parameter as indicated in Fig. 23.

Use the author's notation and, in addition, let z = parameter = $\frac{t}{w}$; $\frac{S_1}{z} = u_1$; and $\frac{S_2}{z} = u_2$.

Therefore,

$$\frac{S}{z} = u_1 + u_2 \dots (109)$$

The equation of the curve then takes its simplest form,

$$y = \frac{t}{w}\left(\cosh \frac{x\,w}{t}\right) \dots (110)$$

or,

$$y = z \cosh \frac{x}{z} \dots (111)$$

For any point of the catenary distant x to the left or right of the Y-axis, the vertical distance below L or R is,

$$v_L = z\left(\cosh u_1 - \cosh \frac{x}{z}\right) \dots (112)$$

$$v_R = z\left(\cosh u_2 - \cosh \frac{x}{z}\right) \dots (113)$$

The derivation of u_1, u_2, and other required elements, is as follows: It may be shown that,

$$\frac{\frac{1}{2}(u_1 + u_2)}{\sinh \frac{1}{2}(u_1 + u_2)} = \frac{S}{\sqrt{l^2 - h^2}} \dots (114)$$

and,

$$\tanh \frac{1}{2}(u_1 - u_2) = \frac{h}{l} \dots (115)$$

From the author's assumed data,

$$\frac{t}{w} = z = 2\,777.7778 \text{ ft.}$$

$$\frac{S}{2z} = \frac{1}{2}(u_1 + u_2) = 0.18000 \text{ hyps†}$$

* With The Port of New York Authority, New York, N. Y.

† Hyperbolic radians, or sectorial ratio.

therefore,

$$\sinh \frac{1}{2}(u_1 + u_2) = 0.18098$$

and from Equation (114),

$$l^2 = \frac{(0.18098)^2 S^2}{(0.18)^2} + h^2 \qquad (116)$$

Therefore,

$$l = 1\,010.405 \text{ ft.}$$

From Equation (115),

$$\tanh \frac{1}{2}(u_1 - u_2) = \frac{100}{1\,010.405} = 0.09897$$

therefore,

$$\frac{1}{2}(u_1 - u_2) = 0.09929 \text{ hyps.}$$

$$u_1 = 0.18000 + 0.09929 = 0.27929 \text{ hyps.}$$

$$u_2 = 0.18000 - 0.09929 = 0.08071 \text{ hyps.}$$

$$\beta_1 = \text{gd. } u_1{}^* = 15^\circ\ 47.9'$$

$$\beta_2 = \text{gd. } u_2 = 4^\circ\ 37.2'$$

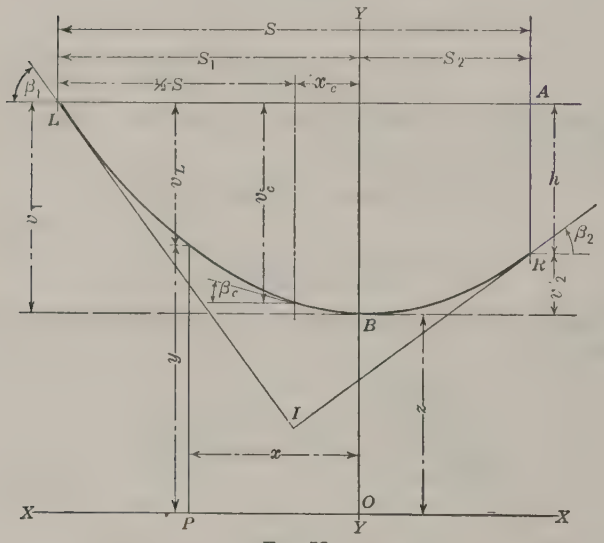

FIG. 23.

No calculation other than interpolation in the hyperbolic tables, is necessary to obtain β_1 and β_2.

$$S_1 = z\,u_1 = 775.806 \text{ ft.}$$

$$S_2 = S - S_1 = z\,u_2 = 224.194 \text{ ft.}$$

$$v_1 = z\,(\cosh u_1 - 1) = 2\,777.778 \times 0.03926 = 109.055 \text{ ft.}$$

$$v_2 = v_1 - h = z\,(\cosh u_2 - 1) = 2\,777.778 \times 0.00326 = 9.055 \text{ ft.}$$

* This equation states that the angle, β_1, is the "Gudermannian angle" corresponding to the hyperbolic sectorial ratio, u_1.

If l_1 and l_2, the arcs, respectively, under S_1 and S_2 are required,

$$l_1 = z \sinh u_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (117)$$

$$l_2 = l - l_1 = z \sinh u_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (118)$$

Let x_c = distance from Y-axis to the center of Span $S = \frac{1}{2}(S_1 - S_2)$, and, let $u_c = \frac{x_c}{z}$. Then,

$$u_c = \frac{1}{2}(u_1 - u_2) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (119)$$

Let v_c = vertical distance from center of span, S, to the curve, then,

$$v_c = z\ (\cosh u_1 - \cosh u_c) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (120)$$

and β_c = the inclination of the tangent = gd. u_c

$$x_c = S_1 - \frac{1}{2} S = 275.806 \text{ ft.}$$

$$u_c = \frac{1}{2}(u_1 - u_2) = 0.09929 \text{ hyps.}$$

therefore,

$$\cosh u_c = 1.00493$$

and, by interpolating as before,

$$\beta_c = \text{gd. } u_c = 5^\circ\ 40.8'$$

From Equation (120),

$$v_c = z\ (1.03926 - 1.00493) = 95.361 \text{ ft.}$$

v_c is designated y_c in Fig. 9 and the result of the calculation is given as 95.225 ft.

The introduction of the author's nomographic charts, Figs. 13, 14, and 15, draws attention anew to the saving in time and labor made possible by this means, with no sacrifice of needful precision. This is an advantage to which reference was made by the writer in his paper* on the designing of such charts.

George Paaswell,† M. Am. Soc. C. E. (by letter).—While the entire paper is so interesting and unusual, both in its topic and in its lucid manner of presentation that the writer would like to discuss every feature of it, he is confining these notes to a treatment of two minor points, the hyperbolic functions and the cubic equation. The former may be computed to any degree of exactness from the trigonometric functions and tables and the latter may be solved directly. Few engineers seem to be aware of this latter fact.

The hyperbolic functions bear a direct relation to the circular function of a characteristic angle the geometric significance of which need not be discussed herein. The relations may be given as follows: $\sinh u = \tan v$; $\cosh u = \sec v$; $\tanh u = \sin v$; $\coth u = \csc v$; $\operatorname{sech} u = \cos v$; and $\operatorname{csch} u = \cot v$. The relation between u and v is given by the formula,

$$u = 2.3025851 \log \tan \left(45^\circ + \frac{v}{2}\right)$$

* "Nomographic Solutions for Formulas of Various Types," *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 1359.

† Engr., Corson Constr. Corporation, Brooklyn, N. Y.

The method of computation will be seen in the solution of the cubic equation. Given a cubic equation in its most general form,

$$x^3 + a\,x^2 + b\,x + c = 0$$

it is reduced to a form,

$$y^3 - 3\,p\,y - 2\,q = 0$$

by substituting $x = y - \frac{a}{3}$.

The roots of the cubic equation in y are then found from the following, depending upon the signs of p and q:

(1) If both p and q are plus and q^2 is greater than p^3, use the substitution,

$$\cosh u = \frac{q}{\sqrt{p^3}}$$

The three roots are then,

$$y_1 = 2\sqrt{p}\,\cosh\frac{u}{3}$$

$$y_2 = -\frac{y_1}{2} + i\sqrt{3\,p}\,\sinh\frac{u}{3}$$

and,

$$y_3 = -\frac{y_1}{2} - i\sqrt{3\,p}\,\sinh\frac{u}{3}$$

(2) If p is positive, q, negative, and q^2 is greater than p^3, use the substitution,

$$\cosh u = \frac{-q}{\sqrt{p^3}}$$

and the three roots are,

$$y_1 = -2\sqrt{p}\,\cosh\frac{u}{3}$$

$$y_2 \text{ and } y_3 = -\frac{y_1}{2} \pm i\sqrt{3\,p}\,\sinh\frac{u}{3}$$

(3) If p is negative,

$$\sinh u = \frac{q}{\sqrt{-p^3}}$$

and the three roots are,

$$y_1 = 2\sqrt{-p}\,\sinh\frac{u}{3}$$

$$y_2 \text{ and } y_3 = -\frac{y_1}{2} \pm i\sqrt{-3\,p}\,\cosh\frac{u}{3}.$$

(4) If p is positive and q^2 is less than p^3, substitute,

$$\cos u = \frac{q}{\sqrt{p^3}}$$

and the three roots are,

$$y_1 = 2\sqrt{p}\,\cos\frac{u}{3}$$

$$y_2 \text{ and } y_3 = -\frac{y_1}{2} \pm \sqrt{3\,p}\,\sin\frac{u}{3}$$

Refer to the cubic equation,

$$0.0000457\ t - 0.474 = \frac{666\ 666\ 667}{t^2}$$

and, to reduce the size of the coefficients, take the unit load as 100 000 lb. The equation then reads,

$$4.57\ t^3 - 0.474\ t^2 - \frac{1}{15} = 0$$

or,

$$t^3 - 0.1037\ t^2 - 0.01459 = 0$$

reducing to the standard form by placing

$$t = x + \frac{0.1037}{3}$$

$$x^3 - 0.003585\ x - 0.0145 = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (121)$$

In Equation (121) $p = 0.001195$ and $q = 0.00725$. This form of the cubic equation comes under Case (1),

$$\cosh u = 175.6$$

Then, from the circular relations already given,

$$\log \cosh u = \log \sec v = 2.2445245$$
$$v = 89^\circ\ 40'\ 24''$$

From the relation between u and v,

$$u = 2.302585 \log \tan 89^\circ\ 50'\ 12''$$
$$u = 5.8602$$
$$\frac{u}{3} = 1.9534$$

To obtain v,

$$1.9534 = 2.3026 \log \tan \left(45^\circ + \frac{v}{2}\right) \log \tan \left(45^\circ + \frac{v}{2}\right) = 0.84835$$

and,

$$v = 73^\circ\ 51'\ 40''$$

$$\cosh \frac{u}{3} = \sec 73^\circ\ 51'\ 40'' = 3.5975$$

The real root of Equation (121) is, therefore,

$$x = 3.5975 \sqrt{(0.001195)} = 0.24873$$

$$t = x + \frac{0.1037}{3} = 0.28363$$

or, reducing to pounds, the real root is 28 363 lb.

These processes illustrate the comparative simplicity of both the computation of hyperbolic functions from trigonometric tables and the direct solution of the cubic equation.

CASPER D. MEALS,* ASSOC. M. AM. SOC. C. E. (by letter).—This comprehensive paper fills a big gap; the wealth of practical, usable data therein bespeaks the concluding thoughts, namely, that aerial tramways are best designed by those who are fitted by experience and training to do so.

Dumping Cradleways, or Contractors' Suspension Bridges.—When calculating the size of the cables to be used, the live load moving on to the platform is to be taken as the empty car weights only, the material being dumped off the cars as they pass on to the platform. For a 9-car trip, 8 empty cars and 1 loaded car will be on the platform, but part of the reaction of the latter is carried on the bank end, so that to consider the moving load as 9 empty cars will be sufficiently accurate.

The platforms are usually 14 ft. wide, 75 to 130 ft. long, and weigh from 170 to 250 lb. per lin. ft. and the suspender rope spacings are from 10 to 18 ft. on centers, the average being 12 ft. The empty cars weigh from 5 000 to 9 000 lb., the average being 6 000 lb. The suspenders are generally made up of $\frac{1}{2}$ or $\frac{5}{8}$-in., 6 × 19, plow steel rope, and two double sheave tackle blocks; 10-in. blocks for the $\frac{1}{2}$-in. rope, and 14-in. blocks for the $\frac{5}{8}$-in. rope.

TABLE 42.—CABLE FOR DUMPING CRADLEWAYS.

Diameter of rope, in inches.	Construction.	Pounds per foot.	Metallic area, in square inches.	Approximate Breaking Strengths, in Tons.	
				Catalog.	Actual.
1⅛	7 × 7	3.70	1.057	90	98
1⅛	7 × 19	4.34	1.257	106	115
1¼	7 × 19	5.10	1.460	124	140
1⅜	7 × 19	5.90	1.680	144	158
2	7 × 19	6.78	1.816	164	175
2⅛	7 × 19	7.60	2.230	185	195
2¼	7 × 19	8.52	2.436	208	220
2⅜	7 × 19	9.5	2.722	232	250
2½	7 × 19	10.5	3.106	256	275
2⅝	7 × 19	11.6	3.522	283	300
2¾	7 × 19	12.7	3.774	310	330
3	7 × 37	15.5	4.243	360	385

The hold-down tackle at the end of the platform is usually of $\frac{3}{4}$-in., 6 × 19, plow steel rope, reeved on 16-in. double sheave blocks. The deflection of the main cables is usually taken at 6 to 7% of the length of the span and the size of the cables may be based on a factor of safety of 3 as a minimum on the actual breaking strengths of the cables. For the one installation of a dumping cradleway noted by Mr. Carstarphen (page 882), the main cables are given as 2½-in., 6 × 37, plow steel rope. A 2¼-in., 7 × 19, galvanized plow steel, bridge cable of approximately the same breaking strength would have been more economical.

The actual breaking strengths of galvanized plow steel bridge cables are in excess of the manufacturers' standard lists, and data pertaining to suitable size of bridge cables for these dumping cradleways are given in Table 42.

* Chf. Engr., Am. Cable Co., Inc., New York, N. Y.

The modulus of elasticity of these cables may be taken at 17 000 000 lb. per sq. in. for new cable, and 20 000 000 lb. per sq. in., for cable that has been repeatedly stressed.

The maximum stress in the main cable span may be determined from:

$$T_{max.} = \left\{ \frac{w\,S^2 + 4\,\rho\,k\,(S-k)}{8\,d} \right\} \sec\,\beta \qquad (122)$$

The unloaded cable deflection (see Fig. 24) at which it must be erected before any dead or live loads are applied, may be determined from,

$$d_1 = d - \frac{15\,\Delta\,L}{16\,(5\,b - 24\,b^3)} \qquad (123)$$

in which,

$$\Delta\,L = \frac{H_1\,S}{A\,E}\left(1 + \frac{16\,b^3}{3}\right)$$

$$H_1 = \frac{4\,\rho\,k\,(S-k)}{8\,d}$$

$$b = \frac{d}{S}$$

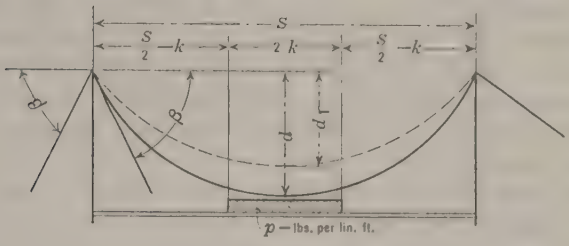

FIG. 24.

Track Cables.—The breaking of a wire in a smooth-coil track strand does give trouble by uncoiling to the nearest tower support or coupling. However, there has been developed for this service a pre-formed, smooth-coil, track strand in which this objection has been eliminated, the wires being pre-shaped to their position in the cable and, therefore, being unrestrained in their place in the strand. The outer wires will stay in place and also will wear to a much thinner section before breaking, thus prolonging the life of the strand.

The physical properties of this type of strand (known as the Tru-Lay Brand), correspond to values given in Table 6. The E-values may be taken at 20 000 000 lb. per sq. in. for a 19-wire strand, and 18 000 000 lb. per sq. in. for the 37-wire strand. For a greater number of wires it will be even less, as there is relatively greater looseness in the strand construction of a 61-wire strand than in that of a 19-wire strand and, consequently, the E-value of the former must be lower.

The deflections of the main cables are usually limited from 2 to 2½% of the span length, S, so as to eliminate steep grades at the towers which would require a larger traction rope and greater engine duty.

The frictional hysteresis loops noted by Mr. Carstarphen (page 893), for progressive and retrogressive loadings of the strands, have been noted also by the writer in tests made of both strands and wire ropes.

The "rocking saddle", shown in Fig. 5, should have the merit of reducing the wear and abuse on the track strand or cable at the saddle by pivoting, and thereby reducing the angle that the cable will make when the carriage is approaching or going off the saddle. If this point is attained, then the rocking saddle would eliminate the use of protection hoods over the track cables at the saddles.

Couplings for Joining Sections of the Track Cables.—The writer was not aware that couplings to smooth-coil track strands were ordinarily attached in the same manner as the locked-coil and wire strands by means of wedges. Certainly, a zinc socket attachment should be more effective, considerably cheaper, and should eliminate the possibility of loose wires in the strand, because, unless extreme care is exercised in driving the wedges in that particular type of connection, some wires will be disturbed and loosened in the strand.

Traction Ropes.—It has been the writer's experience that plow steel ropes will give as economical service as cast steel or mild plow steel; and for severe service, the plow steel rope will prove more economical because, being of a higher grade of steel, it will better withstand wear and offer as great a fatigue resistance operating over the sheave equipment. Occasionally, 6×19 Seale construction and 6×8 flattened strand ropes are used, although the 6×7 is more generally used.

Lang lay ropes offer the following advantages over regular lay ropes of the same length of rope lay:

(*a*) Greater wearing surface, each outer wire having approximately three times the length exposed for wear, leading to lower bearing values.

(*b*) Greater flexibility, because the outer wires of the strand are parallel to the axis of the rope against the manila core and set up less frictional resistance in bending.

(*c*) Lower bending stresses, the bending stress in a Lang lay rope being approximately 80% of that in a regular lay rope of the same construction.

The bending stress in a wire is greater the farther away it is from the axis of the rope and the nearer it runs parallel to the axis. In a regular lay rope, this combination of unfavorable conditions is found. In a Lang lay rope it is not found, because where the wires do lie parallel to the axis of the rope, they are nearest to the axis and are embedded in the manila core of the rope.

A Lang lay rope is inherently "cranky," due to the fact that the wires in the strands, and the strands in the rope, are laid up in the same direction. A Lang lay rope of the Tru-Lay type, fabricated with pre-formed wires and strands, will eliminate entirely the "crankiness" so typical with Lang lay ropes and will also wear longer and withstand bending better because the individual wires and strands of the rope are in an unrestrained position.

Carriers.—Carriages are usually made up with two sheaves of 10 to 14-in. treads in a pivoting frame attached to the bucket bale as described by Mr. Carstarphen. The writer would like to know whether the weights given in Table 8 include the weight of the carriage with sheave and the grip? The carriage, with sheaves, weighs approximately 100 to 150 lb., and the grips from 35 to 75 lb., depending on the type and the loads.

Data pertaining to minimum steel tower weights for 8-ft. gauge cables, for towers, 65 to 100 ft. high, are as follows:

Height, in feet.	Weight, in pounds.
65	10 000
70	11 000
80	13 000
85	14 500
100	17 000

Bolts and washers for timber towers of the closed type, including the anchor-bolts and washers, will be approximately as follows:

Height, in feet.	Weight, in pounds.
10	400
20	425
30	500
40	650
50	800
60	1 100
70	1 300
80	1 800

Tension in Traction Ropes.—The coefficient values as given for K include that of a greasy rope on a rubber-lined and leather-lined sheave. Is it implied from this that such driving sheaves are used? Unless the unit radial bearing pressure of the rope on the rubber and leather lining is kept within a value of 65 to 75 lb., the lining will soon be cut out.

The radial pressure of a rope in a sheave groove is a function of the rope tension and the sheave diameter. It should not be confused with the resultant of the tensions in the rope with regard to the angle the ropes make with each other. The unit radial pressure is determined from:

$$u = \frac{P}{r\,d} \qquad (124)$$

d being the rope diameter; r, the radius of the tread of the sheave, in inches; and P, the load, in pounds.

Size of Track Cables.—If the choice is guided by experience, it will pertain to the construction rather than the size; for, after all, the stress requirements, which are calculable, are the governing consideration in the size and quality. The bending stresses need not be considered because the deflections are relatively so shallow and the traveling loads so light, that the bending of the track cables by the carriage wheels or at the tower saddles is not of

prime importance. Bending stresses and the reduction or loss in strength of a wire rope bent around a sheave are not analogous.

Bending stresses are applicable only to moving ropes operating over sheaves and have to do with their "efficiency" in service and not to their reduction in breaking strength. There must be a limit to the smallness of the sheaves for operating ropes in relation to the rope diameter of various constructions. By this is meant that there is a "critical" sheave diameter, smaller than which the strands of the rope cannot slide past each other to adjust themselves to the bend and, consequently, constructional restrictions are set up within the rope. This condition sets up excessive internal stresses absolutely beyond the scope of mathematical treatment, although the writer is convinced that bending stresses in wire ropes are not susceptible to precise mathematical investigation as there are too many variables involved, such as, relation of wire sizes, core condition and size, strand and rope lays, strand constructions, lubrication, etc.

The critical tread diameters of sheaves for various constructions of ropes are given in Table 43.

TABLE 43.—Critical Sheave Diameter Ratios for Operating Ropes.

Construction.....	6 × 7.	6 × 19 Seale.	6 × 19 Warrington.	6 × 25 Spacer Seale.	6 × 37.	8 × 19 Warrington.	8 × 19 Seale.
Critical ratio, $\frac{D}{d}$.....	28	20	16	16	14	14	16

For sheave sizes less than those given in Table 43, bending stresses are of little value in any calculations.

The reduction or loss in strength of ropes bent around sheaves (this applies only to non-operating ropes) has been reported* quite fully. It is shown that for 6 × 19 ropes the efficiencies are as given in Table 44, in which, D is the tread diameter of the sheave, and d, the rope diameter. Because of these values the writer believes that the loss in strength of a ¾-in., 6 × 19, plow steel rope bent around a 6-in. sheave is 24% instead of 8% as noted by Mr. Carstarphen (page 936).

TABLE 44.—Efficiencies of 6 × 19 Ropes Bent Around Sheaves Under Static Load.

Ratio, $\frac{D}{d}$.....	8	10	12	14	16	18	20	22	24	30
Efficiency, percentage.....	76	79	81	86	88	92	93	95	95	95

The moduli of elasticity of various ropes, given by Mr. Carstarphen in Table 26 are at a variance with values secured by the writer in numerous

* "Some Tests of Steel Wire Rope on Sheaves," *Paper No. 229*, U. S. Bureau of Standards.

tests. However, some of this may have been due to a difference in the strand and rope lays and also in the construction of the strand. Tests made by the writer gave the following values of E, in pounds per square inch:

19 wire strand.....	20 000 000	6 × 19 rope with independent wire rope center	16 000 000
37 wire strand.....	18 000 000		
6 × 7 rope.....	14 000 000		
6 × 19 rope.....	13 000 000	7 × 7 and 7 × 19 bridge cables	17 000 000
6 × 37 rope.....	12 000 000		
8 × 19 rope.....	10 000 000		

These values are for new steel ropes, ½ in. in diameter, and larger. For old ropes that have been in service, the E-values will be approximately 20% in excess of the values given in the tabulation.

To indicate the strand construction variable in the E-values for wire rope: The 2¼-in., 6 × 37, suspender ropes on the Delaware River Bridge between Philadelphia, Pa., and Camden, N. J., were made up of a three operation strand, all wires being laid in the same direction, and the rope had a 7 × 7, Independent wire rope center of Lang lay. The E-value was only approximately 12 000 000 lb. per sq. in., and for the first run or initial loading it was only approximately 8 000 000 lb.* Incidentally, the monograph from which these values were taken, verifies Mr. Carstarphen's data that the E-values increase with an increment in the load on the rope.

F. C. Carstarphen,† M. Am. Soc. C. E. (by letter).—This paper has brought forth a greater discussion, both private and public, than was anticipated by the writer. It appears that the question of stresses in wire ropes, when supporting moving loads, should have been treated with greater detail. This remark may also apply to the derivation and the form of several of the equations presented.

Mr. Strachan finds the equations of the catenary with origin at the support to be inherently complex. He submits a solution of the problem which is a masterful presentation of the power and beauty of the hyperbolic functions in finding the elements of the catenary; and, yet, it seems that the technic was not simplified by shifting the origin from the support to an undetermined position of the parameter.

The possible inference to be drawn from the comment that "without questioning the correctness of the author's formulas relating to unloaded spans", makes it necessary to compare the results obtained by the several formulas when entered by the same argument. The writer believes that all those who make calculations of this nature will find it to be simpler to compute the deflection of an inclined span by Equation (3) than by Mr. Strachan's method. Except for purposes of checking calculations it does not appear that any useful purpose is served by selecting an origin the co-ordinates of which are unknown at the outset of the investigation. For this reason all the cable formulas have been derived, deliberately, with a known position of the origin—

* These values are given in the recent monograph published as a Final Report of the Board of Engineers to the Delaware River Bridge Joint Commission of Pennsylvania and New Jersey, p. 120.

† Cons. Engr., Denver, Colo.

one of the supports—so that the computation of the element desired could be undertaken directly. In this manner one of the great barriers to rapid numerical calculation is swept away.

Accuracy cannot be sacrificed for convenience, unless so stipulated, and it is advisable to weigh the differences between the answers obtained by the several methods of computation.

It will be noted that the writer used four-place tables for values of the hyperbolic functions in solving the problems given on page 909. If $\cosh \frac{w\,s}{2\,t} = 1.01624$, the deflection is 95.336 ft. compared with 95.361 ft. derived from Equation (120). Using $\sinh \frac{w\,s}{2\,t} = 0.18097$,* Equation (6) gives a length of 1 010.358 ft. compared with 1 010.405 ft. by Equation (116). If $\sinh 0.18 = 0.18098$, the length is 1 010.444 ft. These several values are in close agreement, but there is a difference of about 3′ of arc in the direction of slope of the terminal tangents. This is due to the use of sec α as an operator to swing the horizontal span formula to a moderately inclined position. For those who would avoid this device and yet prefer the origin at a support, the hypothetical horizontal span for a cable passing through the other support may be used as follows.

In Equation (1) let:

$$\sinh \frac{w\,x}{t} = A = \sinh \frac{3.6 \times 1\,000}{10\,000} = 0.36783\,;\ A^2 = 0.13530$$

$$\frac{w\,s}{2\,t} = u$$

$$\left(\cosh \frac{w\,x}{t} - 1\right) = B = \cosh 0.36 - 1 = 0.06550\,;\ B^2 = 0.00429$$

$$\frac{w\,y}{t} = C = \frac{3.6 \times 100}{10\,000} = 0.036\,;\ C^2 = 0.001296$$

Then, Equation (1) may be written:

$$A \sinh u - B \cosh u - C = 0$$

$$A \sinh u - B \sqrt{1 + \sinh^2 u} - C = 0$$

$$\sinh^2 u + \frac{2\,A\,C}{B^2 - A^2} \sinh u + \frac{B^2 - C^2}{B^2 - A^2} = 0$$

$$\sinh u = \frac{-A\,C}{B^2 - A^2} \pm \frac{B}{B^2 - A^2} \sqrt{A^2 + C^2 - B^2} \qquad (125)$$

Substituting the given values of A, B, and C, and their squares, $\sinh u = 0.28292$, $u = 0.279277$, and $\cosh u = 1.03926$.

Equation (1) may now be written for the deflection, y, when $x = 500$ ft.:

$$y = 2\,777.7778 \left[\sinh \frac{3.6 \times 500}{10\,000} \sinh u - \cosh u \left(\cosh \frac{3.6 \times 500}{10\,000} - 1\right)\right]$$

$$= 2\,777.7778 \times 0.03432 = 95.333 \text{ ft.}$$

* Smithsonian Tables for sinh 0.18.

The value of the theoretical span is not required, but it may be easily found:

$$s = \frac{2\,t}{w}\,u = \frac{20\,000}{3.6}\,0.279277 = 1\,551.539 \text{ ft.}$$

Hence the value of x for the parameter is 775.77 ft.

The tangent at the left support is,

$$\beta_1 = \text{gd. } u = \tan^{-1} 0.28292 = 15° 47.8'$$

By Equation (4), but without sec α or $\pm \tan \alpha$:

$$\begin{aligned} \tan \beta_2 &= (1.0655 \times 0.28292 - 1.03926 \times 0.36783) \\ &= 0.38227 - 0.30145 = 0.08082 \\ &= \tan^{-1} 0.08082 = 4° 37.2' \end{aligned}$$

The length of cable between supports is given by Equation (6) as,

$$(0.28292 + 0.08082)\ 2\,777.7778 = 1\,010.389 \text{ ft.}$$

A comparison of the results of the three calculations shows them to be in agreement and establishes the use of the operator, sec α, as indicated for rapid calculating.

The writer wishes to thank Mr. Paaswell for his interest in solving the cubic equation of the tension by means of the hyperbolic functions. Here, again, is an illustration of their power in mathematical analysis. This method may be used to advantage when unusual accuracy is desired. For all practical solutions of these particular cubic equations the slide-rule may be used with "neatness and dispatch."

Mr. Paaswell calls to mind the relation between the function and its Gudermannian; that is, gd. u = an angle, v, in the equation,

$$u = \log_e \tan \left(\frac{\pi}{4} + \frac{v}{2}\right)$$

or,

$$u = 2.3025851 \tan \left(45° + \frac{v}{2}\right)$$

The proper value for the sinh 0.18 may be ascertained:

$$\frac{0.18}{2.3025851} = \tan \left(45° + \frac{v}{2}\right)$$

$$v = 10°\ 15'\ 30''$$

$$\sinh u = \tan v = 0.1809797$$

thereby showing 0.18098 to be a better value than 0.18097 as given in the Smithsonian Tables previously quoted.

It is a pleasure to note the comments, and to thank Mr. Meals for his favorable expressions concerning the subject-matter of the paper. It may be of interest to state that the writer does not limit the design of dumping cradleways to the light decks and loads mentioned by Mr. Meals. On the contrary, 12-cu. yd. air-dump cars may be used, weighing 25 000 lb. empty, and cradleway decks weighing 350 lb. per ft., exclusive of rails and supported by suspender tackle on 30-ft. centers. In so far as the deck is always close to the movable tower, if for no other reason than to keep the fill up to grade, Equa-

tions (122) and (123) would give doubtful values for the maximum tension and the proper center deflection of the empty cable. The former would be unreasonably large and the latter too small. However, let this be as it may, contractors are not alert, who fail to inform themselves concerning this handy and economical method of building fills and waste piles.

It has been stated, often, that good ropes require good wire. Good wire can be made only from high quality steel. The transformation of high quality steel billets into No. 5 rods takes place in a rod mill, and the rods are coiled hot on 30-in. spools. Therefore, the rods are formed to a curve having a radius of about 15 in. Later, these rods are taken to a wire bench and are pulled cold, through the die-plate, and wound under high tension on wire blocks 22 in. in diameter or smaller. In fact, the entire wire-making process from billets to ropes is only the winding and unwinding of "process" wire on spools of small diameter, with a few intermediate treatments. Accordingly, when rope wire of ordinary manufacture is assembled, as shown in Fig. 25, it must be kept under tension, for its inherent tendency, when free of restraint, is to assume the position shown in Fig. 26. This is true of wire ropes as well as wires.

That is, under conditions of minimum stress, a wire or rope naturally takes the form of a helix and, by permitting rotation about the axis of the helix, the assembly may be passed over sheaves having a radius of curvature equal to the loops, without imposing on the wires, stresses due to bending in passing the sheaves.

Accordingly, it may be stated that the act of passing a wire rope around a sheave is not, in itself, conclusive evidence that additional stresses have been developed in the component wires. It merely leaves a doubt, to be settled by experiment, as to whether a certain type of rope will find operating conditions favorable, or otherwise, for satisfactory service, and whether its performance will be excellent or poor. Rope manufacturers, therefore, have been forced to develop a great variety of wire ropes, both as to quality and construction, because it has been noted that, if one type of rope fails to discharge a given duty, a different kind may attain success. The maximum number of varieties of construction in wire ropes has practically been reached and, therefore, attention has again turned to wire treatments before rope-laying.

One such treatment attempts to eliminate the "set" of wire manufacture by an additional "permanent set", that is, by pre-forming the wire and strands to assume a definite curvature called "Tru-Lay." While such treatments result in ropes that are more or less "dead"—that is, they do not assume the helical form if free from tension—the same behavior has been found by other methods. The merit of the "Tru-Lay" construction remains to be determined by experience. Already, it is credited with excellent results, and some poor ones, so that it remains to be seen whether the average performance of preformed wire ropes will exceed that of equal grades of ropes of usual manufacture. The history of wire rope is filled with cases that are conspicuous by their success, and failure, and so it may be well to temper Mr. Meals' enthusiastic endorsement of "Tru-Lay" construction for ropes that "will wear

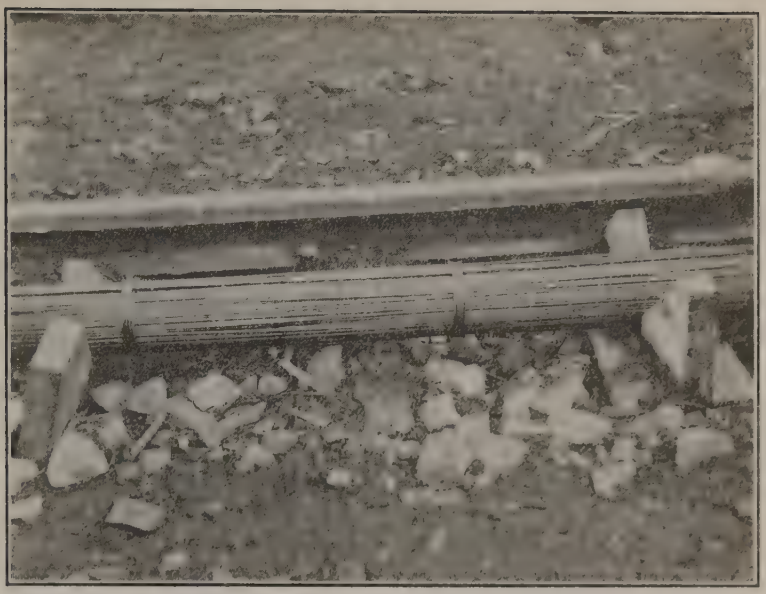

Fig. 25.—Rope Wire Under Tension.

Fig. 26.—Position Assumed by Some Wire and Ropes Not Under Tension.

longer and withstand bending better because the individual wires and strands of the ropes are in an unrestrained position". As it is difficult to see how a pre-formed wire can be free from strain (destructive ones perhaps), it is desirable that performance records of "Tru-Lay" ropes be made available soon to the Engineering Profession.

In closing, the writer expresses his appreciation of the courtesy of those who have read the paper, for in so doing they have helped in establishing aerial tramways to be the product of engineering skill, worthy of confidence as an instrument devised for economical transportation of materials, rather than a contraption offered by the manufacturers of wire rope to provide a remunerative outlet for their products.

Paper No. 1676

STREAM POLLUTION IN THE PACIFIC NORTHWEST*

By William F. Allison,† M. Am. Soc. C. E.

With Discussion by Messrs. William J. Roberts, Augustus Smith, A. H. Dimock, and Kenneth Allen.

The problems presented by the pollution of streams and lakes in the States bordering on the North Pacific Ocean are different from those in older communities only in degree and acuteness. Much of the difficulty that has arisen is due to a feeling that streams and lakes flowing into the Pacific Ocean, and its arms, are unlimited in their capacity to absorb pollution, and that, therefore, population and industry need not seriously concern themselves in disposing of wastes which have little, if any, commercial value.

In the early days the chief form of pollution was caused by the miners who stirred the muck and gravel from the bottom of the streams, and after removing the gold, sluiced the tailings out on the arable land below as the easiest method of disposing of it. Usually, these arable lands were still in the hands of the Federal Government, but this was slight bar to the easiest disposal of waste as placer miners saw fit. The miner will still contend that prior use of stream and land gives him a permanent right to use them for his purposes, regardless of the interest of later comers. Much of the land covered by this waste had agricultural possibilities and was eventually acquired by private parties who, to secure their rights, carried the contest into the Courts. These lawsuits are particularly notable in California, where they have invariably been decided in favor of the farmer. The placer miner, when he stakes a claim, makes the possibility of disposal of tailings one of his chief considerations.

* Presented at the meeting of the Sanitary Engineering Division, Seattle, Wash., July 15, 1926.

† Prof., Municipal and Highway Eng., Univ. of Washington, Seattle, Wash. Prof. Allison died on July 6, 1927.

Agriculture and mining again come in conflict when the lode miner, after running his ore through a stamp mill, seeks a means of disposing of the tailings of the mills. This waste is usually pulverized quartz which, when carried down to irrigation ditches and finally deposited on an alfalfa field, is highly injurious to the growing crops, acting not at all like the silt deposited in the Valley of the Nile during a period of flood.

The farmer, who must use the water of these streams to irrigate his land, must find some method of disposing of this finely pulverized quartz before it reaches that land. Ordinarily, this is done by impounding the water in a reservoir where the suspended particles are allowed to settle. It is periodically removed from the reservoir or settling basin at a cost of a great deal of hard labor and much time.

This sedimentation does not remove the solids in solution which may have a deleterious effect on this water for domestic purposes, and to some extent, for irrigation. Some of the streams of Colorado have an appreciable quantity of sulfuric acid which sedimentation and screening through gravel does not remove. The taste of the water is much impaired and its use in the making of tea and coffee is quite unsatisfactory, inasmuch as the tea takes on the color of ink.

The heavy deposits of pulverized quartz are being cared for nowadays by compelling the mining and milling companies to dispose properly of the wastes due to their operations. However, this is done with some reluctance, as increased cost may result in suspension of work in a basic industry and a consequent unemployment of labor. The problem is similar to that, but not precisely the same as, in the mining regions of the East.

Lumbering is another basic industry in the Pacific Northwest that has a waste problem to solve. This problem is practically the same as that faced by the lumberman of the East. Sawdust and refuse from saw-mills are more easily disposed of by depositing them in a stream than in any other manner. There they rot and in a short time become exceedingly foul, to the destruction of fish, and thus they tend to destroy another basic industry. Quite generally this is overcome by compelling the saw-mill operators to burn their waste, which perhaps causes some danger to plant and surrounding timber. The much heralded danger from forest fires must be considered when plans for burning waste are considered.

A third growing industry that seriously pollutes the water of streams and lakes is the manufacture of wood pulp and paper. The sulfite liquor used in pulp making is harmful to fish life, and it is found that small fibers in the waste become entangled in the gills of fish and cause their death. An economical and satisfactory method of caring for this waste has not yet been found. The problem is an old one and any efforts to solve it should be made along lines which will not injure the pulp and paper business. Competition with European pulp is keen and any irksome restrictions may drive American manufacturers out of business.

The Federal Government is spending much money in the promotion of fisheries on the Pacific Coast. It cannot look with approval on pulp manu-

facture on the coast of Alaska, where there is said to be much suitable pulp wood, if pulp making destroys young fish which have been so carefully reared and protected.

The protection of fish is one of the chief objects of Fish and Game Commissions of the States of this region. Over-fishing and out-of-season fishing are prohibited, but, in any contest with other industries, the fish are likely to be sacrificed to the economic demands of other desirable lines of endeavor.

The effect of sewage pollution has a considerable bearing on the fishing industry of the Pacific Coast, as is common on the Atlantic seaboard. The shellfish industry of Puget Sound has been only partly developed, but already the presence of *B. coli* in the oysters has been observed. It is believed that oyster culture can be greatly increased if steps are taken to prevent raw sewage from flowing into Puget Sound. A proper educational program will be necessary to overcome prevailing ideas in this respect. The sale of oysters grown in certain localities on the Atlantic Coast is generally forbidden by Boards of Health and the same regulations may be anticipated regarding the oysters of the Pacific Coast if steps are not taken to prevent pollution of areas that may be used as oyster beds.

There is a considerable business in the marketing of clams, but inasmuch as clams are almost always cooked before eating, it is felt that there is no great danger from contamination, although clams obtained from sludge deposits would be in little demand from the public and probably would not have the approval of the health authorities.

Sewage seems to be very destructive to fish life that has a high commercial value. A few years ago, near one of the salmon hatcheries in the southern part of the State of Washington, it was observed that young salmon on being turned into a stream near the mouth of a sewer, died very quickly. A considerable portion of the sewage flowing into the stream was traced to a hospital, and it was believed that there was enough poison in the sewage to kill the fish. Probably storm sewage containing oil and gasoline from the streets would have the same effect.

The two most conspicuous examples of sewage pollution of fresh water in this State are the disposal of the sewage of the City of Spokane in the Spokane River, and the pollution of Lake Washington at the eastern edge of the City of Seattle by the sewage of urban and suburban districts bordering on that lake. Spokane permits its sewage to go into the Spokane River, below the city, which, in turn, flows into the Columbia River.

It is contended that the Spokane River, in flowing over a series of falls and rapids and through ponds which act as settling basins, causes the sewage to oxidize to such an extent that it becomes practically harmless when it reaches the Columbia. It is by no means certain that this is true. Typhoid is more or less endemic all along the eastern slope of the Cascade Mountains and is sometimes a menace to the surrounding country. Water used for irrigation is often rather heavily polluted, and workers in the fields and on the fruit ranches are careless about drinking water from the irrigation ditches, being thus exposed to the fever. The occasional cases that are found in the cities of the Puget Sound region are contracted in this manner, and make it

difficult to stamp out typhoid on the Pacific Coast. Regulations and rules of Departments of Health are frequently violated and, for several years, the Board of Health of Washington has carried on a campaign of education in matters relating to the pollution of streams and of the proper disposal of sewage. It has seemed that education of this kind must face the decided opposition of political and commercial interests.

For several years, the before-mentioned pollution of Lake Washington has been a subject of controversy. The lake is a natural receptacle for the drainage of a considerable area. This area lies partly within the city limits of Seattle and includes the rapidly growing district east of the lake. Until a few years ago the lake was the source of water supply for the city. With the growth of the city and the towns surrounding the lake, it became increasingly more difficult to prevent sewage from draining into the lake. Private sewers became a constant source of trouble. After Seattle began to obtain its water from Cedar Lake, forty miles southeast of the city, it was believed by people living near the lake that the difficulty was settled for all time. The best and most accessible fresh-water bathing beaches, however, are here available, and there is much sentiment against their destruction.

The construction of the ship canal and locks prevents for all time the use of lake water for domestic purposes, as the operation of the locks admits an appreciable quantity of salt water into the lake. It has been contended by some that a fresh-water harbor would not compensate the city for the loss of fresh water which, in the future, might be needed for a city supply. However, it seems probable that sufficient water may be obtained from mountain streams for all purposes, although it will probably have to be filtered and sterilized before using. Be this as it may, the flow of sewage into the lake has materially detracted from its value for bathing purposes, and the problem now presented is to treat the sewage in such a manner that bathing may be safe and satisfactory. Bonds have been voted to build intercepting sewers to carry the sewage of this district into Puget Sound, which is an expedient that will improve the water in the lake, but will tend to increase the trouble with the Sound waters. The writer can see no solution of the problem except to treat all sewage flowing into the Sound and to sterilize it to the satisfaction of the State Board of Health.

The City of Seattle has had some trouble because of the location of and opposition to small sewage treatment plants. A careful survey of surrounding property, together with the proper design and operation of such plants, perhaps might tend to reduce the opposition. Certainly, the benefit that may be derived from them should be much greater than the damage caused.

Water obtained from mountain streams is not always free from sewage, although the sources of such streams are springs and glaciers. The City of Wenatchee, Wash., proposed a few years ago to obtain its water from a glacial stream called the Icicle, hoping thus to eliminate the typhoid prevailing in and about that city. Upon examination of water from the Icicle, it was found that a considerable number of *B. coli* was present, and the water could not be approved by the Board of Health unless satisfactorily treated. This, together with the heavy cost of obtaining the water from the Icicle,

eliminated this as a source of supply. A filtered supply from the Columbia River, being cheaper and meeting the requirements of the State Board of Health, was adopted instead.

The Columbia River is the great natural drain for large parts of Washington, Oregon, and Idaho, and whenever it becomes necessary to use this water for a city supply, it must be put through a course of purification. The waters of many of the streams of this region have considerable colloidal clay in suspension, which should be considered in designing any filtration system. Mountain streams, although appearing to be clear, will almost always carry considerable silt. It is well known that rock-fill and earthen or timber dams gradually silt up and become tight with age.

In the main, information and experience gained in building and operating purification plants in the East will apply on the Pacific Coast, and with the information that is available, the engineer in the Northwest must familiarize himself with local conditions and then work out his own salvation.

The engineer will have some difficulty in convincing the people of the need for improvement and of the efficiency of his proposal. Many of them are "from Missouri" and have been hectored by men with something to sell. In 1913 the City of Centralia experienced a serious epidemic of typhoid which was traced to the water supply that came from wells along the river. It was shown that seepage from the river was getting into the wells and was the source of the epidemic. Dr. Eugene Kelley, who at that time was Commissioner of Health of Washington, was asked by the city officials why he did not warn them of the danger impending. Dr. Kelley turned to the files of the local newspapers. In one of the glaring headlines it announced that Dr. Kelley had visited the city and, as a result of his investigations, was maligning Centralia by finding fault with the water supply and insisted that the dangers foreseen were purely imaginary. Had his warning been heeded, this otherwise prosperous community would have escaped the sacrifice of the health of its people and an expenditure of a large amount of money. Needless to say, the City of Centralia now has a good water supply.

DISCUSSION

WILLIAM J. ROBERTS,* M. AM. SOC. C. E.—The author upholds high ideals, and many of them are worthy of heartiest support. It has, however, been demonstrated beyond question that there are places on Puget Sound where it is neither necessary nor expedient to follow the author's advice "to treat all sewage flowing into the Sound and to sterilize it to the satisfaction of the State Board of Health."

An outstanding example is furnished by Camp Lewis, American Lake Cantonment. As Consulting Engineer, collaborating with the Constructing Quartermaster, the speaker found that the water supply and the proper disposal of sewage for 50 000 troops presented many intricate problems. The demand for healthful conditions was no more imperative than the demand for speed in construction; and always the question: "Is it sanitary?" was followed by the remorseless demand: "Can the work be completed on time?"

Fortunately, "Sequalichew Springs" about 1.5 miles from Camp Headquarters, proved adequate in quantity, yielding, when developed, more than 6 000 gal. per min. The quality of this water was pronounced, after frequent tests, to be "as pure as distilled water." Thus, the problem of obtaining an adequate and pure water supply was solved.

The logical disposal of the sewage was into Puget Sound 3.5 miles from Headquarters, without treatment. After a thorough investigation, and careful consideration of all possible objections, the point of discharge was selected at mean sea level, 3.5 miles from the nearest barracks; more than a mile from the nearest dwelling, but only a short distance from a double-track railroad carrying a heavy passenger traffic. The tidal range of the Sound at this point is about 12 ft. At the outlet the channel is about 1.5 miles wide and several hundred feet deep. Thus, the shores of the Sound are thoroughly cleansed twice a day by the large volumes of flowing tides. So thoroughly is this cleansing process carried on that a passenger on the train can not discover, by sight or odor, the outlet of the sewer. No inconvenience or harmful effects of this plan of disposal touched the lives or even the comfort of the soldiers at Camp Lewis nor its environment. If ever there was a place where disposal by dilution and dispersion is permissible, because rational, then this is that place. The demand for perfect sanitation and great speed in construction was satisfactorily met; 40 miles of water mains and 30 miles of sewers were actually laid in 78 days.

It is estimated that the tortuous channels of Puget Sound with all its inlets and islands within the State of Washington amount to 3 600 miles of shore lines. The volume of ocean water pouring into Puget Sound through the Strait of Juan de Fuca, 16 miles wide, with a maximum channel depth in excess of 1 000 ft., assures a satisfactory dilution and dispersion of any sewage discharged into the Sound.

The Sanitary Field Officers at Camp Lewis, remembering the troubles occasioned in some of the camps during the Spanish-American War, were

* Cons. Engr., Tacoma, Wash.

alert to avoid anything unsanitary. Hence it was a pleasure to learn from the best information obtainable that not a single case of typhoid fever could be traced to impure water at the Camp or to bad sewerage during the entire training period from August, 1917, to November, 1918.

As has been well stated:*

"Skimping funds may often lead to danger to the public health, and the enforcement of requirements for an unnecessarily high degree of purification of sewage to useless waste of money."

AUGUSTUS SMITH,† M. AM. SOC. C. E.—It may be of interest to consider what is being done in New Jersey relative to stream pollution. The State has been handling the matter of stream pollution through the State Department of Health. It has also a Fish and Game Commission, which has been very active. Frequently, this Commission has come into contact with the other State Departments because it could not get all the support it wanted in its work of preventing the pollution of streams.

In 1924, the State created the Sanitary and Economic Water Commission, of which the speaker is a member. The idea behind that legislation was to create "a permanent jury", so to speak, to give judgments as to the "economic" policy on the pollution of any stream or water in the State. The new Commission was formed by the Governor appointing one member from the State Department of Health, one from the Fish and Game Commission, one from the Shell Fishery Commission, one from the State Board of Conservation and Development (which has charge of all State lands), and one from the Board of Commerce and Navigation (which deals with problems concerning navigable waters), and the Attorney General of the State.

The Commission has been functioning only since 1925, but one of its first acts was to adopt the method of classifying streams recommended by W. L. Stevenson, M. Am. Soc. C. E. It divides streams into three classes:

(*a*) Those streams, or portions of streams, used or reserved for potable purposes.

(*b*) Those streams clean enough for recreation, for enhancing the value of real estate, and for fishing.

(*c*) Those streams passing through communities where the industrial needs are paramount.

It has seemed to this Commission, that the first step in trying to recover or preserve the purity of the streams, is to arrive at a general consensus of public opinion as to the best use of a stream from an economic standpoint.

A. H. DIMOCK,‡ M. AM. SOC. C. E.—After discussing various ways by which the waters of Puget Sound are polluted, the author comes to the general conclusion that all such polluting matter should be treated and sterilized before discharge. While the speaker is heartily in favor of keeping all waters in the best possible condition, and especially all fresh waters, nevertheless this conclusion seems somewhat sweeping.

† Pres., Bergen Point Iron Works, Bayonne, N. J.

‡ Cons. Engr., Seattle, Wash.

Puget Sound, including Admiralty Inlet, is a body of water about 60 miles long from the Straits of Juan de Fuca to Tacoma, Wash., and from 3 to 6 miles wide. South of Tacoma it narrows to less than a mile and then widens and breaks up into an intricate maze of channels and bays. In this southern portion are situated a number of oyster beds. The bays are shallow, the flat areas extensive, and the movement of water is more or less restricted. The treatment of sewage entering this portion becomes, in general, more desirable. Each particular problem, however, must be decided in the light of its own local conditions.

In the larger part of Puget Sound, north from Tacoma, however, the channel is very deep, varying as much as 120 fathoms. The tides have a range of 16 ft., and there is necessarily a considerable movement of the water. The volume and character of these movements are not definitely known. Oyster beds are few. There is none along the main channel, and the shores, generally, have good slopes. It would seem, therefore, that the oxidizing capacity of this part of Puget Sound is an asset of considerable importance to the towns and cities on its banks, and may be utilized without detriment to health, the public welfare, or private business.

When the speaker was designing the main sewerage system for the larger part of Seattle, Wash., about 1905, extensive observations of currents were made by floats. This survey revealed many beaches which were highly undesirable as points of discharge for sewage, for the reason that the currents set chiefly toward the shore. Some places were found, however, where the currents for 80% of the time were offshore. The outfall of a main sewer 12 ft. in diameter was located at such a place and extended to a point where the water was 40 ft. deep. The only trouble that has been experienced at this point, has been at outfalls where discharge was permitted on the surface or at shallow depths. The remedy is obvious. It would certainly be a "counsel of perfection", under such conditions, to spend large sums for artificial treatment plants, when Nature has provided one far more efficient, the use of which is free of operating charges and involves no menace to health.

The case of Lake Washington, in Seattle, is different. This lake is 20 miles long by 2 to 4 miles wide and lies parallel to the salt-water front at a distance of 2 to 7 miles. Its shore, within the city limits, is used almost exclusively for residential purposes, with the exception of a few ferry landings, one sawmill, and other minor business. The lake is subject to navigation, but this use is small. The sewage from as much of the drainage area as was possible has been intercepted and carried to the salt-water outfalls; but there remained about 4 500 acres, the sewage from which has been discharged into the lake. The growth of population and the largely increased use of bathing beaches created the necessity for some action. It was proposed to build a series of Imhoff tanks and to chlorinate the effluent. The speaker investigated the problem on behalf of the City and came to the general conclusion that Lake Washington was an asset of great value to the city both because of the desirability of the residential sites along its shores, with their entrancing views of lake and forests and snow-crowned mountains, and because of its recreational possibilities; a use which will be more and more essential to the

public welfare as the population increases. For these reasons it was held desirable to exclude from its shores everything that was even suggestive of unpleasant things, and that sewage treatment plants, which would necessarily be more or less visible, and from which odors might emanate, should not be permitted if some other means could be found within a reasonable cost limit.

The speaker sought to determine a standard of purity for the waters of Lake Washington. It is not used as a source of water supply except in the sparsely settled section on the east shore, several miles from the Seattle side. Its main use is recreational. In 1925, 365 000 people used the bathing beaches, which are far more popular than the salt-water beaches due to the higher temperature of the water and the more convenient access. A considerable diversity of opinion as to a proper standard was found to exist among the experts, ranging from not more than 10 *B. coli* per cu. cm. in swimming pools in New York and in salt-water beaches in California to a drinking-water standard insisted on by some authorities. Just how the latter standard can be maintained either at an open bathing beach or in a closed swimming pool is difficult to understand. The chief danger is from infection arising from promiscuous bathing at the same time of diseased and healthy persons. No practicable excess of chlorine can prevent, although it may reduce, this danger. The remedy would seem to lie in proper inspection and regulation and not in the futile endeavor to maintain a drinking-water standard. It was the speaker's conclusion, that, if the water of Lake Washington was negative as to *B. coli* in 1-cu. cm. samples, it would be safe anywhere for individual bathing, and that such a standard might be attained by diverting all sewage. At the bathing beaches, because of the pollution contributed by the bathers themselves, it was thought that regulation of use and chlorination would be essential, even if the water in the lake could be brought to the drinking-water standard.

The means recommended to accomplish the desired results were the diversion from the lake of all sewage plus rain water to a total amount of 0.033 sec-ft. per acre, by the construction in one case of a tunnel and in others of suitable automatic pumping stations discharging into existing intercepting sewers. These stations are to be provided with storm-water overflows discharging in about 30 ft. of water. It is thought that, under the conditions that obtain, no further treatment of storm water will be necessary. The average annual rainfall in Seattle is 33 in. The intensity is remarkably low. The number of storms equal to or exceeding the rates shown during a period of 30 years are, as follows:

0.80 in. per hour.....	0	0.40 in. per hour.....	12
0.70 " " "	1	0.36 " " "	14
0.60 " " "	2	0.30 " " "	30
0.50 " " "	8	0.25 " " "	55

Using a capacity of 0.033 sec-ft. per acre as stated, and assuming a population of 25 per acre and a run-off factor of 0.25, it was found that all rains of less than 0.12 in. per hour would be diverted from the lake and that there would be only 28 hours per year when that rate would be exceeded; an average of 1 hour of rain every 13 days.

KENNETH ALLEN,* M. AM. SOC. C. E. (by letter).—With higher standards of living and an increasing demand for eliminating pollution from rivers and harbors, the danger of going further in this direction than can be properly justified, should be kept in view by State and municipal officials. Public funds available for sanitation should be applied in the most effective manner, and it is quite conceivable that the public may be better served by allocating the entire sum to better water supplies, hospitals, and playgrounds, than to a refined treatment of sewage. Without personal familiarity with Puget Sound, the writer's views on this point are in sympathy with those expressed by Mr. Roberts.

Each case should be considered on its individual merits, and, in approaching the subject, the standard of purity should be considered of prime consideration. If the result of the discharge of crude or screened sewage will not offend the senses or endanger health—as is frequently the case on the seaboard—the additional cost of tanks, filters, or chlorination, had better be applied to other purposes.

This is the policy being followed by the City of New York in its program for sewage disposal, where every variety of condition is met as to dilution, salinity, depth, current, and pollution. Where fine screening will answer, nothing more is planned; but where conditions call for the greatest possible improvement, treatment by the relatively expensive activated sludge process, or its equivalent, will without question be used.

Paper No. 1677

THE SEWAGE DISPOSAL PROBLEM OF LOS ANGELES, CALIFORNIA*

By Willis T. Knowlton,† M. Am. Soc. C. E.

With Discussion by Messrs. A. M. Rawn and Willis T. Knowlton.

Synopsis

The continued and rapid growth of Los Angeles, Calif., has required constant attention to the matter of sewage disposal, and especially since 1920 when the population took such an upward trend that plans were required for a Metropolitan System. Studies were then made for the collection and disposal of sewage from all the area to the north and west of the city.

This paper describes how the outfall sewers required for this area have been planned to serve the Metropolitan Districts, regardless of political boundaries. Considerable data on the basis of design are given. The problem of ocean disposal of the effluent from the screening plants and the final disposal of the sewage screenings will require continued attention as the sewered population increases. In addition to sanitary sewage, the disposal of industrial waste is a problem to which reference is also made.

Early History

The City of Los Angeles commenced the construction of public sewers in 1873, when the population was about 7 000, although there are records of sewers as early as 1863. In 1887 the first comprehensive plan for a sewerage system was made by Frederick Eaton, M. Am. Soc. C. E., then City Surveyor. His plan, designed for sewage only, provided for intercepting sewers which

* Presented at the meeting of the Sanitary Engineering Division, Seattle, Wash., July 15, 1926.

† San. Engr., City of Los Angeles, Los Angeles, Calif.

were to discharge into an outfall sewer having a capacity for a total population of 200 000. This plan before its adoption was submitted to the late Rudolph Hering, M. Am. Soc. C. E., for his examination and approval. In 1900, the area of the city had increased 50% over its size in 1887, the total population was 102 479, and the system contained 160 miles of sewers.

The outfall sewer, as planned by Mr. Eaton, had a capacity of 30 sec-ft. As originally built, it contained two inverted siphons and its ocean end at Hyperion consisted of 24-in. cast-iron pipe laid into the ocean for a distance of 600 ft. This pipe was superseded in 1904 by a 30-in., steel pipe outfall which was laid on a pier to a distance of 940 ft. from shore. This steel pipe sewer was superseded in 1908 by a 34-in. wooden stave pipe, which had a capacity of 116 sec-ft., and provided for a population of 750 000. The wooden stave-pipe sewer discharged into a vertical pipe which carried the flow of sewage to a depth of about 6 ft. below mean sea level, where the water was about 16 ft. deep.

Growth of City

Owing to the continued growth of the city in all directions, the quantity of discharge into the main outfall sewer increased from an average daily flow of 15 000 000 gal. in 1910 to 23 000 000 gal. in 1915. This increase indicated that, to remedy complaints arising from this disposal, the sewage should be treated before discharge into the ocean at Hyperion. Accordingly, a bond issue for a sewage treatment plant at Hyperion was submitted to the voters in 1916, but was defeated. A similar proposition was submitted in 1917, but without success. On account of the World War, nothing was done until 1920, when the increasing volume of raw sewage discharged at this location made it necessary to plan for a new outfall as well as for the treatment of the sewage before disposal into the ocean.

In January, 1920, the population of Los Angeles was 576 673; in 1922, it was about 800 000, and a recent estimate (June, 1926) places it at 1 250 000. All estimates of future population must be considered as speculative, but a conservative estimate of the population of Los Angeles in 1950 would be not less than 4 000 000.

The sewage flow in the outfall during the past six years has increased in practically the same way as the population. In 1920, the sewage discharged at Hyperion averaged 33 000 000 gal. per day. In July, 1922, this flow had increased to 50 000 000 gal. per day, and, at present (1926), the flow from all parts of the city, except the Harbor District, averages 78 000 000 gal. per day.

North Outfall Sewer Planned

Preliminary plans were made in 1920 for a new outfall sewer to supplement the existing one, and also for the treatment of the sewage. These plans provided not only for the conditions at that time, but also for a period of about thirty years thereafter. The plans contemplated the collection of sewage from all areas tributary either to the existing outfall or proposed new outfall, regardless of political boundary lines. The new outfall has been designated

as the "North Outfall Sewer" and the existing outfall as the "Central Outfall Sewer".

After making plans for the North Outfall Sewer an educational compaign was required to acquaint the voters with the needs. Civic bodies and local engineers approved the plans and recommended that bonds be voted for the work. Owing, however, to opposition from those who considered land disposal preferable to ocean disposal and who thought that there should be a reclamation of sewage for fertilizing values, a Special Sewage Disposal Commission was appointed to investigate the entire problem and submit a report. This Commission, consisting of George W. Fuller, the late George C. Whipple, and William Mulholland, Members, Am. Soc. C. E., confirmed the plans and recommended that the North Outfall be built for a capacity of at least 210 000 000 gal. per day and that the sewage be discharged into the ocean after passing through a fine screening plant. Opposition to the work proved, however, to be too great and the proposal was defeated in June, 1921.

Plans for another election were immediately commenced as the sanitary conditions in certain parts of the city were becoming intolerable. To obtain all necessary data, for acquainting the voters of the true situation, an examination of conditions in other cities was made by the City Engineer and the writer. The report of this examination, together with that of the Special Sewage Disposal Commission, was published in August, 1921, following which an educational campaign was conducted. As a result of these combined efforts, the election in August, 1922, approved the issue of sewer bonds.

Temporary Outfall Sewer

In 1922 a temporary relief sewer to carry the overflow from the Central Outfall was built as far as Ballona Creek, about 3½ miles below the point where the Central Outfall was intercepted by this relief sewer. Owing to complaints against the pollution of this creek, the City was ordered to take measures to prevent the discharge of raw sewage into the creek or provide for its treatment if the overflow was to continue. A coarse screening plant was built to remove all floating material before the flow in the Temporary Outfall was discharged into the creek. To prevent further pollution, the effluent from the plant was treated with liquid chlorine.

The upper end of the Temporary Outfall had a capacity of about 40 sec-ft., but owing to the increase of flow from new connections being constantly made to the system, the capacity of the lower end was increased to about 30 000 000 gal. per day. Records of the flow in this sewer from September, 1923, to May, 1924, gave an average of 28.2 lb. of chlorine and 13.4 cu. ft. of screenings per 1 000 000 gal. of sewage. The screens consisted of a double set of vertical units of ½-in. mesh arranged so that one set was in place while the other was being cleaned. The bottom of the channel of Ballona Creek was graded to assist in preventing a nuisance. However, the continued discharge of this treated sewage caused a second suit to be filed against the City by the City of Venice for conditions in the lower part of Ballona Creek where it empties into the ocean near Playa del Rey.

It thus became necessary to continue the construction of the Temporary Outfall to the ocean and to abandon the plans for the settling tanks and sprinkling filters to treat the flow in this outfall. A site of thirty-eight acres had been purchased for this treatment plant, but opposition from property owners compelled the City to continue the Temporary Outfall to the ocean. This sewer having a length of 10 miles was used for disposal of the overflow from the Central Outfall into the ocean from April to December, 1924. The outlet end of the Temporary Outfall which was laid on the bottom of the ocean for a distance of 600 ft. from shore, where the depth was 12 ft., consisted of 44-in. riveted steel pipe. The pipe was assembled on the beach, made air-tight, and bulkheaded. It was then tugged into the water, floated into position, and sunk under a trestle that had previously been prepared for its protection. When the North Outfall was completed so that the Temporary Outfall could be abandoned, the material used for the latter was salvaged.

North Outfall Sewer Drainage Area

Immediately after the successful election held in August, 1922, contract plans were made for the construction of the North Outfall. It was decided at that time that this sewer should be divided into fourteen sections so that the work could proceed simultaneously at various points. Tunnel routes to Hyperion and along the brow of the del Rey Hills were studied. Although longer, it was found that the del Rey route would be cheaper, and accordingly it was adopted for the lower part of the North Outfall. The total length of this sewer, which was completed in November, 1924, is 17.6 miles. The discharge capacity at its lower end is 340 000 000 gal. per day.

When the outfall was proposed in 1920, it was planned to provide for the disposal of sewage from a large Metropolitan District, comprising all the area north of Manchester Avenue, then the southerly border of the city proper, and all the area west of the easterly boundary of the city. This district included a large area in Los Angeles County south of Fernando Pass.

As it was necessary that that portion of Los Angeles County east of the city and south of Manchester Avenue should also plan for the disposal of its sewage, a tentative arrangement was outlined in November, 1924, whereby all areas tributary to the North and Central Outfall Sewers should be planned so to discharge their sewage. Similarly, those areas tributary to an outfall sewer, proposed to discharge into the ocean on the south coast of the County, would be accordingly planned. The dividing line between these two Metropolitan Areas was established by joint action of the engineers of the City and those representing the County Sanitation Districts. The area of the North Metropolitan District, which is tributary to the North Outfall Sewer, is about 513 sq. miles, and that of the South Metropolitan District about 605 sq. miles. On account of the size and continued growth of the city, there are sections which must have their sewage discharged into the so-called South Outfall Sewer which, when built, will be the main outlet for the South Metropolitan District.

In accord with the foregoing, the North Outfall was designed to carry the sanitary sewage from all parts of the city north of Manchester Avenue and include therewith the entire San Fernando Valley. The major part of the Valley added by annexation about 170 sq. miles to the area of the city in 1915, and since then eight other annexations in the Valley have added about 24 sq. miles. There are, however, other cities and county areas in the North Metropolitan District which were considered in the design of the North Outfall. These cities include Glendale, Burbank, San Fernando, Beverly Hills, Culver City, Santa Monica, and El Segundo, which have a combined population of more than 140 000. In view of the rapid growth of this Metropolitan District and the demand for sanitary improvements, considerable study was required for future conditions.

Basic Data for Sewer Design

In the main part of the city it was thought that the business growth would cover the entire congested area extending from Figueroa Street to San Pedro Street and from Sunset Boulevard southerly to Washington Street.

Careful records were made of the water consumption in the different parts of the business district and a maximum allowance of 0.15 sec-ft. per acre and 0.02 sec-ft. per acre of floor area was provided. In the industrial districts a factor of 0.2 sec-ft. per acre was measured. Owing to the rapid increase in the number of laundries, creameries, canneries, and other plants discharging much waste water into the sewers, the use of zones created for such plants has proved to be of much benefit. In the Hollywood District it was found that water used for washing the films in the laboratories of the moving picture plants would add about 0.5 sec-ft. per plant. For an average of the industrial district it is believed that the waste water amounts at least to 10 gal. per capita per day.

Records of sewage flow in the residential districts show a variation of 30 to 80 gal. per capita per day. From gauging in several parts of the city it is believed that 60 gal. per capita represents the average flow, and the records of adjoining cities where sewer gauging has been made, give 50 to 70 gal. per capita for a similar flow. At a point on the Central Outfall Sewer, records of the sewage flow have been kept since 1906. These records show an increase in the average flow per capita during the period, 1922-26, of 72 to 82 gal., which is due to industrial growth with possibly some infiltration.

The problem of designing for the proper density for large areas in the Metropolitan Districts, which at this time are but partly developed, has received much study. The present population varies from 34 per acre in the center of the city to 10 per acre 5 miles from the center. For the entire municipal area the density is 4.2 persons per acre. In the San Fernando Valley an allowance of 1 person per acre was made in 1920, but in a recent study this factor has been increased to 3. It should be noted, however, that in the different centers of population in the San Fernando Valley, such as Van Nuys, Lankershim, and Owensmouth, the density to be planned for will vary from 15 to 30 persons per acre.

In connection with the study of the future population a check has been made of the present population by applying a factor to the number of registered voters, the school census, the number of water, gas, and electric meters in use, and the directory. For the registered voters the factor used has been 3.37; for the school census, 3.54; for water meters, 5.5; for gas meters, 4.0; for telephone service, 4.5; and for the directory census, 2.25. At present (July, 1926), the population of the City of Los Angeles is estimated at 1 250 000.

Hyperion Screening Plant

The construction of a screening plant at Hyperion was included as a part of the work of building the North Outfall Sewer. This plant is divided into two parts. In order to clarify the sewage from the Central Outfall at the earliest possible date and to prevent any further pollution of the adjoining beaches, the southerly plant was built and placed in service in 1924. The North Plant began operation in March, 1925. The combined capacity of the two plants is now (July, 1926), 230 000 000 gal. per day, with space for additional units that will make a total capacity of 420 000 000 gal. per day.

These plants use drum-type revolving screens and include pits, elevators, and pneumatic sludge ejectors with complete electrical equipment. At the South Plant there are eight 8 by 8-ft. screens, each with a capacity of 10 000 000 gal. per day. Each screen is driven by a 5-h.p. motor and has a separate enclosed bucket elevator driven by a 1-h.p. motor to raise the screenings into metal hoppers from which they are ejected by compressed air. The sewage entering the plant passes through inclined bar screens. At the North Plant only one-half the screens, or one row of five screens, is now in use. These screens are 14 ft. in diameter and 12 ft. long, each with a capacity of 30 000 000 gal. per day. Each screen is driven by a 40-h.p. motor and equipped with a screening elevator driven by a 2-h.p. motor. The screenings are discharged into metal hoppers 3 ft. in diameter and 10 ft. deep, from which they are ejected by air pressure. This plant is operated by six men in the day shift and two in each of the two night shifts. After leaving the drum screens, the effluent from each plant is measured by a Venturi recording meter.

Table 1 shows the volume of sewage flow that has passed through the Hyperion Plant, together with the quantity of screenings removed from the flow for an 18-month period.

The average cost of the maintenance and operation of the plant during 1925 was $105 per day, or $1.26 per 1 000 000 gal. At present, these screenings are buried in the sandhills adjacent to the plant, but studies are in progress to determine the feasibility of using screenings for fertilizing purposes after a sufficient reduction of the *B. coli* and moisture content.

Ocean Disposal

The screened effluent from the Hyperion Plant is discharged through the 7-ft. reinforced concrete pipe sewer laid below the bottom of the ocean for a distance of 5 093 ft. from shore, where the depth is 54 ft. below mean sea level. The outer end of this ocean section is divided into two 5-ft. branches which have an average length of 210 ft. from their junction with the 7-ft. sewer.

* Average.

Biological surveys have been made since 1925 of the surf waters along the beach adjacent to the Hyperion Plant, to determine the number of *B. coli* present. These surveys made at semi-monthly intervals indicate that, except for the mile directly in front of the plant and adjacent to the outfall, there has been no count of more than 10 *B. coli* per cu. cm., which condition has been considered by the California State Board of Health as safe. In the outer ocean and on each side of the outfall, surveys were made in January, May, and October, 1925, and in January, 1926, to determine the area affected by the discharge of sewage. In all four surveys the sewage field containing 10 or more *B. coli* per cu. cm., has been outlined, and the results obtained are as given in Table 2.

On account of the discharge of raw sewage and the fact that there were some leaks in the outfall, the results obtained are not considered final and further surveys are being planned. However, it is considered that the discharge from the Hyperion Outfall receives sufficient dilution to prevent pollution of the adjacent beaches. After the repair of the leaks in the outfall, the effect of the diffusion and dilution should be much more in evidence than has previously been noted. The absence of any sewage odor, even over the point of discharge of the outfall, has been one direct result of the construction of the Hyperion Plant and Outfall Sewer.

In addition to the surveys for *B. coli,* the quantity of dissolved oxygen in the ocean waters adjacent to the end of the outfall has been determined at irregular times. These records indicate an average value of about 90% saturation within ½ mile radius of the sewer outlet, and at no point is it less than 84 per cent.

DISPOSAL OF INDUSTRIAL WASTES

Surveys are in progress to determine whether waste liquids and solids are being discharged into the sewerage system, that should not be permitted to enter. Especial attention is given to the disposal of refuse from fruit and vegetable canneries. Such waste not only overtaxes and clogs the system, but causes additional cost for treatment at the ocean disposal plant. Gasoline and oil are not permitted to be discharged in the sewers, but such disposal is in evidence at times. Some consideration has been given in some cities to a special charge for the disposal of such industrial waste, but should not the remedy be made at the plant of the industry?

In this connection it may be added that in the disposal of sewage from other cities and county sanitation districts into the City System, a clause in the contract with the City of Los Angeles states that all requirements imposed by the City shall likewise apply to such outside areas, thus establishing a standard for the Metropolitan District. The City has made contracts for sewage disposal with seven outside cities and four county sanitation districts. The total sewage from these outside areas is estimated eventually to be 59 000 000 gal. per day. The total length of public sewers in the city on July 1, 1926, was 1 457 miles.

DISCUSSION

A. M. Rawn,* M. Am. Soc. C. E. (by letter).—From Mr. Knowlton's paper, covering the history of the development of the Los Angeles City Metropolitan Sewer System, the writer abstracts two facts of outstanding importance that bear directly on the design and progress of similar works in other parts of California and elsewhere.

It is apparent that there is room for much study regarding the action of sewage when discharged into salt water; especially with reference to the direction and depth of discharge below the water surface and the amount of diffusion into the sea water. The selection of material used in the construction of the ocean section of the outfall plays an important part in determining whether the capacity life will be reached prior to elemental destruction.

The outfall sewer, designed for the City of Los Angeles in 1887, according to Mr. Knowlton, with the ocean end constructed of cast iron and extending 600 ft. into the ocean, provided for a capacity of 19 000 000 gal. per day, which should have provided for disposal into the ocean until about 1910. Nevertheless, it is found to have been superseded twice during its capacity life; once in 1904, with a steel pipe outfall extending 340 ft. farther seaward and, again, in 1908, with a wood stave pipe outfall of a length equal to the steel pipe, but with a different method of discharge into the water at the ocean end.

The wood stave outfall was designed with a capacity of 75 000 000 gal. per day and should have sufficed the needs of the city as an outfall sewer until about 1923. It has been superseded twice since construction; once, in 1918, with a wood stave line extending 2 000 ft. seaward and, again, in 1925, with the present outfall which extends about 1 mile seaward, discharging under 60 ft. of water. Thus, eight years prior to reaching capacity, the outfall constructed in 1908 was abandoned for a larger one (which is still (1927) in existence); and the latter, in turn, was abandoned for a still longer and larger one.

It would appear from this, which is an outstanding example, and which finds its parallel in many ocean outfalls constructed elsewhere, that sufficient experimental work and study should be conducted to enable the engineer to predetermine, with a fair degree of accuracy, the length of the outfall and other requirements of discharge that will enable him to construct the ocean end of the system with the same degree of permanency as the part on shore.

The second outstanding feature is the policy of the City of Los Angeles in building its sanitary sewer structure for the use of many communities not a part of its municipality and not bonded for its construction and then selling the allocated capacity to such communities, instead of attempting the organization of a large sanitary sewer district in the first place and attempting to persuade the communities for which sewerage facilities were to be provided, to participate in the original cost of construction.

* Asst. Chf. Engr., Los Angeles County Sanitation Dists., Los Angeles, Calif.

A well constructed outfall sewer is always a merchantable commodity in a growing district if it can be reached by a community which otherwise needs to resort to expensive local treatment, and this is clearly shown by the avidity with which the cities surrounding Los Angeles, and for which capacity has been provided in the North Outfall, are seizing the opportunity to discharge sewage into the North Outfall Sewer System under conditions dictated by the City of Los Angeles.

The writer is an advocate of the sedimentation process, as compared with fine screening, as a means of clearing up the effluent prior to disposal by dilution. Such treatment tends to reduce the dilution necessary, with consequent reduction of ocean-section costs; and, furthermore, the settled material resulting from sedimentation is much more responsive to reduction treatment than it is to screening.

Willis T. Knowlton,* M. Am. Soc. C. E. (by letter).—The writer has read with much interest the discussion by Mr. Rawn, and considers that the depth of the sewer outlet below the surface is an important factor in disposal into salt water. The distance from shore must also be taken into account. The Los Angeles Outfall of 1887 was of sufficient capacity for more than twenty years, but its proximity to the surf and the action of the waves caused its destruction.

Although the steel pipe outfall of 1904 had a capacity that was ample for many years, the action of the salt water and moisture caused the material to disintegrate, and this sewer was replaced four years later by a wooden stave pipe. The abandonment of the outfall of 1908 ten years later was probably due to different causes. First, the condition of the pier, which had been in use for fourteen years, was not satisfactory. Winter storms and floating material dashed against it at such times had weakened its construction. Similar damage also occurred to other piers in the vicinity, and in one case it was necessary to abandon more than 1 000 ft. of one not far from the sewer pier. Second, the metal bands around the wooden stave pipe became rusty and, consequently, leaks were found at various points along the line of the outfall. These conditions were not uncommon at that time in other outfalls of that type, especially where they were exposed to the elements.

In 1918 the City of Los Angeles built an outfall sewer into the ocean for a distance of about 2 000 ft. from shore. This sewer consisted of a 52-in. wooden stave pipe laid below the floor of a pier. This floor and pipe were practically level, having a fall of only 1 ft. in the entire length. At the outer end of the pier, the average depth of the ocean was about 30 ft. and sewage was discharged at this end through five outlets, each extending 18 ft. below mean sea level.

When this 1918 outfall was built, it was not considered that the sewage could be discharged into the ocean without treatment. As stated by the writer, unsuccessful bond issues for a treatment plant at Hyperion were submitted in both 1916 and 1917.

* San. Engr., City of Los Angeles, Los Angeles, Calif.

It was realized in 1918 that the disposal of sewage would require more attention than would be afforded by the 2 000-ft. outfall, which, in itself, had capacity for twenty years or more. Plans for Imhoff tanks and sludge beds at Hyperion had been prepared, but no funds for such construction were available. Consequently, the plans made in 1920 for a new outfall and treatment of sewage resulted in the construction, in 1924, of a 7-ft. reinforced concrete pipe sewer laid below the bottom of the ocean for a distance of 5 093 ft. from shore, where the depth is about 60 ft.

Considerable experimental work and study can and should be made in advance of the construction of outfall sewers, so that the engineers may predetermine the proper length and capacity of ocean sections, but the writer does not think that the same degree of efficiency can be obtained for the ocean end as is obtained for the land sections. The use of metal in the earlier Los Angeles outfalls was not advised in the outfalls of 1918 and 1924, and it is believed that the durability of the 1924 outfall is sufficient for many years. There are, however, some construction details in an ocean outfall which may not permit the sewer to be water-tight and which will permit leaks. If these leaks should occur at sufficient distance from shore, their effect may be negligible.

Paper No. 1678

THE WORK OF THE LOS ANGELES COUNTY (CALIFORNIA) SANITATION DISTRICTS*

By Albert K. Warren,† Assoc. M. Am. Soc. C. E.

In May, 1923, the Governor of California approved an enactment known as the "County Sanitation District Act of 1923", providing for the creation, government, and maintenance of County Sanitation Districts. The governing body of these Districts is empowered to employ engineers and other persons; to acquire real or personal property and rights of way; to issue bonds of the district; and to levy and collect assessments on real property.

For several years the south coast cities of Los Angeles County—Manhattan Beach, Hermosa Beach, and Redondo Beach—had attempted to provide a satisfactory method of sewage disposal. Immediately after the Act became effective those cities united in what is known as the South Bay Cities Sanitation District.

Even before the Act became effective citizens of Watts, Compton, and the vicinity, took steps toward the formation of a district to include six incorporated municipalities and some contiguous unincorporated area. It was first believed that this area, known as County Sanitation District No. 1, was the only one having urgent need of sewage disposal facilities. It was contemplated that this District could resort to local disposal until other areas might desire to join in the construction of a more comprehensive system. To the contrary, however, other areas in the Metropolitan Area of Los Angeles County took action almost immediately, with the result that six districts had been formed by July, 1923, and since that time three additional districts have been organized.

There are now (1926) nine County Sanitation Districts in Los Angeles County, covering approximately 432 sq. miles and including 35 incorporated cities, 35 unincorporated communities, and a rather large rural area, with a total population of about 521 400, as shown in Table 1.

* Presented at the meeting of the Sanitary Engineering Division, Seattle, Wash., July 15, 1926.

† Chf. Engr., Los Angeles County Sanitation Dists., Los Angeles, Calif.

TABLE 1.—Sanitation Districts in Los Angeles County, California.

District.	Area, in square miles.	Present (1926) population.	Incorporated cities included within districts.
South Bay Cities....	11.89	20 000	Hermosa Beach, Redondo Beach and Manhattan Beach.
District No. 1.....	38.4	99 000	Huntington Park, Maywood, South Gate, Lynwood, Compton, parts of Vernon, Long Beach, and Los Angeles.
District No. 2.....	59.8	64 000	Montebello, and a part of Los Angeles.
District No. 3.....	51.7	121 000	Long Beach and Signal Hill.
District No. 4.....	2.2	12 000	Part of Los Angeles.
District No. 5.....	72.3	55 000	Inglewood, Hawthorne, Torrance, and a part of Los Angeles.
District No. 6.....	74.26	27 400	Whittier, and a part of Long Beach.
District No. 7.....	90	120 000	San Marino, South Pasadena, Alhambra, San Gabriel, Monterey Park, Sierra Madre, Monrovia, Arcadia, El Monte, Azusa, Glendora, Covina, and West Covina.
District No. 8.....	31.8	3 000	A part of Long Beach.

It was possible, therefore, to disregard any temporary expedient and to work for a final solution of the problem.

There is a well-defined drainage divide along the southern and eastern boundaries of Los Angeles. All the territory north and west of this divide drains naturally into the Los Angeles City Sewerage System which has already been constructed, and that south and east of the divide drains to the south, and with this the Los Angeles County Sanitation District plan is particularly concerned.

The Los Angeles City Sewerage System discharges through the recently constructed North Outfall Sewer. The South Bay Cities Sanitation District and County Sanitation District No. 4 lie within the area which drains to this system, and contracts have been made with the City of Los Angeles whereby the sewage from the two Districts will be discharged into the City System and disposed of through the North Outfall Sewer. Both these Districts have voted bonds to provide the necessary funds. Construction work in the South Bay Cities Sanitation District and County Sanitation District No. 4 is completed. County Sanitation Districts Nos. 1, 2, and 5 voted $9 120 000 in bonds in February, 1925, for the construction of the Los Angeles County Sanitation Districts Metropolitan Sewerage System.

In the plan of the Metropolitan Sewerage System there were five steps of procedure:

First.—The determination of a satisfactory plan for sewage disposal on which to base an estimate prior to a bond election.

Second.—The conduct of a bond election in each Sanitation District.

Third.—If the bond election is successful, to adapt the preliminary plan to one modified by conditions subsequent to the bond issue.

Fourth.—The construction of the project.

Fifth.—Its operation and maintenance.

County Sanitation Districts Nos. 1, 2, and 5, at present (1926), are in the fourth stage. Districts Nos. 3, 6, 7, and 8, directly concerned in the joint undertaking, are prepared with a plan and are in a position to call elections to

determine whether they will provide the necessary funds. Fig. 1 gives the outlines, physical characteristics, and plan of the Los Angeles County Sanitation Districts as organized.

In this paper, the writer will discuss the problems in bringing the formation and plan of the County Sanitation Districts to its present stage of completion, with particular reference to the engineering organization in determining a satisfactory means for sewage disposal prior to a bond election, and to the activities of the engineering organization in conducting the bond elections.

FIG. 1.—GENERAL MAP OF METROPOLITAN SEWERAGE SYSTEM IN LOS ANGELES COUNTY SANITATION DISTRICTS.

At the time the comprehensive sanitary sewerage system was planned for Los Angeles County, the North Outfall Sewer System of the City of Los Angeles, previously mentioned, was under construction. The North Outfall drained a well-defined area so that the problem was confined to an area lying south and east of Los Angeles and draining normally south to the ocean.

For such an area the natural process of accumulation would be through lines running in a general north and south direction accumulating sewage at, or near, the southerly ends of any districts formed. The final design for

the Sanitation Districts finds trunk sewers extending north and south through the Districts, converging with other trunk lines to the south and concentrating at the southerly boundaries of the several districts.

The Districts have steep slopes in the northerly extremities where the sewage flows are light, and relatively flat slopes in the southerly reaches where sufficient sewage will be concentrated to assure good velocities on relatively flat grades.

The design for a system for central accumulation was, therefore, comparatively easy, the principal problem being the means of disposal. The choice was limited to one of two means, namely, that of disposal by refined treatment, such as the activated sludge process; or by disposal in the ocean, sufficiently offshore to avoid nuisance.

In a district where water is scarce, as in Southern California, serious consideration must be given to any means of disposal that will conserve the water content of the sewage. The saving of the water in the sewage was, in fact, the outstanding argument in favor of local treatment. As against the seemingly only outstanding virtue of water conservation there existed the following arguments against local disposal:

1.—In the past few years land values in Southern California have increased to such an extent in Los Angeles County that there is little, if any, area available for a local disposal plant so situated as not to depreciate property values in its vicinity. Numerous cities included in the Sanitation Districts have attempted local disposal, and, in every instance, have been unable to obtain property within a reasonable distance.

2.—The cost of producing a relatively pure effluent from an activated sludge plant, which might be used for irrigation water, is too great. With the probability of an adequate water supply from the Colorado River the use of sewage effluent as irrigation water during the next twenty to thirty years becomes of still more doubtful value. Even if a water supply produced from an activated sludge plant were to be used during the irrigation season the problem of wasting the effluent during certain seasons still remains. Unfortunately, the maximum flow in the sanitary sewers in Los Angeles County occurs when there is the least use for irrigation water. It was considered out of the question to attempt to develop any other use of the water for the area considered.

3.—The suggestion of local disposal raised such a storm of protest that it was evident that it would be practically impossible to secure funds for disposal by local treatment.

4.—The activated sludge process cannot be considered as a permanent means of disposal. It is undergoing many changes in the method of application of air to sewage and the treatment and disposal of the sludge. Although many theories have been advanced for its solution, the method of sludge disposal still remains unsolved and, at best, presents a problem involving a tremendous expense in operation and construction.

5.—It was early determined that the cost of an activated sludge treatment plant was approximately the same as that of a joint outfall sewer to the ocean, if a site could be selected where such disposal would not create a nuisance.

As opposed to the activated sludge process, the Sanitation Districts had recourse to a plan for disposal in the ocean, provided a suitable point of disposal could be determined.

Economy of construction and of operation and maintenance, permanency, established practice and custom, and deference to public opinion, all indicated that a jointly constructed outfall to the ocean would be the most adaptable solution.

The foregoing outlines briefly the problem presented to the County Sanitation Districts prior to bond election. The plan, as finally prepared, proposed a jointly constructed outfall to the ocean, and, based on this plan, the three Districts then concerned successfully carried bond elections by large majorities.

One of the most difficult problems was the control and regulation of a campaign prior to bond elections in the Districts. It was recognized that in a community with as many cities and communities involved, misinformation might spread rapidly, and that it would be much more difficult to correct a misapprehension than to register the correct information in the first place. For this reason it was decided that at every public meeting held in the interest of bond elections a representative from the Chief Engineer's office should attend to present facts. The Chief Engineer or his Principal Assistant, therefore, attended every public meeting where sewer bonds or sewage disposal was under discussion. The results were very gratifying. In each of the three Districts where bond elections were attempted under the plan as first proposed, the issues carried by overwhelming majorities.

There is only one other feature in the preparation of the plan for sewage disposal of the County Sanitation Districts that is of especial interest, namely, that of determining a future population on which to base the capacity life of the sewer system to be constructed. There is no well-established criterion for indicating a future population for districts in Los Angeles County. Few, if any, communities have ever made such forward strides in population as this area, and, therefore, predicted populations for Los Angeles County appear exceedingly optimistic if compared with past population increases for most counties of similar size in the United States.

In predicting future population, it was recognized that the population in certain areas would increase much faster than in others, and that no method of proportioning the increase directly over the entire district would be successful. The growth of each community, therefore, was studied separately, its future population predicted from year to year, and the future population curve of the district as a whole determined as a summation of the predictions for individual communities. Based on such a method the curves of growth for the districts are believed to be reasonably correct.

Prior to the design of the trunks sewers, a population density and concentration map was prepared, which served as a guide in predicting the quantity of sewage to be cared for at the expiration of a definite period of years. It was necessary to outline areas that would probably become industrial centers. It is impossible to predict the location and type of future industries, but

presuming a fair average of manufactured products, the quantity of waste from industrial areas has been determined with some degree of accuracy. No attempt was made to lump industrial wastes, but the total quantity to be cared for is a summation of the quantities resulting from predicted development of industries, based on predicted population growth.

In a project of this size, proposing to discharge a relatively large volume of sewage into the ocean, it is inevitable that the property owners near the outfall should feel uneasy regarding the outcome. For this reason the State Board of Health has deferred final action on a permit for the location of the ocean end of the outfall until a detailed investigation of the entire plan can be made. In the meantime, construction work is in progress on the interior trunks of the several Districts.

Paper No. 1679

THE LAKE WASHINGTON SHIP CANAL, WASHINGTON*

By W. J. Barden† and A. W. Sargent,‡ Members, Am. Soc. C. E.

With Discussion by Messrs. Ernest B. Hussey, Charles Evan Fowler, Joseph M. Clapp, L. C. Sabin, and W. J. Barden and A. W. Sargent.

Synopsis

The Lake Washington Ship Canal, lying wholly within the limits of the City of Seattle, connects Puget Sound with a large fresh-water harbor comprising Salmon Bay, Lakes Union and Washington, and connecting waters, with a total area of about 25 000 acres. A dam and two locks, one large and one small, near the canal entrance hold the waters of the lakes 25 ft. above extreme low water of the Sound. This paper gives a general description of the locality, the original condition, a brief history of the improvement, and a description of the locks, dam, and appurtenances, and of the construction methods. The traffic developed is given, together with a summary of the beneficial results of the work. Under the headings, "Maintenance and Operation" and "Salinity", are given some of the results of the ten years' experience of operation and observation, with suggestions as to changes that might be desirable in future work of a similar character.

General Description

Seattle, the largest city of the State of Washington, is situated on Elliott Bay, an arm of Puget Sound, 47 miles south of the Strait of Juan de Fuca and 147 miles from the Pacific Ocean. Elliott Bay, 2 miles wide and 4 miles long, is protected from all severe storms and is accessible to the largest vessels afloat at all times. Deep water extends close to the shore except at Smith's Cove at the northern end and at the tide flats of the Duwamish River at the southern end. In these flats two waterways, each 750 ft. wide, 34 ft. deep, and 1 mile or more in length, have been excavated and the lower part

* Presented at the meeting of the Waterways Division, Seattle, Wash., July 15, 1926.

‡ Civ. Engr., U. S. Engr. Office, Govt. Locks, Seattle, Wash.

of the Duwamish has also been straightened and dredged to form a waterway suitable for commercial purposes with authorized depths of 15 to 30 ft.

To this commodious salt-water harbor the construction of the Lake Washington Ship Canal has added a fresh-water harbor of approximately 25 000 acres, comprising Salmon Bay, Lake Union, and Lake Washington, and connecting waters. (Fig. 1.) This improvement lies entirely within the city and extends from Puget Sound through Shilshole Bay, Salmon Bay, Lake Union, Portage Bay, and Union Bay, to deep water in Lake Washington. The distance by channel from deep water in Puget Sound to deep water in Lake Washington is approximately 8 miles. The tidal reach extends to the locks, approximately 1¼ miles. The extreme tidal range is 19 ft. The range between mean lower low water and mean higher high water is 11.3 ft. and between mean lower low water and extreme low water, 4 ft.

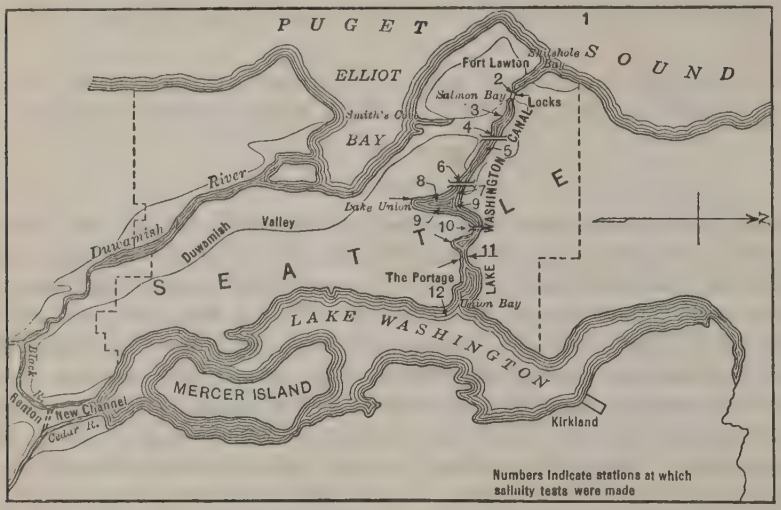

FIG. 1.—OUTLINE OF SEATTLE HARBOR AND LAKE WASHINGTON SHIP CANAL.

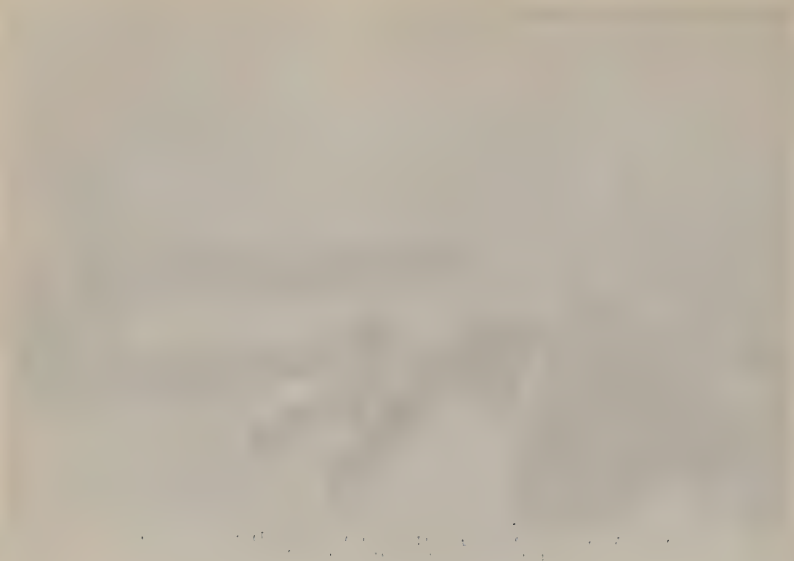
The double lock and fixed dam with movable crest are at the Narrows, at the westerly end of Salmon Bay, and hold the waters of Salmon Bay and the lakes 25 ft. above extreme low water in Puget Sound, with an allowable variation of 1 ft. above and 1 ft. below this plane.

The dredged channel below the rocks is 300 ft. wide at the bottom and 34 ft. deep at mean lower low water, with a passing basin and log basin in the turn below the Great Northern Railway Bridge which is just below the locks and dam. (See Figs. 2 and 3.) From the locks to Lake Union the channel is 100 ft. wide on the bottom and 36 ft. deep. From the easterly end of Lake Union to deep water in Lake Washington the channel is 75 ft. wide at the bottom and 25 ft. deep. These dimensions will be increased to meet the needs of commerce. The main body of Lake Union required no dredging.

The large lock is 80 ft. wide and will accommodate vessels with a maximum length of 760 ft. and a draft of 36 ft. The small lock is 150 ft. long and 30 ft. wide, with a depth of 16 ft. over the sill.

FIG. 2.—LAKE WASHINGTON SHIP CANAL: LOCK AND DAM, LOOKING EAST FROM GREAT NORTHERN RAILWAY BRIDGE.

FIG. 3.—VIEW OF UPPER END OF LARGE LOCK, LAKE WASHINGTON SHIP CANAL, SHOWING RECESSES IN WHICH FOUNDATIONS FOR EMERGENCY DAM WERE CONSTRUCTED.



Original Condition

Originally, there was no connection between Lake Union and Lake Washington, and Lake Union had no navigable connection with Salmon Bay. Lake Washington, through the Black and Duwamish Rivers, had a navigable connection with Puget Sound with sufficient capacity for the transportation of logs.

Lake Union, the smaller of the two lakes, situated in the heart of Seattle, has an area of nearly 1 000 acres, of which 500 acres has a depth exceeding 40 ft. The general elevation of Lake Union was originally 25.5 ft. above extreme low tide in Puget Sound. Between Lake Union and Puget Sound is a high ridge, cut by a low valley at the extreme western end of the lake. Through this valley the natural drainage of the lake found its outlet to Salmon Bay.

Salmon Bay extends in a westerly direction to Shilshole Bay, an arm of Puget Sound. Salmon Bay and Shilshole Bay were originally navigable at high tide, but both were practically dry at extreme low tide. At mean lower low water a narrow, crooked channel, approximately 2½ miles long and 3 ft. deep, extended from Puget Sound to near the head of Salmon Bay.

South of this valley and of Salmon Bay are two high hills between which is a low narrow valley connecting the head of Salmon Bay with Smith's Cove, an indentation in the north end of Elliott Bay.

Lake Washington forms the easterly boundary of the City of Seattle. It is 19 miles long, with an average width of 2 miles. The elevation of the lake originally fluctuated between 33 and 37 ft. above extreme low tide in Puget Sound. It is separated from Lake Union and from Elliott Bay by a high ridge, extending along its western side. In this ridge is a low depression at a point where the shores of Lake Union and Lake Washington approach each other to within 2 000 ft. At this point, known as "The Portage", a narrow channel had been cut by private enterprise about 1888, for the passage of logs. The natural outlet of the lake was at the southern end through Black and Duwamish Rivers to the waters of Puget Sound at the southern end of Elliott Bay. Cedar River, which entered the Black River about ½ mile below the outlet of Lake Washington, is subject to annual floods, due to the melting of snow in the head-waters of the river in the Cascade Mountains. During the height of these floods the direction of the current in Black River between Lake Washington and the mouth of Cedar River was reversed, and a large quantity of water emptied into the lake, which acted as a storage reservoir preventing excessive flooding of the Duwamish Valley.

When the canal was constructed, Salmon Bay was raised and Lake Washington lowered to the level of Lake Union. Cedar River was diverted from the Black River into Lake Washington and the outlet through Black and Duwamish Rivers no longer exists.

History

The idea of a canal to connect Puget Sound with Lake Union and Lake Washington is practically as old as the City of Seattle, and the subject

received Federal recognition as early as December 9, 1867, in a report of a Board of Engineers for the Pacific Coast, which recommended the lakes as a site for a Naval Station on Puget Sound. From then until 1890 it was frequently referred to in official reports, but more from a naval than from a commercial point of view.

The River and Harbor Act of 1890 authorized the appointment of a board of three officers "to select and survey the most feasible location and estimate the expense of construction of a ship canal * * *". The Board's report, dated December 15, 1891, considered five possible routes. The present general route, being less expensive and having a better alignment, was considered preferable.

Several later investigations and reports were made, but the existing project, adopted by the River and Harbor Act of June 25, 1910, is based on the report of December 2, 1907, of the late H. M. Chittenden, M. Am. Soc. C. E. The terms of local co-operation required that, in addition to furnishing all rights of way, the County of King, or other local agency, should do the excavation in the waterway above the lock, and hold the United States free from any claim for damages on account of lowering the level of Lake Washington, raising the level of Salmon Bay, or any other alterations of the levels of any other part of the waterway.

In September, 1911, construction work was actually begun under the direction of the late Col. James B. Cavanaugh, Corps of Engineers, U. S. A., the District Engineer, who was in charge of the entire project, both as to Federal and County expenditures, until the completion of the main part of the work.

The total amount expended by the Federal Government has been approximately $3 500 000; King County has expended about $750 000, and the State of Washington about $250 000, in addition to the cost for right of way.

The cost of maintenance and operation, which is borne by the permanent indefinite appropriation for operation and care of canals, is about $80 000 per year.

Spillway Dam

The spillway dam (Fig. 4), extends from the small lock to the south shore of Salmon Bay. It is 240 ft. long, with six spillway openings, each 32 ft. long. A fish ladder for the passage of salmon to the spawning grounds above the locks, and an opening for discharging salt water from the upper pool, are provided through the dam. There are two walks extending the entire length of the dam, one at the elevation of the lock-wall, for pedestrians, and one at a higher elevation, from which the gates are raised and lowered. These are carried on arches spanning the piers which separate the spillway openings.

The fixed part of the dam is of ogee section with a vertical up-stream face and a toe 4 ft. long extending up stream. The total width of the base is 46 ft. A concrete apron, with its top 10 ft. below extreme low tide, extends 114 ft. below the dam. The total height of the dam, not including cut-off walls, from the foundation to the spillway crest, is 37.75 ft. The latter is

17.75 ft. above extreme low tide. The six spillway openings are closed by Taintor gates. The gates are arranged to rotate around the trunnions until they rest on the lower footwalk of the dam, when necessary for painting or repairs. The gates are raised and lowered by two chains which are attached when desired to cross-heads on an electrically driven machine which can be moved from gate to gate on the upper walk of the dam. The cross-heads are moved back and forth by means of revolving screws, and a gate can be raised wide open in one operation.

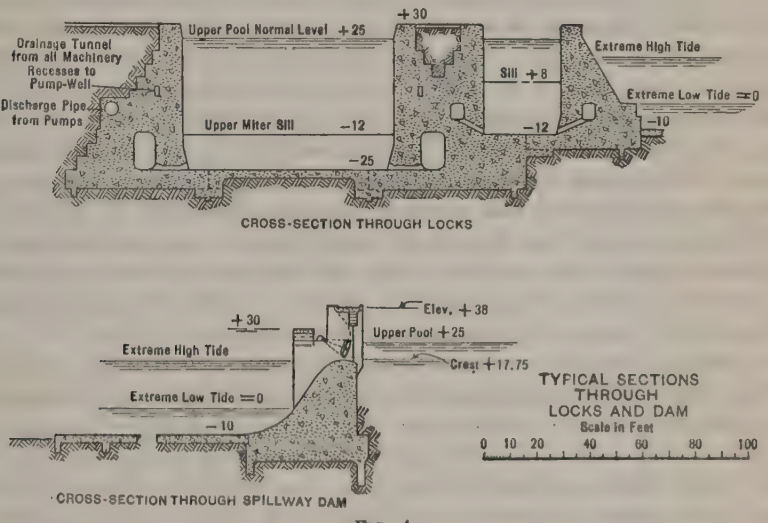


FIG. 4.

The capacity of each spillway opening is 2 350 sec-ft. at normal upper pool level, and with all the gates open no trouble with scour has been experienced beyond the lower edge of the apron. The dam was constructed in sections, 36 ft. long, each section consisting of three horizontal layers well keyed together. After two horizontal layers had been placed the piers were constructed, then the spillway sections, after which the footwalks were built.

LOCKS

Table 1 gives the principal features of the locks.

TABLE 1.—PRINCIPAL FEATURES OF THE LOCKS, LAKE WASHINGTON SHIP CANAL.

Item.	Large lock.	Small lock.
Clear width of chamber, in feet	80	30
Maximum available length, in feet	760	123
Maximum lift, in feet	26	26
Depth on upper miter-sill at low water in upper pool, in feet	36	16
Depth on intermediate miter-sill at mean lower low water, in feet	29	....
Depth on lower miter-sill at mean lower low water, in feet	29	16

The large lock is 825 ft. long and is divided into two chambers by an intermediate gate, the lower and the upper chambers being 375 ft. and 450 ft. long, respectively. The small lock, alongside and south of the large lock, is designed to accommodate with the minimum of delay the large number of launches, tugboats, and small craft continually passing in and out of the canal.

The locks are constructed on a bed of hard impervious clay. At the upper end this clay bed slopes off rapidly, but below the locks the hard formation extends almost to Puget Sound. The double-track bascule railway bridge of the Great Northern Railroad Company which crosses the channel about 700 ft. below the locks, is supported on concrete piers constructed without piles directly on the clay. Tests indicated that the clay would safely carry a load of 5 tons per sq. ft. The lock-walls (Fig. 4), approximately 62 ft. high, are designed with a broad base, with a toe extending 10 ft. beyond the face, and a toe-block 10 ft. wide to distribute the pressure on the clay foundation. In designing the wall sections the resultant pressure was kept well within the middle third, and where the wall was back-filled to the top with earth it was assumed that there would be hydrostatic pressure along the back, for the full height of the wall, and under the heel, one-half the pressure due to the total head, decreasing to zero at the toe. Under this assumption the pressure at the center of the toe-block is about 4 tons per sq. ft.

In general, the walls were constructed in sections 30 ft. long and in 5-ft. courses, with a view to applying the weight to the foundation uniformly; the top layers in adjoining sections were kept at approximately the same level. Key-blocks were cast on top of each layer, projecting upward into the next layer. Keys were also built into the ends of each section extending the full height of the wall. Concrete cut-off walls, 4 ft. deep, or more, and 18 in. thick, were built under the heels of the walls, under the miter-sills, and under the entire length of the dam to the south bank. Below the floor level, lead stop-waters were placed between all wall sections, down the cut-off walls, between floor sections, and between the toe of the wall and the floor; also, between the sections of the dam. At the upper end of the large lock beyond the guard-gate, where the foundations were not as satisfactory as over the remainder of the area, cellular walls were built.

The floor of the large lock, which is only 3 ft. thick, was designed merely as a pavement to prevent scour in the lock. No relief valves were provided against hydrostatic pressure, reliance being placed on the cut-off walls to prevent excessive leakage. No difficulty has been experienced from this source when the lock is unwatered; in fact, holes drilled through the floor a few years ago to ascertain if there was any pressure, showed that, although a small quantity of water had accumulated under the floor, no pressure had developed due to the 50-ft. head along the outside of the lock, showing that the precautions taken as to cut-off walls and lead stop-waters had been successful.

Gates.—The gates of both locks are of the mitering type. In the large lock there are five gates, the upper and lower guard-gates, and the upper, intermediate, and lower service gates.

The lower guard-gate, which is used only when the lock is unwatered for purposes of repair and inspection, is designed to withstand a head of 43 ft. It is 46 ft. high and each leaf weighs 207 tons. The lower service and intermediate gates are each 56 ft. high and designed to withstand a head of 26 ft. Each leaf weighs 237 tons. The upper service and guard-gates are smaller, being only 43 ft. high, but are subjected to a head of 38 ft. when the lock is unwatered. Each leaf weighs 180 tons.

All gates of the large lock are constructed with horizontal girders spaced equi-distant on 3½-ft. centers, and five transverse vertical frames built in between the girders extending from the bottom to the top of the leaf. The skin-plates extend the full height of both up and down-stream sides of the gate. The lower part of the gate forms an air chamber to lighten the weight on the pintle and anchors, while water is allowed to run freely in and out of the upper part, through openings in the up-stream skin just above the air chamber and through the girders and vertical frames.

Provision is made for blowing out by compressed air any water that may enter the air chamber. A 2½-in. pipe extends down to and is attached to the top of the chamber. Through this pipe a 1¼-in. pipe extends almost to the bottom of the gate, the air entering through the large pipe and the water being forced out through the smaller one.

Access is provided to all parts of the interior of the gates through openings in the girders and vertical frames and through the manhole which extends from the top of the gate, through the water chamber, into the air chamber.

The wall reaction bearing consists of a structural steel, built-up member embedded in the concrete, to which are bolted steel castings which have a slightly concave surface, with which the convex reaction casting on the gate comes in contact when closed. The miter edge of the gate has adjustable steel bearing pieces extending the full height, behind which Babbitt metal was poured to bring it into proper alignment.

The forged steel pintle is supported on a steel casting embedded in the concrete. The top surface is hemi-spherical in shape, and the bushings on which the gates rotate are of vanadium steel held in place in a steel casting on the heel of the gate. The pintle is free to move on its foundation whenever the gate is forced out by obstructions on the sill.

The gate anchors are heavy steel trusses embedded in the concrete and connected with the gate by forged steel eye-bars and pins. The eye-bars are bronze-bushed and are connected by sleeve nuts with a square thread, 1-in. pitch in the one half and ¾-in. pitch in the other half, both right-hand threads, so that when the coarse thread is being taken up the finer thread is being unscrewed, and *vice versa*.

At the lower edge of the down-stream side of the gate greenheart timbers were fastened into a structural steel channel. When the gate is closed, the timber comes in contact with a similar timber fastened in a steel chair on the miter-sill. After four years of service it was found that the timbers on the lower guard-gate of the large lock had been honeycombed by marine borers and that it would be necessary to replace them with other material. Iron

bark was tried, but in two years it was found that this also had been destroyed by marine borers and that the timbers attached to the miter-sill were partly destroyed. Considerable study was then given to determine the best method of overcoming the difficulty. It was thought impracticable to replace the timbers on the miter-sill by diver. A coffer-dam could only be constructed at considerable cost and would also necessitate the closing of the lock for a considerable period. The plan finally adopted was to remove the timber on the sill with the assistance of the diver. The gate was then removed and docked, and steel castings were made and attached to it. These castings (Fig. 5) extend out so as to come in approximate contact with a steel chair which formerly held the timbers on the miter-sill, and take the pressure in case of failure of the leaves to miter properly. A lip extending downward from the castings carries a heavy piece of rubber belting which forms the water-seal between the gate and the concrete sill. This arrangement proved to be satisfactory and a similar device has been placed on the lower guard-gate of the small lock. No such trouble has been experienced with any of the other gates, probably because the service gates are regularly used and the water at the upper guard-gates is mainly fresh.

The gates of the small lock (four in number, two service and two guard) are composed of horizontal I-beams with skin-plates on one side only. Mitering devices, consisting of a jaw at the top of one leaf, which engages a post on the other leaf as they swing together, are provided on all gates.

Culverts and Valves.—The culverts in both locks are in the side walls, with laterals extending into the chambers at the floor level (Fig. 4). The ends of the culverts are between the service gates and the guard-gates, and all gates and valves are accessible when the lock is unwatered, except the exterior surfaces of the guard-gates.

The culverts of the large lock are 8½ ft. wide and 14 ft. high, with corners rounded to a radius of 3.5 ft. The intake end is increased in size to 16 ft. in width and 14 ft. in height, and the discharge ends are 10 ft. wide and 16 ft. high. Both ends turn at an angle of 90° horizontally into the lock. The bottoms of the culverts are at the floor level except at the discharge end where they are raised 5 ft. with a view to overcoming difficulties attendant on the difference in density of the water above and below the gates. The laterals are 4 ft. wide and 2 ft. high. There are twenty-four entering the upper chamber and twenty-eight for the lower chamber.

The valves of the large lock are of the Stoney gate type, raised and lowered by means of two vertical screws revolving in fixed nuts in the cross-head which is attached to the valve stem. The valve stem passes through a stuffing-box in a water-tight bulkhead which closes the bottom of the machinery recess. The latter is about 22 ft. below high-water level in the lock. The valves are equipped with roller trains which are raised and lowered with the valves, but at half speed, by pulleys over which a chain is taken. One end of the chain is fastened to the cross-head on the valve stem and the other passes through a stuffing-box in the water-tight bulkhead over the valve. The valves of the small lock are of the cylindrical type.

Signal lights installed in the controllers in the operating houses indicate whether the valves are in the open or closed position. Limit switches are provided for controlling the travel of the valves.

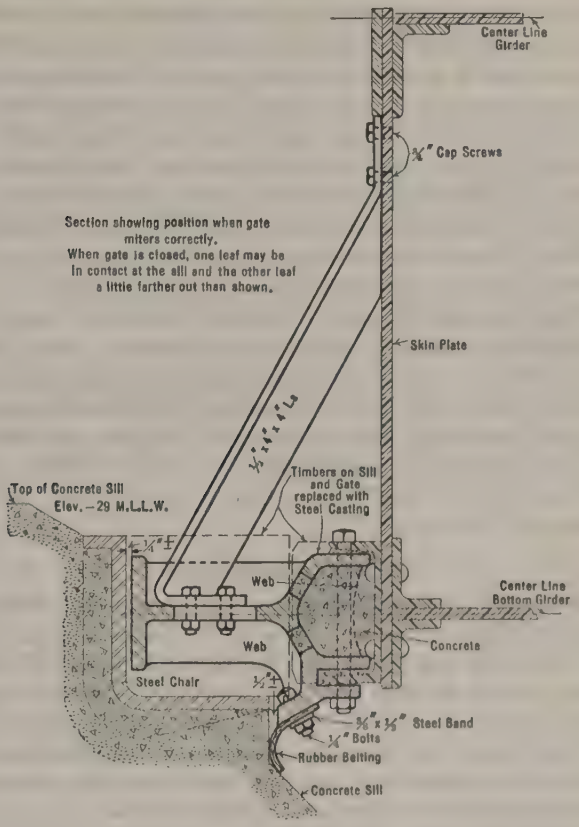

FIG. 5.—LAKE WASHINGTON SHIP CANAL, WATER SEAL, LOWER GUARD GATE—LARGE LOCK.

OPERATING MACHINERY

The gates are operated by electrically driven winding drums acting through cables attached to the gates near the outer end of each leaf. The cables pass from the drum over rollers and round sheaves, through passages in the lock-walls to the two sides of each gate leaf, the operation of each leaf being entirely independent of the other. The opening cable is 1 in. in diameter and the closing cable ⅞-in., 6/19 plow steel rope. The drums are spirally grooved, driven in the large lock by 20-h.p. motors through worm and spur gears. The drums are connected with the spur gears through adjustable slip friction clutches arranged so that in case of an excess load the clutch will slip. The radii of the drum spirals are proportioned so that there will be no excess slack in the cable as the gate swings through its arc of revolution. The ends of the cable are attached to the drums through adjustable screw fastenings, in order that the slack due to the stretch of the cables can be taken up.

Gate latches are provided for each leaf of the service gates of the large lock to hold them securely in the open position. A movable latch bolted to the lock-wall engages a catch on the gate leaf. The latch is operated by a flexible wire rope attached to a nut traveling on a screw which is attached to the motor shaft. A projection on the nut is provided for reversing a double pole switch at each end of the travel. By closing a switch in the controller in the operating house, current is sent through the latch motor and the catch is released. At the end of the travel the double pole switch is reversed, thus reversing the circuit through the latch motor, and closing the circuit through the solenoid-operated stop in the controller. The motor is provided with a solenoid brake which stops the motor instantly when the circuit is broken. Signal lights are installed in the controller in the operating house to indicate whether the gate latch is open or closed.

For quick replacement in case of serious damage to gates or operating machinery interchangeability of parts was provided as far as practicable in the design. As already stated, the upper guard-gate and upper service gate are of the same size and the intermediate gate is the same size as the lower service gate. All the Stoney gate-valves are of the same size and all parts of gate and valve machines are interchangeable. The machines at the intermediate gate provide a complete set of spare parts which can be used at either the upper or lower gates.

Construction Methods

The construction of the locks and dam was carried out within the protection of two independent coffer-dams (Fig. 6). The total length of the coffer-dam wall for the locks was 1 320 ft. The two ends were tied into the bank along the north side of the site, leaving a temporary channel along the coffer-dam on the south side for boats entering and leaving Salmon Bay. The coffer-dam within which the dam was constructed extended from the wall of the small lock to the south shore and was built after the construction of the locks was completed and the coffer-dam therefor removed, the gates of the large lock being left open for navigation.

The coffer-dam walls, which were 20 ft. apart, were constructed of round piles, wales, and Wakefield sheet-piling, and were tied together by iron rods. The sheet-piles were driven a short distance into the underlying hard material, not quite to refusal. It was found that if they were driven too hard it was difficult to hold them up close together, and they had a tendency to move off line away from the wales. A better job was obtained by not driving them to refusal. The material for filling and banking was supplied from excavation in the lock-pit. This material was excavated by dipper dredges before the coffer-dam was completed, and the foundation was cleaned to grade by pick and shovel. The surplus material was removed by crane and skip to the bank just inside the coffer-dam. Although at high tide the deepest part of the excavation was 58 ft. below water level, there was practically no seepage through the coffer-dam or through the clay foundation into the lock-pit, and two or three 2-in. centrifugal pumps, at different points within the enclosure, were more than ample to handle all seepage and rain water.

All concrete work in the locks and dam, the construction of permanent buildings, and the work on the grounds were done by hired labor and Government plant. Separate contracts were let for the excavation and coffer-dam, gates, machinery, permanent pumping plant, and the removal of the coffer-dams, as well as a number of smaller contracts for minor parts of the work.

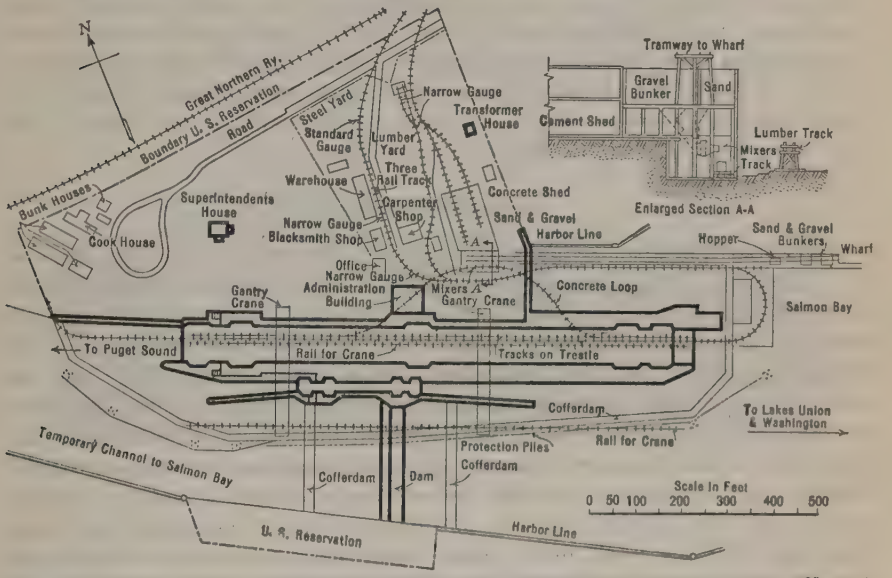

FIG. 6.—GENERAL LAYOUT, WASHINGTON SHIP CANAL, PERMANENT LOCKS AND DAM (HEAVY) AND CONSTRUCTION PLANT (LIGHT).

All concrete in the locks was handled by two gantry cantilever cranes which were constructed across the lock-pit, one rail being along the axis of the lock just above the floor level and the other partly on top of the coffer-dam and partly on pile trestle. Each crane was equipped with two 30-h. p. electric hoists which operated two trolleys, each capable of lifting 5 tons. The concrete was delivered from the mixing plant, consisting of three 1½-cu. yd. mixers, into bottom dump buckets, which were carried on cars by steam locomotive to the cranes, where they were picked up, two at a time. Six buckets were placed on the cars in each train so that two could be filled simultaneously at the mixers, and two picked up at the same time by the crane. As much as 1 140 cu. yd. was placed in an 8-hour day, and the highest monthly average was 24 000 cu. yd. Approximately, 150 000 cu. yd. was placed in 9 months (from May, 1913, to January, 1914). The bulk of the concrete in the locks was placed at a cost of $4.00 per cu. yd., and the average cost of all concrete in the locks, dam, and permanent buildings was approximately $5.50 per cu. yd.

The forms were mainly of the cantilever type, fastened to the wall with ⅞-in. bolts, 2 ft. long, with threads on both ends. The outer end was made square so that it could be easily turned by a wrench while the concrete was setting. On the inner end a nut and a washer 3 in. square were used, which

were left in the concrete. The bolts were removed when the forms were taken off and were used again repeatedly. Each form was used five or six times and then knocked down, the lumber being utilized for building rough forms.

After the completion of the locks one of the gantry cranes was lifted up and supported on top of the lock-wall, and on a tower near the dam. With the crane in this position concrete was carried across the locks in bottom dump buckets and deposited in a hopper, from which it was drawn out into chutes and deposited in the dam. In this position the crane gave sufficient clearance so that all traffic in and out of Salmon Bay could pass beneath it during the construction of the dam. All the concreting in the dam was completed in less than three months after the form work was commenced.

Emergency Dams

Subsequent to the original construction, emergency dams were provided for both locks. For the large lock studies of two types were made, namely, the balanced cantilever turn-table bridge type, which is swung across the lock with the necessary machinery installed on the bridge and the girders and wickets suspended from the bridge ready to be lowered into place; and the adopted type, which is almost the same, except that all the parts are stored on the lock-wall and are placed in position in the lock by a stiff-leg derrick. This type is less expensive than the first mentioned and was adopted principally on that account. It takes longer to place, about 4 hours as against 1 hour, but this feature was not considered of great importance as it was estimated that the levels of the lakes would not be lowered to a sufficient degree during the time required for placing it to cause serious damage.

Figs. 7 and 8 show the dam in storage position on the lock-wall and a down-stream view when in position. Fig. 9 shows a cross-sectional view. The dam consists of two removable bridges which span the lock when in use, six wicket girders which form the framework, twenty-four wickets which complete the closure, a stiff-leg derrick, and the necessary operating machinery for handling the various parts. Needles are also provided for closing the clearance between the vertical rows of wickets.

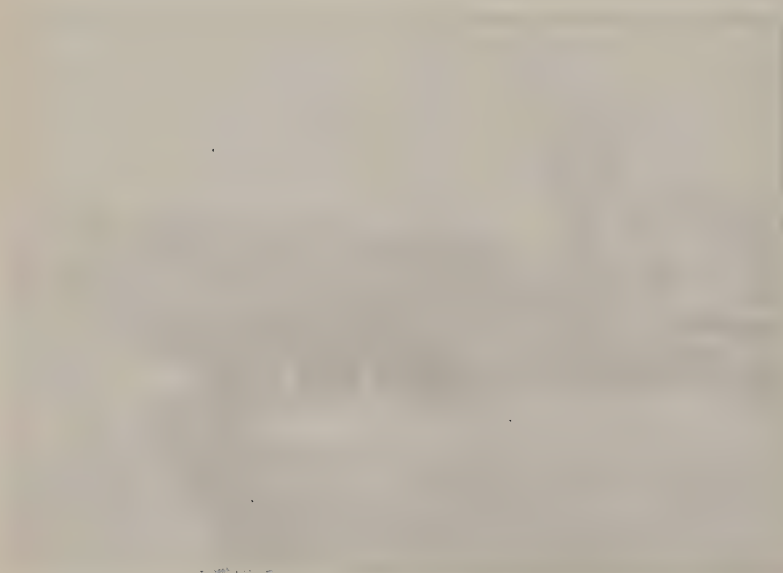
The wicket girder bridge consists of a horizontal truss which supports the upper edge of the dam and two vertical trusses which support the dead load. It is placed by the derrick in recesses provided in the lock-walls. Its weight is approximately 72 tons.

The operating bridge is placed about 35 ft. up stream from the girder bridge and carries the machinery for lowering the wicket girders against the sill in the lock floor which supports the lower edge of the dam. The machinery consists of a two-speed electric hoist with six drum units operated through a line shaft, each unit consisting of two drums which are geared to the line shaft and are engaged or disengaged by means of jaw clutches. Each drum unit operates the hoisting tackle which is provided for lowering a wicket girder.

The six wicket girders, the skeleton of the dam, are delivered one at a time by the derrick in a horizontal position. They are then lowered until the

FIG. 7.—LAKE WASHINGTON SHIP CANAL: EMERGENCY DAM IN STORAGE POSITION ON LOCK WALL.

FIG. 8.—VIEW OF PLACING NEXT TO LAST WICKET, LOOKING UP STREAM, EMERGENCY DAM, LAKE WASHINGTON SHIP CANAL.



upper end is hooked over pins provided on the up-stream face of the girder bridge, the hoisting tackle on the operating bridge is attached to the lower end and, after the derrick tackle has been disconnected, the girder is lowered to a bearing against the sill.

The wickets are twenty-four in number and consist of steel frame and buckle-plates. They are on roller-bearing wheels and are guided into place over a track on the up-stream flanges of the wicket girders by the derrick. They are placed across the channel in four horizontal rows, six wickets in each row. There is sufficient cable attached to each wicket to fasten the upper end over hooks on the girder bridge after it has been disconnected from the derrick hook, so that the wickets can be readily removed after use.

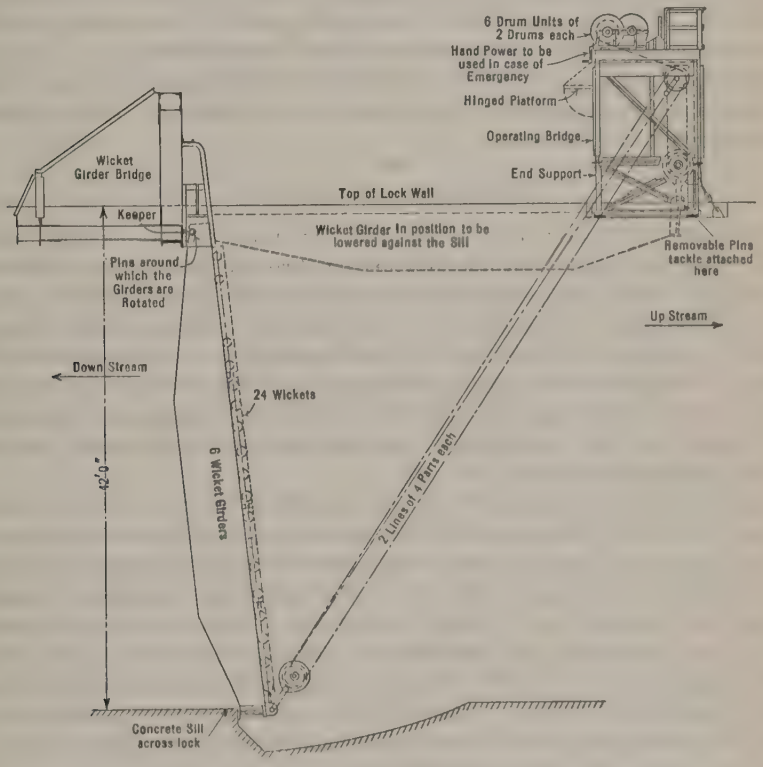


FIG. 9.—LAKE WASHINGTON SHIP CANAL EMERGENCY DAM: CROSS-SECTION OF DAM IN THE LOCK.

The capacity of the derrick is 75 tons at 60-ft. radius. The mast is 45 ft. high and the boom 102 ft. long. The main hoist tackle has twelve parts and is used only for handling the wicket girder bridge and the operating bridge. Farther out on the boom is an auxiliary tackle designed for the rapid handling of the wicket girders and the wickets. The wickets are hoisted on a single line at 125 ft. per min., and the girders are handled at half this speed by hooking the end of the line to the boom and hanging a snatch-block in the

bight. The boom tackle is designed for a load of 309 000 lb. and has seventeen parts. The maximum vertical uplift on the stiff legs is 300 000 lb.; the speed of the boom fall is 93.7 ft. per min.; and that of the main hoist and auxiliary hoist falls is 125 ft., per min. The speed of the swinger cable is 31 ft. per min.

The derrick is operated by an electric hoist with three drums, each drum being connected through worm gearing to its own 100-h.p. motor. The swinger hoist is of standard design operated by a 40-h.p. motor. The hoist on the operating bridge for lowering the wicket girders in the current is operated through a worm by a 40-h.p. motor. It has two speeds, 8 and 32 ft. per min., respectively. The slow speed is for raising the wicket girders in the current in case of an emergency, such as releasing an obstruction between the girder and the sill. The fast speed is for lowering the girder in the current or raising it in quiet water. The total approximate cost was $175 000.

The dam for the small lock consists of five rolling gates which are lowered in recesses in the lock-walls, one on top of the other, by a hand-operated stiff-leg derrick.

Maintenance and Operation

The locks are operated 24 hours daily, by three shifts working 8 hours each. Each shift consists of one lock master, two operators, and two linesmen for the large lock, one operator and two linesmen for the small lock, and one pier man stationed on the pier below the locks for mooring boats which are required to wait for the lock and for giving directions to the masters of the boats as to which lock to use. As all employees are allowed one day off in seven, additional men are required for relief work. Machinists, carpenters, and laborers are also employed for maintenance and repair work, the total regular force averaging about 45.

The operators are required to keep a record of the time of entering and leaving of all boats, and masters of boats are required to submit statements on forms provided, showing the net registered tonnage, amount and kind of cargo, number of passengers, etc., for use in compiling commercial statistics.

The time required for a lockage depends on the stage of the tide and the size of boat. Tugboats pass through the small lock in about 5 min. Barge traffic in the large lock requires 15 to 20 min., while large ships and log rafts require from 30 to 50 min. The entire cost of operation is borne by the Federal Government, there being no fees of any kind required for lockage.

As was to be expected, some difficulties have been experienced with the opening of the gates and in navigation through the locks due to the difference in density of the fresh water above and the salt water below. In theory, this difference would cause the flow through the culverts in filling or emptying the lock to cease when equal pressures were reached there, which would be before the level above the gate had fallen to that below, and there would remain a positive pressure against the lock-gates making it difficult to open them. In practice, this is so in different degrees dependent on the stage of the tide, the admixture of salt and fresh water, the somewhat different condi-

tions at the upper, intermediate, and lower service gates, and the methods of lockage.*

At the upper gate of the locks, which is generally used as such, and with either the intermediate or lower gate used as a lower gate, this difference in pressure is quite marked. The difference in head is usually 3 or 4 in., but sometimes it is as much as 6 in. There is some over-travel of the water through the culverts with temporary corresponding rise of the water in the lock, as explained subsequently, and advantage is taken of the resulting diminution of the pressure against the gates to open them before the condition of equilibrium has been reached. When the difference in head is more than 4 in., it is preferable in order to reduce the strain on the cables and operating machinery to freshen the water in the lock by lowering and refilling before the gate is opened.

When the lower chamber is used and the intermediate gate becomes the upper gate there is a marked over-travel of the water in the culverts before the filling ceases and at the same time the forebay is temporarily lowered so that the water in the lock rises slightly higher than the level above the gates which thus become subjected to a reverse head tending to open them. This condition lasts only momentarily, and equilibrium is soon reached, with the level of the water above the gates higher than that below, due to the difference in density. As an illustration the following example is given: With the upper pool at Elevation 25 ft. 7 in. and the tidal elevation at 8 ft., the lower gate was opened and time allowed for the water in the lock to reach full salinity. The intermediate gate was then closed, the upper chamber filled, the upper gate opened, and time allowed for the water to become quiet. The lower gate was then closed, the valves of the intermediate gate opened, and the lower chamber filled. The water in the forebay, that is, the upper lock chamber, was lowered somewhat when the valves were first opened and surged up and down for a few minutes. The lower chamber filled to Elevation 25 ft. 7 in. The miter broke and actually pushed the gate away from the sill until held by the cables. No attempt was made to open the gate and in less than a minute it moved back against the sill. The water in the lower chamber lowered quite rapidly 7 in. to Elevation 25 ft., while above the gate the water became quiet at Elevation 25 ft. 7 in., or the upper pool level. The pools then remained with this difference of elevation of 7 in. against which it was impracticable to open the gate. To do this it was necessary to lower the water in the chamber and re-fill. Under substantially similar conditions the difference in head after equilibrium has been established, when the upper gate is used, is about 5 in. The over-travel of the water and the surge in the pool elevations is also less, probably partly due to the shorter length of the column of water in motion through the culverts. Due to these more unfavorable conditions at the intermediate gate the lower chamber is seldom used, the smaller boats being always taken into the upper chamber when only part of the lock is required.

* Quite a complete mathematical discussion of this matter will be found on pp. 85–99 of the Annual Report of the Isthmian Canal Commission for 1911, together with measures proposed to obviate the anticipated difficulties that would arise therefrom.

Not much difficulty is experienced in the opening of the lower gate or of the intermediate gate when used as a lower gate. The miter frequently breaks, probably due to the over-travel of the water through the culverts and the momentary surge in elevation above and below the gate. After equilibrium is reached there is some difference in elevation and some head on the gate, but generally it can be opened easily. There does not appear to be much difference in the conditions at the two gates.

Immediately after opening the lower gate a strong surface current sets up, which lasts for several minutes, running out of the lock with the corresponding under-current running in. This is troublesome to the smaller vessels entering and leaving the lock, and they are often held in the lock for several minutes until the current subsides. Vessels with tows are also delayed several minutes when leaving the lock at the upper end due to the strong surface current flowing into the lock when the upper gate is opened and the salt water in the lock chamber flows up stream.

The locks are unwatered at least once each year for painting the service gates and for general repairs to machinery, valves, etc. The lower guard-gate of the large lock, which is in salt water, is removed and painted at least once every 4 years and the upper guard-gate once in about 6 or 7 years. This is accomplished with the assistance of the snagboat *Swinomish*. The openings for admitting water into the water chambers are closed at low tide and the water remaining in the chamber is pumped out; at the same time fresh water in sufficient quantities to preserve its equilibrium, is pumped into the bottom of the leaf. Then, at a little before high tide, when the resultant weight of the leaf is only a little greater than its buoyancy, the outer edge of the leaf is raised by the boat's tackle until there is no weight on the hinges. The hinge-pins are then removed, the leaf is lifted and towed out of the way of traffic, and the air chamber is unwatered by compressed air. The leaf, now floating on its straight side, which is the heavier, has heretofore been beached for cleaning and painting, but a small dry dock is now being constructed for this purpose. It is then towed back to the lock, and the air chamber is partly filled with water until the leaf stands almost upright. The boat then lifts it back on to the pintle and the anchors are attached. The operation of removing and replacing the hinge-pins must be done very quickly at the lower gate, as a slight fall in the tide will often change the buoyancy of the leaf so that the lift will be too great for the boat to handle safely. To provide for this emergency a pump is kept at hand for removing the water from the leaf as the tide recedes. The removal of the upper gate in water of constant elevation is a much simpler undertaking.

The guard-gates of the small lock are hoisted by an **A**-frame and tackle on to the lock-wall, where they are cleaned and painted and then lowered back into place.

A pumping plant consisting of two 30-in. pumps with a capacity of about 50 000 gal. per min., one 10-in pump, with a capacity of about 2 000 gal. per min., and a 3-in. sump pump, all electrically operated, has been provided for unwatering the locks. The pumps are located in a well under the admin-

istration building, the intake being through the lock-wall from a sump just above the intermediate gate. The discharge is carried in a concrete pipe supported on the back of the lock-wall and emptying just below the guard-gate. The pumps are installed near the bottom of the well at about the elevation of the lock floor and have vertical shafts. The large pumps are driven by 300-h.p. motors and the 10-in. pump by a 75-h.p. motor, all located over the well on the basement floor. The pump-well is never allowed to fill with water, the seepage being pumped out by the sump pump which operates automatically. The drainage from all the machinery recesses in the lock-walls is carried through tunnels to the pump-well whence it is removed by the sump pump. It usually requires about eight hours to unwater the large lock, and the painting and repairs are usually accomplished in a week.

The lowering of Lake Washington made it necessary to carry all the water from the Lake Washington and Cedar River water-sheds (580 sq. miles) through the canal to the sea. The maximum known run-off from the water-shed is 12 000 sec-ft. for a period of 24 hours; 6 000 sec-ft. for a period of 10 days; and 3 600 sec-ft. for a period of 90 days. In the low-water season the run-off from the land area is at times so small that it does not equal the evaporation from the lake surface. These periods, however, are of brief duration and occur only when extreme drought and high temperature reduce the run-off and correspondingly increase evaporation from the water areas. Owing to the large capacity of the reservoir formed by the lakes and Salmon Bay the control of this variable run-off can be easily taken care of with an allowable fluctuation of 2 ft. by raising the lake levels to about the high-water elevation before the commencement of the dry season and by lowering the level during the winter months to take care of sudden floods. The discharge over the spillway dam is regulated so as not to cause excessive currents below the locks, and the current through the canal above the locks is never troublesome to vessels.

Electric power for the operation of the locks is delivered at the transformer station at the locks at 13 200 volts and is transformed at the lock site to 2 300 volts, 220 volts, and 110 volts, for operating motors and for lighting the grounds and buildings. The lock-gates and valves are controlled from operating stations on the lock-walls. Three stations are provided for the large lock and one for the small lock. All operating machinery is placed in covered recesses in the top of the lock-walls. For replacing broken cables and doing necessary under-water work, a complete diving equipment is provided, and a diver who is ordinarily employed as an operator on the lock force is sent down to make the necessary repairs.

The delay due to broken cables, which almost invariably affects one or more vessels, has been considerable, probably 2 to 4 hours for each break. Although the gate-operating method is otherwise satisfactory the difficulties arising from this feature suggest that if another lock were to be constructed in the future it might be advisable to try the spar and bull-wheel method similar to that used at Panama, which has all the operating mechanism above water.

As noted previously a small dry dock for docking one leaf of the guard-gates at a time for painting and repairs is being constructed back of the north wall of the large lock, a little below the upper service gate. The lock-wall forms one side of the dock and the quay wall one end. The other side is constructed of two rows of round piles and sheet-piles tied together with iron rods, and filled and banked with clay. The other end will be closed by a timber gate-sill and the gate, which consists of a horizontal girder and needles.

The time required for filling the large lock is about 8 min. at medium low tide. If the culverts were somewhat larger, this time would be decreased. It may be questioned, however, whether this decrease in time would be commensurate with the necessary increase in cost of the original construction of larger valves and operating mechanism.

As constructed, the number of laterals in the lower half of the lock is greater than in the upper half. The idea was that this would result in a more nearly uniform filling of the lock. In practice, it appears that the filling takes place faster in the lower end, resulting in a slight up-stream current in the lock. This has not been particularly troublesome, but in a new design the number of laterals in the lower half should probably be made the same as, or even less than, in the upper half.

Also, in a new design, a larger salt-water sump and outlet would undoubtedly be provided as suggested under the discussion on "Salinity", and if part of the water now passing over the spillway were carried through the dam at as low an elevation as practicable some additional salt would be carried off.

The concrete work of the locks and dam has now been subjected to the action of both fresh and sea water for more than ten years and does not show any appreciable deterioration, except that the face of the lock-walls has been worn off to a limited extent by the rubbing of vessels and other craft. It is true that it is not subjected to extreme changes of temperature, nor to the action of ice, but its general excellence is such as to make it interesting to record in more detail its composition and method of placing.

The mixture used was practically 1:3:6. The sand and gravel were obtained by washing the material from a bank with sea water, using screens of the desired mesh. The sand was well graded, but the gravel had an excess of fine material and generally in mixing 2½ parts of sand to 6½ parts of gravel were used. The proportions, 1:2:6, would give nearly the maximum density for the materials used. The cement was manufactured by the Superior Portland Cement Company and tested in accordance with specifications of the U. S. Bureau of Standards, except that 85% instead of 75% by weight was required to pass the 200-mesh sieve. The concrete was mixed in 1½-cu. yd., Smith, tilting dump mixers, 2 min. being required for each batch. Each batch was dumped into bottom dump buckets which were carried on flat cars about 1 000 ft. to the site. The buckets were picked up by crane and lowered so as to leave just enough clearance for the doors to open before the batch was emptied. All concrete was spread out in layers and carefully spaded, especially next to the form. No tamping was required. The con-

sistency of the mixture was such that a man would sink about half way to his knees. No parts of the work were subjected to the action of sea water until the concrete was thoroughly cured.

Salinity

The up-stream under current of salt water and the down-stream surface current of fresh water during lockages due to the difference of density have been referred to previously. The flow of salt water into the upper pool would eventually turn the lakes into a salt-water reservoir if some means were not provided to return the salt to the lower pool. To meet this difficulty a salt-water basin about 2 000 ft. long and 200 ft. wide, with its bottom 4 to 8 ft. below the elevation of the upper miter-sill was dredged immediately above the lock. From the lower end of the basin a pipe 30 sq. ft. in cross-section extends to the spillway dam. Its outlet is 4 ft. below high tide, which gives a maximum head of 11 ft. and thus forces the salt water from the bottom of the basin through the drain into the lower pool. The flow is continuous and at the rate of 100 to 200 cu. ft. per sec. This discharge of salt water from the upper pool is increased by opening the valves in the culverts at times when the lock is not busy and when water can be spared for that purpose. These measures are ordinarily effective, but when there are a number of consecutive lockages during the dry season the salt-water basin becomes filled with sea water faster than the drain carries it off and it then overflows and some salt water flows up the canal into the bottom of Lake Union. The lake acts as another settling basin, preventing the flow of salt water into Lake Washington. It has been found that the sea water that enters Lake Union tends to distribute itself throughout the waters of the lake, owing to natural diffusion, disturbances caused by currents, changes in temperature, and the passage of boats. However, it is believed that the greater quantity of the sea water will remain below the 40-ft. level.

To determine accurately the extent of this infiltration into the lakes, the services of Professor E. Victor Smith, of the Department of Chemistry, of the University of Washington, were engaged to conduct a continuous set of observations at different points in the canal and lakes and these have been carried on since the canal was opened in 1917. Professor Smith and his colleague, Professor Thomas G. Thompson, were much interested in this work and presented a paper* before the American Chemical Society giving the results of their studies. What follows is extracted from that paper.

The device generally used for sampling the waters for analysis is a reversing water bottle of the Eckman type, with attached reversing thermometers. For determining the quantity of chlorine present in the water, various methods were studied. Attention was given to conductivity and specific gravity methods, but results of considerable variation were obtained, owing to difference of temperature and contamination from industrial plants along the waterway. The Mohr method gave the most concordant results. Parts per

* "The Control of Sea Water Flowing into the Lake Washington Ship Canal," *Industrial and Engineering Chemistry*, Vol. 17, No. 10, October, 1925, p. 1084.

million of chlorine were determined, which was considered to give a relative measure of the concentration of sea water. These results were checked by running, on several occasions, complete analyses of the water from Lake Union and comparing the data with those secured from sea water, calculating for the dilution of the water from the lake. Samples were also occasionally checked in the laboratory by the Volhard method.

As from one hundred to two hundred analyses were necessary for each study it was almost impossible to collect samples and transport them to the laboratory. Accordingly, an improvised laboratory was set up on the U. S. Motor Boat *Orcas*, and as fast as the samples were brought aboard they were analyzed by pipetting off 100 milli-litres and titrating. Two standard solutions of silver nitrate of different concentrations were used, one for water of low salinity and the other for water of high salinity. Possible discrepancies due to temperature changes were within the ordinary experimental error, there seldom being a variation greater than 7° cent. in the temperature of the water throughout the entire year.

The chlorine content of the waters at various depths in and near the locks is shown in Table 2. All the samples from which the data were secured were collected the same forenoon. Series 1 shows, in parts per million, the chlorine obtained from the water taken at various depths in Puget Sound about 1 mile from the entrance to the locks. The effect of drainage water from the land into the sea is distinctly indicated in this series of analyses, as the concentration of chlorine on the surface is decidedly lower than that secured at greater depths.

The collection of samples under Series 2 was started 10 min. after the lock was opened to the sea and during an ebbing tide. The samples were taken at a point midway between the two lock-gates. The data indicate how

completely the sea water replaces the fresh water in the locks when they are opened to the sea.

Immediately after securing the samples of Series 2, those of Series 3 were obtained on the fresh-water side of the upper lock-gate. On the completion of this operation the lower gate was closed to the sea, the water in the lock raised to the level of the upper pool, and the upper gate opened. As soon as the currents in the lock had ceased, samples were taken from the same position as that from which those of Series 2 had been secured. The results, given under Series 4, demonstrate that the sea water had largely disappeared by flowing into the basin above the lock. The sample taken from the bottom of the lock below the elevation of the upper miter-sill was the only one showing a high degree of salinity.

It is impracticable to show all the data secured during the eight years that this investigation has been under way. From those presented in Table 2 it is obvious that the waters of the canal near the locks undergo constant change. However, as the distance from the lock increases, the analyses of the water indicate fairly constant conditions. For example, in Lake Union the change is relatively slow, so that remarkably constant results may be obtained from month to month, especially at the greater depths. Samples were taken at the different stations, indicated in Fig. 1, at every 10 ft. Table 3 gives the relative distances of the respective stations from the locks.

TABLE 3.

Between Stations.	Distances between the various stations, in feet.	Distance from locks (Station 2), in feet.
1 and 2	.....	.....
2 and 3	1 500	1 500

10 and 11	4 500	27 200
11 and 12	10 500	37 000

In Table 4 are given analyses obtained on February 21, 1920, October 8, 1921, and June 10, 1922, at various depths and at the different stations. The results of February, 1920, are illustrative of minimum conditions of salinity, although, in March, 1921, the entire system was cleared of sea-water contaminations. The worst conditions of the eight years were encountered in October, 1921, after a very dry summer, and were due in part also to the clogging of the salt-water drain for a time by a sunken log. This shows very well the ease with which the waters of the canal and lakes might have become contaminated if proper control had not been provided. The data for June, 1922, indicate the effect of drainage resulting from winter rains and spring freshets. In Fig. 10 the logarithms of the parts per million of chlorine for the maximum and average conditions are plotted for the various depths at the different stations along the waterway.

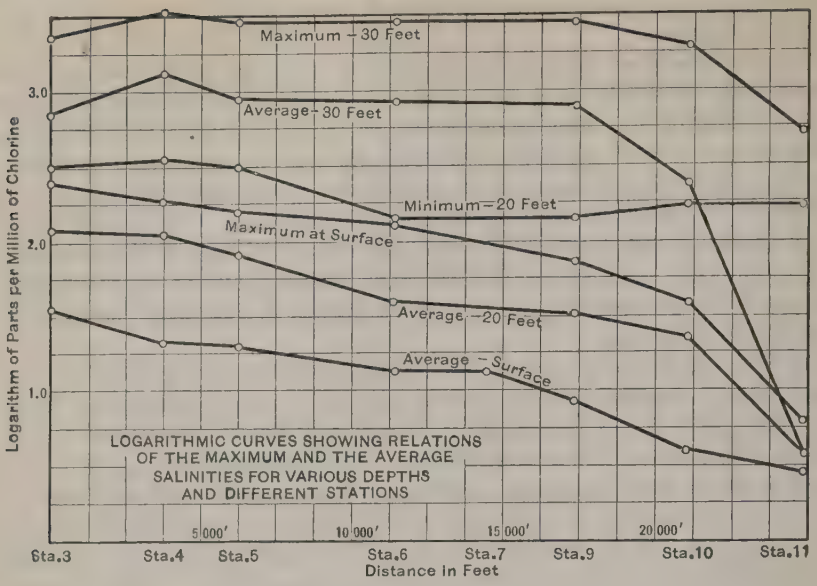

FIG. 10.

Rather peculiar results for maximum conditions at depths of 20 ft. and 30 ft. and for average conditions at 30 ft. are indicated by the curves in Fig. 10 at Stations 3 and 4. The former, being nearer the locks, should show a

greater degree of salinity, but much of the data collected show that Station 4 generally gave higher concentrations. This is probably the result of countercurrents.

The following conclusions were reached:

(1) That the concentration of sea water in the Lake Washington Ship Canal is dependent on the amount of rainfall, the number of lockages, the proper functioning of the salt-water drain, and the methods of disposal of surplus water.

(2) That if the surplus waters are conducted as much as possible through the lock culverts, the degree of salinity can be maintained at a minimum far lower than if the surplus is permitted to run wholly over the spillways.

(3) That greater efficiency could undoubtedly be obtained if the salt-water basin were enlarged in length and width, or depth.

(4) That Lake Union serves as a secondary salt-water basin and prevents the contamination of the waters of Lake Washington.

(5) That storage of surplus water of the winter and spring months is used as far as practicable for drainage through the lock-culvert valves through the dry season which aids materially in decreasing the salinity of the canal system.

The discharge through the spillway gates of the dam is very small between February and October, and from July to October there is usually no discharge, except that for lockages, passing through the salt-water pipe and over the fishway. The large lock is usually filled from 200 to 400 times per month and the small lock from 500 to 1 000 times.

Traffic

The canal has been in operation since August, 1916, and there has been a substantial increase in traffic and in the value of commodities from year to year. The commerce for 1917 was 872 359 tons of freight, valued at $4 254 202 and, in 1920, 1 368 898 tons, valued at $15 567 829. In 1925, it amounted to 2 418 613 tons valued at $14 712 520, and consisted of 1 192 540 tons of floated and barged timbers, valued at $6 372 380; 898 892 tons of sand and gravel, valued at $898 892; 174 677 tons of lumber products valued at $2 649 020; 54 634 tons of fuel oil, with a value of $524 486; 23 350 tons of refined oil, valued at $1 097 800; 23 433 tons of coal and coke, valued at $187 764; 19 950 tons of hogged fuel, with a value of $11 970; and 31 137 tons of miscellaneous, valued at $2 970 208. The number of passengers carried was 49 792. In addition, there were carried by general ferries 269 031 tons and 1 401 037 passengers in 1925.

The bulk of the traffic passing through the locks is between points on Puget Sound, Salmon Bay, Lake Union, and Lake Washington, but lumber is shipped through the canal to points on the Pacific and Atlantic Coasts, and to foreign countries, and there are considerable imports of logs, coal, etc., from Canada.

Vessels using the canal are increasing in size as well as in numbers. During 1917, 22 392 vessels with a net registered tonnage of 591 310 passed through the locks; in 1920, there were 27 377 vessels, with a net registered

tonnage of 1 120 591; and, in 1925, this had increased to 35 433 vessels, with a net registered tonnage of 2 279 131. The largest number of vessels passing through the large lock in a single day has been 104, which included small boats, as the small lock was closed. The greatest number of vessels passing through the small lock in a single day has been 157.

Practically all freight passes through the large lock and about one-half of the total consists of logs, floated loosely between boom sticks in rafts. At times, there has been some congestion of traffic, and an examination has been authorized by Congress with a view to determining the necessity for an additional lock. It does not appear, however, that the capacity of the lock has been fully reached. Delays to boat traffic could be largely reduced by restricting the passage of log rafts to the night time when other traffic is normally at a minimum. If this were done a mooring ground, safe from storms, should be provided in Shilshole Bay near the entrance from Puget Sound.

Greater efficiency of operation could be obtained if the logs were made up in sections of deeper draft or transported in barges. During 1924 there was some traffic in logs transported in barges from British Columbia, 400 000 to 800 000 ft. B. M. being carried in each barge. Logs transported in this way are not subject to delay on account of stormy weather and for long hauls transportation by barge is found quite economical. From Puget Sound ports, however, where the haul is relatively short, the additional expense for loading, upkeep of barge, etc., would more than offset the expense saved in towing and loss by storms, and if a restrictive regulation of this kind were put into effect it would tend to increase the price of logs entering the canal from all Sound ports.

On account of the current previously referred to caused by the meeting of fresh and salt water in and near the locks, and the current from the spillway dam when the gates are open, a material saving in time would be accomplished if the use of only powerful tugs were permitted for bringing heavy tows into the locks.

The small lock, which is 30 by 150 ft., was designed primarily to accommodate small craft, such as tugs without tows, pleasure boats, etc., and the dimensions for this class of traffic are sufficient. The increase in traffic, however, shows the need of a lock of greater width, capable of handling barge traffic when the large lock is unwatered for annual repairs, as well as relieving the latter from some of this traffic at other times. A lock, 34 to 38 ft. wide and 160 to 170 ft. long, would handle the present traffic more efficiently than the lock as built.

Results

The beneficial results of the construction of the canal may be generally summarized, as follows:

(*a*) It has opened to commercial and industrial use a fresh-water harbor, lying in and adjacent to the City of Seattle, with an area of 25 000 acres and a shore line of 100 miles. This harbor consists of three distinct bodies of water, Salmon Bay, Lake Union, and Lake Washington, all standing at the

same level and connected by free and unobstructed channels. This harbor is perfectly protected from storms and free from tidal fluctuations and currents, and, with the salt-water harbor on Elliott Bay, affords harbor facilities which are possibly unsurpassed in the United States.

(*b*) A large and important commerce has already been developed, and Lake Union, located less than a mile from the business center of Seattle and accessible to both rail and deep-water shipping, with depths ranging from 40 to 50 ft., and an area of 905 acres, seems logically destined to become a great distributing center and warehouse district.

(*c*) In the fresh water of these lakes untreated pile and timber structures may be maintained free from destruction by marine wood borers, the marine growth on ships' bottoms is killed by contact with fresh water, and ships may be more economically loaded and unloaded on account of having a fixed water level.

(*d*) The lowering of Lake Washington and the diversion of Cedar River from the Black and Duwamish Rivers into the lake has practically ended the annual floods which formerly visited the Renton, Duwamish, and Sammanish River Districts, and former swamps have been converted into favorable sites for industries, the principal of these tracts being in the Renton District at the south end of the lake, easily accessible to all the railroads entering Seattle, and in the Bothell District at the north end of the lake.

DISCUSSION

ERNEST B. HUSSEY,* M. AM. SOC. C. E. (by letter).—The treatment of the subject of selecting one of five possible routes for the location of a ship canal to connect Lake Washington with tide-water is a valuable digest of the varied and interesting events that finally culminated in the adoption of the route chosen. With this phase the writer was identified in a consulting capacity and had occasion to go into the subject somewhat exhaustively. The final selection by the Government and the subsequent operation of the canal leaves no doubt but that the right location was adopted and that future generations will sustain that judgment.

The lowering of the surface of Lake Washington to that of Lake Union, thereby eliminating a lock between the two lakes, was unquestionably a sound plan; not especially from the point of economy in construction, but more particularly from that of efficiency in transportation. Further, Lakes Union and Washington become a prospective great fresh-water harbor for the commerce of Seattle and its hinterland.

While cut-off walls were placed 4 ft. deep under the heels of the walls of the locks and under the miter-sills, no valves or other devices were provided to relieve possible hydrostatic pressure. The fact that holes drilled through the 3-ft. floor of the large lock showed a very small quantity of accumulated water indicates how well the work of installation of the cut-off walls was accomplished. However, it is the writer's opinion that measures should be adopted in such construction to relieve automatically any hydrostatic pressure that may develop. The use of drains from the areas protected by the cut-off walls, freely discharging into sumps readily accessible for observation, is a measure of precaution well worth its cost in works of such importance, particularly as the heavy floor might be subjected to 53 ft. of hydrostatic head when the lock is unwatered. Much reliance may be placed on the hard impervious clay substrata; but such a foundation is the safer, and the imposed works are the more surely preserved, if ample automatic tell-tale drainage is provided.

The inclusion of greenheart timbers on the bottom of the gates as contacts between similar timbers on the miter-sills appears to be good design. Probably these timbers would not have been affected by marine borers if the gates and miter-sills had been protected by a flow of fresh water. This could have been accomplished by using small conduits in the side-walls of the locks, conveying fresh water from the upper pool and discharging it continuously along the lower guard-gate and its miter-sill.

The method of replacing the timbers is especially commendable under the existing circumstances, necessitating the practical re-design and installation of contact members between the bottom of these particular gates and their respective miter-sills. It is a question, whether the remedy can be considered better than the original installation of greenheart timbers, provided the timbers had been protected against the activities of marine borers. To have

* Cons. Civ. Engr., Seattle, Wash.

installed the re-designed contact members without placing the lock out of commission, is a notable feat. It illustrates impressively the ingenuity of man when put to the test.

The emergency dams installed subsequent to the original construction were wise provisions against accident. Some such device was undoubtedly in contemplation at the time of the original design of the locks. The use of wickets and girders stored on the lock-walls, to be placed in position in the lock by a stiff-leg derrick in an emergency, effects a considerable saving over other forms of emergency dams, but, in view of the importance of these works, the writer believes that the comparatively quicker and more positive balanced cantilever turn-table type, having wickets ready to be lowered into place, would have been preferable. The value of the varied commercial structures damaged by undue delay would justify the additional installation cost and carrying charges. In an emergency, moments of time conceivably may cause hundreds of thousands of dollars of property damage. The best and most rapid type of emergency dam is then none too good or too expensive. It is at such times that the difference in cost is entirely lost to sight and the engineer is hardly thanked for any saving.

Possibly by enlarging the design described practically all the sea water entering Salmon Bay through the locks might be trapped and conveyed back to tide-water. The creation of a salt-water basin above the locks to the greatest reasonable depth would probably be much more effective in trapping the salt water than would result if the basin was only increased in width.

The authors' praise of this fresh-water harbor of 25 000 acres is well justified. It is a signally remarkable harbor. The writer is of the opinion that these works afford harbor facilities that are unsurpassed in the world. The authors are certainly justified in their summarization of the beneficial results to commerce by virtue of the construction of these waterways.

Charles Evan Fowler,* M. Am. Soc. C. E. (by letter).—The writer became interested in the Harbor of Seattle on his arrival there in 1900, when the city had a population of only 85 000, and the harbor facilities consisted of a limited number of pile and timber wharves located on the immediate deep-water front on Elliott Bay. Contracts were soon entered into, by the Company of which the writer was President and Chief Engineer, for the excavation of the East and West Waterways at the head of Elliott Bay and the filling of the eastern portion of the tide flats, which comprised about 1 200 acres. Only 75 acres of this fill had been completed in the five years prior to 1900.

The Waterways were dredged to a width of 1 000 ft. with pier-head lines 500 ft. apart, and a depth of 38 ft. at low tide. The permanent bulkheads were of fir brush, from 12 to 24 ft. in length, laid up to a 45° slope, with the butts outward as the filling progressed. The temporary bulkheads were of piles and plank, of the stepped type, and were used for bringing sections to the grade of 2 ft. above high tide, so that certificates could be issued by the State of Washington for completed work. These certificates drew 8%

* Cons. Engr., New York, N. Y.

interest and were a first lien on the land so created. The cost allowed by the State was 16 cents per cu. yd., with an added general profit of 15%, or a total of 18.4 cents per cu. yd. The first contracts up to 1905 were for a total of about 12 000 000 cu. yd., which was excavated and pumped to a distance as great as 5 300 ft. by two 20-in. hydraulic dredges.

As a Trustee of the Seattle Chamber of Commerce and a member of its Harbor Committee, the writer became interested in the promotion of the Lake Washington Canal, and, later, in the formation of the Port of Seattle. One of the first efforts was to convince the War Department and Congress of the necessity, or at least the desirability, of the canal, and that in place of a $7 000 000 two-lock canal, a one-lock canal was all that was required. It is interesting to note that the cost estimate made at that time by the writer, was $3 800 000, and this type of project was finally adopted. Construction was begun by dredging the entrance from deep water in Puget Sound to a place near the present lock site in Salmon Bay. This contract was secured by the writer's Company at 26.7 cents per cu. yd., and much of the material was of the hardest type of blue clay hardpan. The dredge built for the work was of the dipper type, with machinery for a 7-yd. dipper, but, owing to the hard material to be dug, a 3½-yd. dipper was used.

The second contract entered into was for the test borings over about 2 miles of the canal route, up to the Ballard Bridge. This was carried out by using a floating pile-driver rig, on the gins of which was placed a square drill shaft turned by a pulley at the deck level, through which the drill bar passed loosely in a square hole. The drills were 2 to 2½-in. augers. The cost of the work under this contract was about 50 cents per vertical ft. The third contract, for additional excavation through Salmon Bay, was carried out by the use of the dipper dredge at a cost of about 43 cents per cu. yd.

The construction of the lock was carried out in a manner that calls for the highest praise of the late Colonel Cavanaugh and the authors, and also reflects the greatest of credit upon the U. S. Corps of Engineers. The extremely low unit cost of the concrete was due to some extent to the low price obtained on cement at that time, and to the fact that the finest kind of sand and gravel was purchased at 25 cents per cu. yd. on the Government scows at the Point Defiance gravel pits, and towed a distance of about 30 miles to the lock site by the Government tug, *Gen. J. M. Wilson*. Notwithstanding all this, a record was probably set for all time in the matter of cost for such a great piece of work.

The writer also had charge of the final dredging of the canal through Salmon Bay, Lake Union, and Union Bay in Lake Washington. This work was undertaken at a very low price, less than 9 cents per cu. yd., so that the only way possible of reaching profitable figures was to sell the dirt for filling low lands along the line of the canal. All that excavated in Salmon Bay was so used, although much of it came out of the 22-in. pipe so soupy as to cause a great deal of it to be lost. The material in Lake Union was sold for a large fill, but much of this was so soft as to make it impossible

to bring all the fill to grade. The excavation in Union Bay was in soft silt and peat, which was pumped on to Park property, a distance of 4 000 ft., with an output of as high as 47 000 cu. yd. per day. The digging of the old logging canal to full size, between Lake Union and Union Bay, required the excavation of a large quantity of very tough material (hardpan and cemented gravel), which was as hard as soft concrete. This digging was done by using a rock cutter on the 22-in. electric hydraulic dredge, and pumping the material a distance of about 2 000 ft.

The whole work was most difficult in many respects, yet it was well worth while as one feature of the opening of the last frontier, and was a great step in the building of the Metropolis of the Northwest.*

Joseph M. Clapp,† M. Am. Soc. C. E. (by letter).—The writer had the Lake Washington Ship Canal as his home work, under the direction of the District Engineers, for the ten years from 1901 to 1911; gathered much of the physical data used in solving the problems in relation to the project; is familiar with the locality and its geological characteristics; and takes pleasure in adding a few details relating to this great project.

Something has been said of the late Colonel Cavanaugh's connection with this project and the manner in which he directed it. It is only fair that greater stress should be laid to the fact that much pertaining to the details of design and the actual work of construction was done by Mr. Sargent, the very efficient Engineer Assistant. It was his untiring efforts that made possible the economical design of the system and of the plant and its operation during construction; all of which resulted in the very low cost of the locks and dam as a whole.

It has been stated that the lowering of Lake Washington and the outflow of the Cedar River, *via* Ballard and the locks, has lessened the flood problems in the Duwamish Valley. While this is so, it is not as great a factor as the divorcement of the waters of the White River from the Valley of the Duwamish to its new channel *via* the Puyallup Valley to the Sound. The run-off from the White River shed during flood seasons is several times greater than that from Lake Washington and its tributaries.

A hard clay formation is the bed-rock of the country and, once it is well defined, is considered sufficient to support the structures that are built in this section. To use piles under the walls where this clay formation is met, if the weight is less than 5 tons per sq. ft., is superfluous and may result in poor construction for the reason that, to drive wooden piles to any penetration into the clay means to upset the fiber, cause the pile to telescope, and thus destroy its bearing value for heavier weights. Steel or reinforced concrete piles would have to be used if greater weights were to be supported.

In the early days of this work it was the writer's duty to direct the excavation of a ditch so as to bring the outlet of Lake Union through a channel located wholly on the canal right of way and under the control of the War Department. The Northern Pacific Railway crossed the right of way at a

* Many of the details have been omitted, as they can be found in the writer's book entitled "Sub-Aqueous Foundations."

† Cons. and Contr. Engr., Seattle, Wash.

point north and west of Fremont, Wash. The Railway Company constructed its trestle crossing in the dry and before excavation in its vicinity was begun. On working the excavation under the trestle many of the piles were exposed, and it was found that they had telescoped and were of no real value. The crossing had to be rebuilt, and sills and posts were substituted for the piles.

At the portage separating Lake Union from Lake Washington, where the narrow channel was provided for the passage of logs in 1888, it might be mentioned that at first a lock was actually provided, 50 ft. long, 18 ft. wide, and 4 ft. deep, for the passage of small steamers. Several lockages of steamers were made, but there was no profitable business. Eventually, the locks were allowed to decay and a raceway for the passage of logs was constructed and operated on a toll basis by the Lake Union Mill Company.

In determining the location for the canal, the routes through Salmon Bay were canvassed and the present route determined by a Board of Engineers, all prior to 1896, when the writer first became familiar with the project and the District Office was established at Seattle. Later, about 1906, another route was canvassed to enter Lake Washington by way of the Duwamish Valley, with a canal to be dug through Beacon Hill and the territory intervening between the Duwamish Valley and Lake Washington, about on line with Spokane Avenue.

The plan contemplated the excavation of a canal between Lake Washington and Lake Union and either the raising of the waters of Lake Union to the level of Lake Washington; lowering Lake Washington to the level of Lake Union; or lowering one and raising the other to some intermediate point. This plan was advocated by a company interested in the reclamation of the tide-flats at the mouth of the Duwamish River, known as the Lake Washington Canal Company.

The cross-country canal involved excavation through a hill about 130 ft. high and the moving of a great many million cubic yards of material. It was the writer's duty to make comparative estimates for the information of the Board of Engineers that judged this work. After careful consideration the Board discarded this route, for obvious reasons, in favor of the present very logical route, which had been previously determined upon by other Boards of Engineers.

Some consideration was also given to a possible canal by way of the Black River and the Duwamish River to Puget Sound. Thus, it will be noted that careful consideration was given the matter of routing this canal.

L. C. Sabin,* M. Am. Soc. C. E. (by letter).—This comprehensive and interesting paper has one serious defect. The entire installation worked so well that nothing is left for adverse criticism. Possible exceptions to this general statement are the complications arising from the fact that the upper pool is fresh, while the lower pool is sea water, and the suggestions of the authors that the laterals from the main culverts should have been distributed in a different manner.

* Vice-Pres., Lake Carriers' Assoc., Cleveland, Ohio.

The former condition has been carefully studied and practically corrected. The latter seems not to have received corresponding attention, and it is to this feature that this discussion is addressed. In lock design there are several considerations that render it impracticable to predetermine accurately by theory the action of a certain proposed arrangement of culverts, valves, and ports or laterals. For the emptying culverts, where the flow is from a restricted chamber to the open canal, the arrangement seems to be comparatively unimportant as to its effect on surge in the chamber; but in filling, considerable and variable differences in level may occur at the two ends of the lock with consequent objectionable currents within the chamber.

According to the data given in the paper there are two culverts in the 900-ft. lock, each having an area of 108.5 sq. ft. The ports or laterals are generally 4 ft. wide and 2 ft. high but eight of the laterals are 6 ft. high to afford easy access to the culverts for inspection and repairs to valves. Four of the larger ports and twenty of the smaller ones enter the upper chamber, 450 ft. long, while four of the larger and twenty-four of the smaller ports enter the lower chamber, 375 ft. in length.

Considering the lock as a whole the ratio of port area to horizontal cross-section of the chamber is approximately:

$$\frac{(2 \times 6 \times 4) + (4 \times 2 \times 20)}{450 \times 80} = 0.0058$$

for the upper portion, and

$$\frac{(2 \times 6 \times 4) + (4 \times 2 \times 24)}{375 \times 80} = 0.0080$$

for the lower portion. The authors state that,

"The idea was that this would result in a more nearly uniform filling of the lock. In practice, it appears that the filling takes place faster in the lower end, resulting in a slight up-stream current in the lock. This has not been particularly troublesome, but in a new design the number of laterals in the lower half should probably be made the same as, or even less than, in the upper half."

In the Pedro Miguel Lock of the Panama Canal the main culverts discharge into small laterals under the floor which, in turn, communicate with the chamber through ports through the floor. Disregarding the area between service and guard-gates and considering the chamber as a whole, there are in the upper half, six laterals from the side culverts and four laterals from the center culvert, each having an area of 41 sq. ft. (although apparently restricted by openings from the culvert having an area of but 33.2 sq. ft.), giving a total area of laterals of 410 sq. ft. In each lateral there are five ports having an area of 12.24 sq. ft. each, or a total area of ports of 612 sq. ft.

In the lower half there are five laterals from the side culvert and six from the center culvert, giving a total of 451 and 673 sq. ft. for laterals and ports, respectively. The ratio of lateral area to horizontal cross-section of lock is thus, approximately:

$$\frac{410}{110 \times 500} = 0.0074$$

for the upper half, and,

$$\frac{451}{110 \times 500} = 0.0082$$

for the lower half. The ratio of port area to horizontal cross-section of lock chamber is approximately 0.0111 for the upper half and 0.0122 for the lower half. There is nearly equal distribution of ports throughout the lock, but with more ample provision of port areas than in the Lake Washington Lock.

In the latest locks at St. Marys Falls Canal there are six culverts under the floor in each lock. The outer culverts have forty ports each and extend only about half way down the lock. The other four culverts extend the entire length of the lock and each is provided with fifty-nine ports spaced 30 ft. apart at the upper end, this spacing being gradually reduced to 15-ft. centers at the lower end. Each culvert has a net cross-sectional area of 88.07 sq. ft. and the ports are each 1 by 3 ft. In the upper half of the 1 350-ft. lock chamber there are about 178 ports fed by six culverts and in the lower half about 138 ports fed mainly by the four central culverts. The design contemplated that in actual operation the valves of the central culverts would be opened first and those in the outside culverts only when filling had progressed so far that ample opening under the reduced head would not result in surge.

The fact that the several culverts communicate with each other near the upper end to relieve side pressure on the culvert walls complicates any analysis of flow conditions when only part of the valves are opened, but when all the valves are open, the ratio of port area to horizontal cross-section of lock chamber is:

$$\frac{178 \times 3}{80 \times 675} = 0.0100$$

for the upper half, and,

$$\frac{138 \times 3}{80 \times 675} = 0.0077$$

for the lower half.

For these three locks the ratios of port area to horizontal area of lock chamber are given in Table 5.

TABLE 5.—Ratio of Port Area to Horizontal Area.

Lock.	Upper half of chamber.	Lower half of chamber.
Lake Washington	0.0056	0.0080
Pedro Miguel	0.0111	0.0122
Sault Ste. Marie	0.0100	0.0077

In the Lake Washington Lock, with the area of ports in the lower half of the chamber 138% of that in upper half, the authors state: "It appears that the filling takes place faster in the lower end, resulting in a slight upstream current in the lock."

In his paper on the action of the water in the Panama locks* H. F. Hodges, Maj.-Gen., U. S. A. (*Retired*), M. Am. Soc. C. E., states:

"When any one of the locks is filled, using the side wall culvert only, the discharge is noticeably greatest at the opening in the floor farthest from the culvert, and nearest the middle wall. The velocity of flow in the laterals evidently carries the water past the first two or three openings without giving them their full share of the discharge. Were the laterals lengthened, doubtless this effect would become less and less marked; and, finally, the maximum discharge would be found at some opening nearer the source of supply. With the proportions which they have, however, there is no doubt that the openings nearest the middle wall discharge a larger volume of water than those nearer the side wall, when the side culvert only is used. The result is a slight slope of the water's surface, which draws vessels away from the middle wall toward the side wall. This effect is not serious and disappears when both culverts are used.

"The side culvert occupies much the same relation to the laterals which draw from it as does each lateral to the openings through which it discharges. The side culvert is, however, made longer, and it is not plain to the eye which one of the laterals gets the largest share of the water at any instant. The ones farthest up stream discharge first, the boils from these beginning to show in about one minute after the first motion of the valves. The flow becomes apparent to the eye progressively down through the length of the lock, the lateral at the lower end—that is, the one farthest from the filling valve—showing flow last of all."

At the Sault locks,† where the area of ports in the lower half is only 77% of that in the upper half, it appears that when filling with either four or six valves the boils begin to show first at the upper end and the water at this end momentarily rises faster, but the water in the chamber is nearly level for the first minute, and the down-stream end is then higher for about a minute, the maximum difference being nearly 2 ft. Thereafter, the level fluctuates back and forth, the water being first higher at one end and then at the other, with a maximum difference of about 1 ft. and gradually reducing.

In view of these several observations it appears that immediately after opening the valves the ports at the upper end of the locks will begin to discharge first, but as soon as the inertia of the water has been overcome the level will be higher near the down-stream ends of the culverts for a short time. This seems to hold true whether the ratio of port area to chamber area at the lower end is 40% greater or 23% less than the same ratio for the upper end. Accordingly, it appears to be impracticable to correct the situation by variation in this ratio in the design of the culverts.

Unless this fluctuation is extreme the effect ordinarily is not great, but it has been entirely overcome at the Sault by the method of operation. At first, the plan adopted was to open the central pair of valves first, the intermediate pair after 3 min., and the outside pair 3 min. later. This confined the rate of rise in the chamber to a maximum of 4 ft. per min. Later, it was found that still smoother operation could be secured by opening each pair of valves very slowly, consuming about 1½ or 2 min. in opening each pair. By this method

* "Action of Water in Locks of the Panama Canal," *Professional Memoirs*, Corps of Engrs., U. S. A., Vol. VII, No. 31, p. 18.

† "Filling and Emptying the Third Lock at St. Marys Falls Canal." *Professional Memoirs*, Corps of Engrs., U. S. A., Vol. IX, No. 44.

the tendency to surge is eliminated and only very moderate stress on the mooring lines is required. While the lock can be filled in about 6 min. by opening all valves simultaneously, about 10 min. are consumed in ordinary operation.

TABLE 6.—COMPARISON OF CULVERT AND PORT DESIGNS.

Subject.	Lake Washington Canal.	St. Marys Falls Canal.	Pedro Miguel Lock.
Horizontal dimensions, in feet	80 by 825	80 by 1 350	110 by 1 000
Horizontal area, in square feet	66 000	108 000	110 000
Net Area:			
Main culverts, in square feet	217.0	528.4	510.0
Area ports, in square feet	448	948	1 285
Ratio, culverts to chamber	0.0033	0.0049	0.0046
Ratio, ports to culverts	2.06	1.79	2.52
Ratio, ports to chamber	0.0068	0.0088	0.0117
Approximate time, in minutes, to fill from 18-ft. head to zero	7⅛	6	5

Although the data at hand are not entirely sufficient, a comparison of the culvert and port design and the approximate time of filling the three locks referred to may be of interest. The data as far as available are given in Table 6.

The Sault installation gives a value for the coefficient of flow in culverts of 0.75 for six valves; the value for the Panama locks is given as 0.78. From such data as are given in the paper, it is inferred that the coefficient for Lake Washington is about 0.70.

The more rapid filling of the Pedro Miguel Lock seems to be due to the ample port area, since the culvert area has about the same relation to the chamber as in the Sault lock. On the other hand, the flow into the Lake Washington Lock appears to be throttled by the culvert area since the relation of ports to culverts is somewhat greater than at the Sault although less than at Pedro Miguel. This does not indicate, however, that the culverts should have been larger, as the rate of filling would seem to be entirely satisfactory for the traffic concerned.

W. J. BARDEN* AND A. W. SARGENT,† MEMBERS, AM. SOC. C. E. (by letter).—The authors are appreciative of the information given and comments made in the discussions of their paper.

Mr. Hussey thinks that more direct and positive provision should have been made for the relief of possible hydrostatic pressure under the lock floor, and suggests the use of valves or a system of drains. Both these methods have been used in some instances, but have not always been found entirely satisfactory. The present practice, where the floors are not designed to resist full upward pressure, appears to be to use a paving of concrete blocks with weep-holes. In the Seattle Lock, having in mind the more or less impervious character of the foundation, the cut-off walls provided, and the clay back-fill

* Col., Corps of Engrs., U. S. A., Headquarters, 2d Corps Area, New York, N. Y.
† Civ. Engr., U. S. Engr. Office, Govt. Locks, Seattle, Wash.

which was carried to a depth of 20 to 30 ft. over the steps on the back of the walls, the designers evidently considered that hydrostatic pressure sufficient to endanger the lock floor was unlikely to develop and the results have apparently justified their conclusion. It may be added that should failure occur in the future, repairs would not be difficult, and sufficient provision against subsequent trouble could probably be made by drilling a system of weep-holes.

The suggestion that a flow of fresh water conducted along the timbers of the guard-gate and miter-sill would have protected them from marine borers is of much interest. It is possible that such a procedure might be effective in keeping the steel gates free from barnacles which adhere to and destroy the paint, necessitating extensive cleaning and repainting every year.

Approval has been secured to deepen and widen the present salt-water basin and to lower the intake of the salt-water drains 7 ft. It is believed that this will materially reduce the quantity of salt water passing into the lakes. The latest salinity tests, taken at the end of the dry season, show a little less salt than usual at such times, due probably to an unusually cool summer with resultant smaller evaporation, thus allowing more water to be wasted through the locks.

Mr. Fowler gives interesting additional historical data and details on canal construction. The following costs may be of interest: The cost of cement f. o. b. cars at the lock site was $1.49 per bbl.; unloading, 2 to 4 cents per bbl.; testing, 5 cents per bbl.; sand and gravel f. o. b. barge at pit, 23.8 cents per cu. yd.; towing, 12 to 18 cents per cu. yd.; and unloading and delivering to bunkers at mixer plant, 5 to 8 cents per cu. yd. These costs do not include plant costs or overhead.

Mr. Clapp also gives some interesting historical data and a description of previous studies leading to the adoption of the present plan. Limitation of space prevented the authors from giving more details concerning these features. The statement that the diversion of the waters of the White River to the Puyallup has a greater beneficial effect in the prevention of floods in the Duwamish Valley than the construction of the canal, is correct. It was intended to list this feature merely as a collateral benefit.

The authors agree with Mr. Sabin's comment that,

"In lock design there are several considerations that render it impracticable to predetermine accurately by theory the action of a certain proposed arrangement of culverts, valves, and ports or laterals".

His analysis of the designs of the Pedro Miguel Lock of the Panama Canal, the latest locks at St. Marys Falls Canal, and the Lake Washington Lock, so far as these features are concerned, is of great interest, but his statement as to the experience in operating the locks at the two former places would seem to indicate that no materially better results were secured by the designs adopted there than at the Lake Washington Locks. At the St. Marys Falls Canal Locks, where the culverts are under the lock floor with a system of ports distributed over the floor area, it appears that fluctuations of level from one end of the lock chamber to the other occur with a maximum difference of about 1 ft. While the lock can be filled in about 6 min. by opening all

valves simultaneously, in order to reduce this surge, about 10 min. are consumed in ordinary operation. At the Lake Washington Lock, culverts and laterals were designed to fill the lock in 8 min., but the actual time is only about $7\frac{1}{2}$ min. There are no noticeable cross-currents and the up-stream current is not perceptible until the chamber is practically filled and it is then insufficient to affect ships. The latter are always moored to the north wall and the opening of the north valve is started a few seconds before that of the south valve, so as to avoid the possibility of any cross-currents that would tend to pull the ship away from the wall.

At the Pedro Miguel Lock, where the main culverts discharge into small laterals under the floor, the water apparently passes the first two or three ports in the laterals. The discharge is greater near the wall opposite the culverts, and this results in approximately the same distribution as with the laterals or ports in the side walls discharging directly into the chamber. In general, it would appear that whatever the design may be, the most satisfactory results in operation can only be secured as the result of experience and the exercise of good judgment on the part of the operating force.

Paper No. 1680

THE WORK OF THE PORT OF SEATTLE, WASHINGTON*

By George F. Cotterill,† Esq.

With Discussion by Messrs. D. W. McMorris, Joseph M. Clapp, and Charles Evan Fowler.

The "Port of Seattle" must be considered in a dual sense: First, in its broadest meaning as the great harbor of the North Pacific, with a continent for a hinterland and an outlook on the ocean highways, strategically located by Nature and equipped by development to serve the needs of world commerce; and, second, in its lesser scope as the official designation of a municipal corporation charged with certain powers and duties in the development and service of commerce in the Harbor of Seattle.

Strategic Location of Seattle

In geographical terms, the Port of Seattle may be described as situated on Elliott Bay, on the eastern and continental side of Puget Sound approximately 125 miles from the open Pacific Ocean, passage being made through the Strait of Juan de Fuca, Admiralty Inlet, and Puget Sound. The Strait is about 15 miles wide at the Pacific entrance between Cape Flattery and Carmanah Lights, and extends eastward, with an average width of more than 10 miles, between the State of Washington on the south and Vancouver Island on the north, for about 50 miles to Race Rocks, on the Canadian side, there expanding to the northeast and continuing eastward, with an average width of 18 miles, for 30 miles, connecting northward through Georgia Strait into the Canadian waters east of Vancouver Island, thence back to the North Pacific and inside passages of Southeastern Alaska, also connecting southerly through Admiralty Inlet into Puget Sound extending for 75 miles into the

* Presented at the meeting of the Waterways Division, Seattle, Wash., July 15, 1926.
† Civ. Engr. and Port Commr., Seattle, Wash.

heart of Western Washington. The Strait of Juan de Fuca extends eastward from Cape Flattery to Point Wilson, about 85 miles, there connecting southward into Admiralty Inlet and Puget Sound, which have a width from 3 to 5 miles, continuing for 40 miles to the Port of Seattle and 30 miles farther south to the Port of Tacoma. Both Strait and Sound are of ample depth, varying from 150 fathoms at Cape Flattery to 25 fathoms minimum at the Admiralty Inlet entrance to Puget Sound, which has similar variations of depth from 150 to 25 fathoms minimum at the opening into Elliott Bay—the Port of Seattle. Here is a natural harbor, with 9.7 miles of shore line, including 3 800 acres of surface area, very deep and free from natural obstructions or dangers throughout its entire extent—a land-locked bay indenting the continent from an inland sea, the open hand of a mighty arm of the ocean extended 125 miles inward for the largest service of commerce with utmost safety and convenience.

Viewed from the continental hinterland the Port of Seattle demonstrates the most strategic location, nearest to central for seven, and the focal Pacific port of concentration for three, transcontinental railway systems. Two northern routes traverse Canada from the Atlantic to the Pacific, finding a Pacific outlet at the Port of Vancouver, but with rail and water connections to the Port of Seattle, 150 miles to southward. Likewise, two routes from the Middle West and the Pacific Northwest find their way down the Columbia River to the Ports of Portland and Astoria in Oregon and to the new Ports of Vancouver and Longview in Washington, but these railway systems have also joint ownership and common-user operating rights over the 150 miles of almost water-grade railway northward from the Columbia River to Puget Sound and the Port of Seattle. Midway between these four connecting routes of Canada and the Columbia River are the three great American northern transcontinental systems, covering the great Northwestern Empire from the Great Lakes and the Upper Mississippi Valley to the Pacific slope—these converge at the Port of Seattle.

The Climax of a World Quest

There is a historical background worthy of note before turning from the geographic picture of the Port of Seattle and passing to detail consideration of its development and progress. Columbus, seeking the westward route "to India and Cathay", found it blocked by two continents linked by an isthmus barrier. Diaz and De Gama demonstrated the southeast passage *via* the Cape of Good Hope to India and the East Indies; to which Magellan soon added his momentous contribution of the southwest route by the Straits which bear his name, to the Indies and the first circumnavigation of the globe. Balboa meanwhile crossed the Isthmus of Panama and discovered the "South Sea", along which Spain soon extended her conquests southward to Peru and northward to the Gulf of California. Then began the search for a "Northwest Passage" to China around the supposed north coast of, or through, North America. It was first pressed by England, then by France in the North Atlantic. Meanwhile, Spain was extending her knowledge of the North Pacific. Two Philippine ships in 1584 and 1595 made a dim record;

in 1602, Viscanio from Spanish Mexico went north to the Bays of San Diego and Monterey, and on to 42° latitude—the northern boundary of California. In 1603, Martin Aguilar reached 43°, named Cape Blanco and claimed to have discovered the mouth of a large river. Globes and maps of this period began to indicate an indefinite "Strait of Anian", probably the expression of a hope of an opening eastward, somewhere north of known discoveries and fading away into the unknown.

Discovery lagged after the first third of the Sixteenth Century, while the nations of Europe turned to exploration, development, and extension of their domains and claims on the continent that barred the way to the Orient. On the Pacific side, Spain coasted north from Mexico, Cabrillo in 1542-43 exploring the southern coast of California and Ferrelo in 1543 as far north as the Oregon coast. The name, California, is first found in a Spanish romance of 1510, described as being "on the right hand of the Indies, very near the terrestrial paradise", hence it was applied by Cabrillo to the coast he explored in 1542. Lower California was considered an island and so mapped up to 1721.

The war between Spain and England in the Elizabethan era was carried to all the seven seas, over which Spain held sway as the mistress of world commerce. Bent on a mission of war destruction, Sir Francis Drake left England in December, 1577, went down the east coast of South America, through the Straits of Magellan (September, 1578), plundered Spanish possessions in Chili and Peru, seized ships, and demoralized Spanish Pacific commerce all the way up the coast to Mexico and California, particularly intercepting their treasure ships from the Philippines and East Indies en route to Panama and the Atlantic. Laden with rich prizes of war—after landing and refitting at Drake Bay, near San Francisco—Drake sought a shorter route to England by way of the supposed "Northwest Passage". He proceeded north, up the California and Oregon and perhaps the Washington coast, seeking an opening or trend of the coast to the eastward. Whether he stopped at 43° North Latitude or continued to 48°, just south of the great strait opening into Puget Sound, accounts differ. It was late summer of 1579, and Drake feared that even if he continued north and found an eastward passage it would only lure him into the frozen regions of the North Atlantic. Hence, he turned westward across the Pacific, doubtless making the first trans-Pacific voyage by the northern route, and continued by way of the Indian Ocean and the Cape of Good Hope to England in 1580.

At this stage there was published by an English author the purported memorandum of Michael Lok of a conversation at Venice in 1596 with an old Greek pilot, Juan de Fuca. By this third-hand authority there came the story which pointed the finger to an unknown Puget Sound as the Pacific portal of the Northwest Passage—the American exit of the trade route to the Orient. Juan de Fuca was reported as giving the story of a voyage in 1592, sent out by the Viceroy of Nova Spania (that is, Western Mexico).

For a century and a half the search for the Northwest Passage and the trade route to the Orient languished. Before the middle of the Eighteenth

Century came the awakening. In 1728, the Danish explorer, Bering, in the service of Russia, demonstrated that Asia and North America were two continents, with a sea and strait between, connecting from the Pacific to the ice-bound Arctic. Also, in 1741, Bering coasted North America down to 54° 40′. The fur trade of the North Pacific developed and the merchants of all nations sought to enter it. England, meanwhile, had taken over the Portuguese possessions in India and Southeast Asia and was securing trade footholds in South China. On the American Continent her Hudson's Bay Company was stretching westward up great rivers toward the mountains and the Pacific that lay beyond. The only available market for the North Pacific furs were the Ports of South China and India. England reopened the book of discovery after nearly two centuries, at the page turned down by the Juan de Fuca story of 1592, and offered a $100 000 reward for the demonstration of the "Northwest Passage". With this incentive, Captain James Cook—just 200 years after Drake's vain effort of 1579—sought the prize. It was the third and last voyage of this greatest of British navigators. Sailing on March 7, 1778, from the Sandwich Islands—which he had discovered and named on a previous Pacific voyage—he sighted the coast at the North California or Spanish boundary and followed it northward to Nootka Sound on the west coast of Vancouver Island, observing neither the Columbia River or other opening in the Coast line, having been driven to the open ocean by a gale.

Fourteen years after Cook failed where Drake fell short two centuries before, the lot fell on Captain George Vancouver to solve the problem and dissolve the mystery of three centuries. The British Admiralty having accepted the conclusion recorded by Cook, the fur trade developed from the Nootka base, with the South China and East India market, participated in by British and American merchantmen after the treaties of 1783 closing the Revolutionary War. Suddenly, in 1790, the news was brought to London by Captain John Meares, of the Spanish seizure of his two British merchantmen at Nootka, with their cargoes of furs. The menace of war was aroused, but soon there was an Anglo-Spanish treaty, including apologies and reparation. More important than his news of seizures and demand for reparation, however, Meares had brought to London the news of new discoveries in the North Pacific, and particularly that "John de Fuca's Strait" really existed, despite Cook's 1778 record of non-existence. Meares confronted the 1790 London world of geography with a map entitled "A Chart of the Interior Part of North America; Demonstrating the Very Great Probability of an Inland Navigation from Hudson's Bay to the West Coast". The map showed "John de Fuca's Straits" entering from the ocean eastward to an undefined open end; a dotted line around to the northward and back into the Pacific Ocean north of Nootka, marked "Sketch of the Track of the American Sloop *Washington* in 1789"; an indication of "The Sea" to the eastward; a short section of the "Oregon River" in the interior, with dotted lines indicating probable connection to the inland sea and straits; also an intricate system of lakes and rivers covering the Continent to the north and eastward. By this Meares map and

information, all the doubts and hopes of a Northwest Passage as the great trade route from Occident to Orient were renewed. The British Admiralty acted promptly, deciding to combine with the Naval Expedition to adjust the Spanish seizures at Nootka, a final and thoroughly equipped scientific solution or dissolution of the North Pacific mystery. Hence, the Vancouver Expedition of 1791-93.

Captain Vancouver faithfully discharged his mission, entered the Straits of Fuca, spent the season of 1792 in a survey and charting of the right-hand coast line of the Continent, testing out every inlet of the intricate ramifications of the inland sea, east and south and north and northwest, until at last he came out into the Pacific north of Vancouver's Island. The high point of this great voyage of discovery was reached May 26, 1792, when Vancouver rounded the point into Commencement Bay, the Harbor of Tacoma. The record reads:

"Towards noon we landed on a point on the eastern shore * * * round which we flattered ourselves we should find the inlet take an extensive easterly course. This conjecture was supported by the appearance of a very abrupt division in the snowy range of mountains immediately south of Mt. Rainier, which was very conspicuous from the ship, and the main arm of the inlet appearing to stretch in that direction from the point we were then upon.

"We here dined, and although our repast was soon concluded, the delay was irksome, as we were excessively anxious to ascertain the truth, of which we were not long held in suspense. For having passed round the point, we found the inlet to terminate here in an extensive, circular, compact bay, whose waters washed the base of Mount Rainier".

Thus ended the search for the "Northwest Passage". The dream was dissolved into the reality of a North Pacific "Mediterranean", with sheltered harbors destined for great ports, ready to serve the continents through the giant gateway of the spacious straits to the world highway of the greatest ocean.

The age of steam and steel, dawning a half-century after Vancouver, made possible the realization of the Northwest Passage and the world's greatest trade route by the steamship and the railway. On Vancouver's Puget Sound of 1792, the story of the Port of Seattle was started sixty years later. It is the realization of a vision, the fulfillment of destiny.

Development of the Port of Seattle

The Port of Seattle, in its limited official scope, is a municipal corporation, covering the territory of Seattle and its surrounding County of King, organized and operated under authority of Washington State Law in 1911.

Prior to this public port organization, Seattle had developed, during the preceding forty years:

(1) A large "mosquito fleet" commerce covering the intricate ramifications of Puget Sound and tributary inland waters, serving the suburban vicinity and the industrial and agricultural communities of the Puget Sound region, which always included more than one-half the population of Washington;

(2) A coast-wise, inland waters, and deep-sea commerce with British Columbia and Alaska, and with the California port; and,

(3) A trans-Pacific commerce initiated by the Great Northern Railway in connection with a Japanese steamship company in 1896, and, later, with its own great American cargo steamer, the *Minnesota*. There was occasional service by British companies in the Oriental trade; also,

(4) An industrial commerce in lumber to South American, Australian, and other Pacific markets, and some small share of the grain shipments from the Inland Empire to the United Kingdom and Europe.

The port facilities for the handling of this growing volume of commerce prior to 1911, had developed from the original Yesler Mill Wharf of 1853, around which the city was founded, to a considerable magnitude by 1889, when an $8 000 000 conflagration destroyed the central business section, including the entire water-front, with perhaps $1 000 000 of wharves and warehouses. All were rebuilt on larger scale in 1889-90 and expanded to meet the growing needs of commerce. Before 1911 and public port organization, there had been developed about thirty wharves and piers, owned by railroad and steamship companies, industrial concerns, and a few commercial dock companies, all privately owned and operated, under slight degree of regulative State authority in some cases.

The extent and growth of these port facilities prior to 1911, may be gathered from the statistics of 1910 as compared with those of 1890 as given in Table 1.

TABLE 1.

	1890.	1910.
Seattle population	42 837	233 194
Water-borne tonnage	430 260	860 000
Value of shipments	$48 000 000	$96 091 040

During this 20-year period, while the population increased fivefold, the volume of port commerce only doubled. It was evident to all studious observers for several years prior to 1910 that commercial development was not keeping pace with the rapid growth of the city. It became apparent that the port facilities and equipment were inadequate to attract and hold increasing commerce. The Panama Canal was approaching completion, and it was plain that it would mean a re-adjustment of routes of commerce. Looking north and south, Seattle saw every Pacific port from Vancouver to San Diego, planning great port improvements, backed by the public credit of their communities. With freight rates from the interior on a practical parity to all Pacific ports, and trans-Pacific ocean rates identical from all to Oriental ports, with a likelihood of similar parity in intercoastal traffic with the oncoming Panama régime—it was clear that those ports which offered commerce the most adequate facilities and efficient service at the lowest cost would hold their own and go forward in the new era of world commerce which impended with the opening of the Panama Canal; and, *contra*, that any port which failed to prepare for the new era would find itself left in the race.

Seattle girded herself to prepare for this new era. It was obvious that private investment could not be induced or attracted to meet the situation.

With tariff rates, necessarily fixed by competition with other Pacific ports, all backed and supported by public credit and taxations, as required, there could be no profit in constructing port facilities in advance of their need, sufficient to invite investment of private capital in common-user water-front terminals. It was absolutely necessary that there be authority for public port organizations in the State of Washington, if it was to hold its own with the public ports of British Columbia, Oregon, and California.

Civic committees besieged three State Legislatures, in 1907, 1909, and 1911, before gaining the required general law of port authorization. Briefly, the law enables any harbor district, including part or all of a county, to organize by vote of the people, as a port municipal corporation, endowed with the public credit up to 3% of the assessed total of taxable resources of the district, with taxing power for debt charges and up to 2 mills per year for any port purpose. The port is managed by a commission of three, one elected annually for a 3-year term. Port development must proceed on a comprehensive plan, with specific units of improvement, adopted by majority vote of the electors of the district, and bonds for indebtedness by a 60% vote.

The Port of Seattle was the first to avail itself of this authority and was organized in September, 1911. Tacoma, Bellingham, Everett, Gray's Harbor, Olympia, Port Angeles, Port Townsend, Longview, Vancouver, and several smaller harbor cities of Washington have applied the same general law.

Progress of Port of Seattle

Space forbids the detail description of the accomplishments of the Port of Seattle in its fifteen years of history. Seven port terminals and equipment affording service for the varied needs of commerce have been provided at cost of about $9 000 000, with an eighth terminal site purchased for $600 000, and an area of State land valued at $600 000, dedicated free for port industrial sites. Most of the construction was done before World War prices prevailed, and even with full allowance for depreciation, the present (1926) value of port properties and improvements is at least $12 000 000. These terminals include:

(1) Salmon Bay Terminal; headquarters for fishing fleet; industrial sites, etc.; present value	$600 000
(2) Smith's Cove Terminal; two great ocean piers, 40 and 41; largest in world; special equipment for heavy lifts, facilities for oils, molasses, etc.; industrial area adjoining; present value	3 400 000
(3) Bell Street Terminal; central water-front wharf; four-story concrete warehouse and office buildings; six-story, 80 by 104-ft. cold storage annex; present value	960 000
(4) Marion Street Ferry; single slip landing; two-story business and office frontage; present value	110 000
(5) Stacy-Lander Terminal; double wharf, with transit sheds and two-story warehouse frontage; four-story concrete warehouse, 78 by 318 ft.; present value	1 050 000
(6) Hanford Street Terminal; 1 000 000-bushel grain elevator, conveyors, and water-side loading facilities; wharf and two-story transit shed; present value	1 100 000

(7) Spokane Street Terminal; wharf and two-story transit shed, 90 by 882 ft.; two-story salmon warehouse, 147 by 514 ft.; fish-freezing and storage facilities, 121 by 172 ft., and 101 by 109 ft.; ice storage, 5 000 tons; cold storage building, seven stories, 147 by 195 ft.; compressor, refrigerating, and ice plant; present value $1 300 000

(8) Unit No. 15; central water-front site, 26 acres; cost, $600 000; present value..... 1 800 000

(9) Canal waterway (vacated); industrial sites..... 600 000

Since these public port facilities have been added to the service of commerce the development during fifteen years may be summarized as in Table 2.

TABLE 2.

	1910.	1925.
Seattle population	237 174	400 000*
Water borne tonnage	860 000	7 995 083
Value of shipments	$96 091 040	$730 668 972

* Estimated.

Since the organization of the Port of Seattle, the population has almost doubled, while the volume of water-borne commerce has increased eightfold. Manifestly, this remarkable commercial progress did not result entirely through the efforts and operations of the Public Port Corporation, but it is capable of utmost demonstration that the organized Port of Seattle, sustained by the public credit, made possible the provision of modern port facilities, attracting new and varied forms of commerce, presenting a community front to the whole world of trade, and stimulating the older forms of private initiative to expansion and larger activities. It has been the policy of the Public Port Corporation not to supplant but to supplement existing facilities; to plan and build in advance of need, and especially to develop new lines of commerce to swell the community total.

All the public port facilities, except the second and larger Pier 41 of the Smith's Cove Terminal, were planned, constructed, and ready for service by 1914, the year of the completion of the Panama Canal. The Port of Seattle was prepared and equipped to meet the new era of re-adjustment of world routes of commerce; but the clouds of war suddenly impended and four years of world conflict absorbed all energies. Normal commerce was destroyed or brushed aside, but an abnormal war commerce, meeting emergency war needs, sprang into existence. Shipping from the Orient, the East Indies, and India, driven from its normal Suez route to Europe by the torpedo menace in the Mediterranean Sea and South Atlantic Ocean, turned eastward to the Pacific ports of America and the protected routes eastward under neutral auspices. When the United States entered the war in 1917-18, the volume of war supply commerce was vastly augmented. The Port of Seattle, with its strategic location, new port facilities, and adequate equipment, seemed as if providen-

tially prepared for the service of this abnormal period. Its commerce suddenly swelled to a volume of foreign trade second only to that of the premier American port, New York. Without suggestion of profiteering, the Port handled this tremendous volume of war-period commerce, with financial return sufficient to carry the entire public investment without need of supporting tax levy, creating also a surplus of almost $1 000 000 which was available and applied to additional port improvements without need of bonds and debt.

Re-Adjustment and Revival

After the war came the slump and re-adjustment period. The war commerce faded away like a dream, and the awakening of America and the world to a commerce rebuilt from the bottom was a slow process. The Port of Seattle was prepared for this new era and progress has been steadily upward. The upward turn came in 1922, since which time the record of water-borne commerce, foreign and domestic, shows as follows:

1922	5 888 044	tons
1923	6 662 889	"
1924	7 886 137	"
1925	7 995 083	"

During this post-war period the public terminals of the Port of Seattle have been maintained and operated with the financial showing noted in Table 3.

TABLE 3.

Port of Seattle.	1921.	1922.	1923.	1924.	1925.
Earnings	$877 521	$920 591	$964 988	$1 059 374	$1 054 201
Expenses	657 493	712 284	737 742	772 298	716 451
Operating gain	$220 058	$208 307	$227 341	$287 076	$337 750
Interest and depreciation	$469 872	$511 864	$467 308	$463 718	$468 065
Net loss	$249 814	$303 557	$240 067	$176 642	$130 315

It may be noted from Table 3 that the sum total of these annually decreasing net investment losses for the five years, 1921-25, approximately equal and offset the net investment surplus accumulated during the preceding five years of abnormal war commerce. Considering, therefore, the entire period from the initiation of operations following the construction period of 1912-13, up to and including 1925, the Port of Seattle has been self-sustaining, carrying the full investment of the public credit, without tax support for any of its operations. The Port is now fully established as a going concern, on a sound financial basis, facing a future of continued expansion to meet the largest demands of commerce with ample resources and credit.

It will be interesting to note the sources and destinations of the 7 995 083 tons of commodities water-borne to and from the Port of Seattle in 1925, as follows:

Domestic (U. S.) Commerce:

	Tons.
Puget Sound and local	3 408 239
Pacific coastwise	2 223 233
Atlantic ports	594 639
Alaska	395 503
Gulf ports	54 636
Total domestic tonnage	6 676 250

Foreign Commerce (also, Hawaii and The Philippines):

Orient, Japan, China	404 685
British Columbia	260 327
United Kingdom and Europe	135 663
Hawaii	97 602
Philippines and East Indies	85 262
South and Central America, Mexico, West Indies	42 034
Australia and New Zealand	36 624
Canada, Africa, and all others	264 318
Total foreign tonnage	1 318 833
Port of Seattle, 1925 tonnage	7 995 083

Exports and Imports

Illustrative of the service of the Port of Seattle to the producers and industries of its vicinity and tributary hinterland, the following are some of the commodities exported in foreign trade:

914 683 boxes of apples.
5 622 tons of automobiles.
8 282 tons of canned goods (except fish).
22 692 tons of coal and coke.
13 040 tons of raw cotton.
42 984 tons of fish, canned, pickled, etc.
62 406 tons of flour.
13 361 tons of fodders and feed.
1 339 734 bushels of grain.
12 210 tons of hardware, iron and steel manufactures.
140 325 million ft., B.M., lumber, logs, piling, etc.
4 903 tons of machinery.
9 114 tons of canned milk.
13 932 tons of crude oil and products.
14 746 tons of paper.
3 340 tons of potatoes.
7 767 tons of tobacco.
4 214 tons of wood manufactures (except furniture).
6 795 tons of chemicals.

These are the leading items in a total of 649 581 tons exported (foreign) from Seattle. More than twice this total of these and other commodities are exported (domestic) over Seattle wharves—1 333 082 tons of domestic exports.

Foreign imports through the Port of Seattle in 1925 totaled 669 252 tons, of which some of the leading items were:

11 200 tons of burlap and bagging.
26 954 tons of cement.
91 270 tons of coal and coke.
19 834 tons of coal-tar and products.
2 634 tons of coffee.
3 553 tons of cotton, raw and waste.
4 626 tons of fodders and feed.
1 239 tons of glass.
71 514 bushels of grain (except rice).
5 396 tons of hemp and jute.
12 455 tons of iron and steel.
6 675 tons of lime and plaster.
6 399 tons of minerals.
42 899 tons of oils (bean, cocoanut, peanut, wood, etc.).
30 278 tons of paper.
9 720 tons of peanuts (and other nuts).
9 432 tons of porcelain and pottery.
3 534 tons of seeds and bulbs.
7 736 tons of shingles.
14 597 tons of silk, raw and waste.
2 809 tons of sugar.
13 468 tons of syrup and molasses.
4 613 tons of tea.
4 919 tons of wood, pulp and paper stock.
6 446 tons of carpets and rugs.
1 849 tons of prepared eggs.
$444 089 value of furs and manufactures.

The domestic imports to and through the Port of Seattle reached a 1925 total of 5 343 167 tons, eight times the foreign volume.

Seattle Realizing Its Destiny

As an evidence that Puget Sound and the Port of Seattle are winning the commerce of the great trade route between the Occident and the Orient, the 1925 record shows that Oriental commerce with American Pacific ports, compared on a tonnage basis, is distributed, as follows: 39.7% through Washington ports; 32.0% through Oregon ports; and 28.3% through California ports.

When the comparison is based on valuation rather than tonnage, the northern route to Puget Sound—shorter by 281 miles than the northern route from San Francisco to Yokohama, and by 1 230 miles as compared to the southern route from San Francisco *via* Honolulu—the strategic location of the Port of Seattle is emphasized by the fact that the silks of the Orient, at the rate of $229 000 000 in 1925, were drawn across the short North Pacific route, whereas less than one-quarter of that volume used the longer route *via* the Golden Gate.

Witness, then, the dream of centuries realized in the actuality of to-day, and the vision of a greater to-morrow. American railway systems converging

on Puget Sound and the Port of Seattle serve the old European Occident and the New World of Columbus in trade relations over the shortest Pacific path to the hundreds of millions of the Orient. The fabled "Straits of Anian" of the Sixteenth Century and the demonstration of Puget Sound in the closing Eighteenth Century, have, in the dawning of the Twentieth Century, revealed a "Northwest Passage" beyond the hopes of Drake, the dream of de Fuca, and the achievements of Vancouver and Gray. And the Port of Seattle stands at the gateway to serve world commerce.

DISCUSSION

D. W. McMorris,* M. Am. Soc. C. E.—There was a very interesting incident in connection with the development of the Port of Seattle, that Mr. Cotterill has not touched upon; the so-called "Bush Terminal Plan of Improvement", that was developed by a number of persons who desired to obtain control of practically all port facilities.

There was a strong sentiment among the more progressive and aggressive members of the community to provide such ample and convenient facilities for trans-oceanic shipments of freight and merchandise as to care for not only all business that would probably reach the port, but also to offer special inducements to new business seeking a Western shipping terminal.

Much was said about the type of development that had been in successful operation at Brooklyn, N. Y., by the Bush Terminal Dock and Warehouse Company.

The report on the "Plan of Seattle" had been recently made by the late Virgil G. Bogue, M. Am. Soc. C. E., with whom the speaker had been associated, laying out a similar plan of development on Harbor Island. "The Harbor Island Terminal Company" was formed and a tentative agreement prepared setting forth with considerable detail the plan of development and the terms of a proposed lease of all the Port's property on Harbor Island.

The effect of the proposed agreement was to have the Port provide the funds necessary to carry on an elaborate construction program and then lease the entire Harbor Island project to the Terminal Company. The sentiment in favor of the project was so strong that it was seriously proposed by some that the Commissioners' regular program give way to the Company's plan which would have made the Port merely a means of financing the promoter's project.

Finally, the alluring possibilities of the Harbor Island plan were set aside and the Port development proceeded on more conservative lines. The speaker has always felt disappointed, however, that some way was not found to modify the proposed agreement with the Harbor Island Terminal Company so as to have justified the Port Commission in having had the development completed, as it is certainly an ideal location for such an improvement.

Joseph M. Clapp,† M. Am. Soc. C. E.—In his interesting and valuable paper Mr. Cotterill may have left the impression that the Port of Seattle owned all the water-front area and had developed part of it at a cost of about $10 000 000 which, together with certain areas deeded the Port from the State, made the value of the Port property about $12 000 000. The citizens of the District were not unanimously favorable to the development as at present accomplished.

Seattle Port is one of the land-locked harbors of Puget Sound on which a large commercial city is located. There are five such harbors or ports, all located on the mainland and at the mouths of rivers draining into Puget

* Asst. City Engr., Seattle, Wash.

† Cons. and Contr. Engr., Seattle, Wash.

Sound. Puget Sound has a coast line of approximately 2 000 miles composed of a ribbon of sand, flanked on one side by high bluffs and on the other by deep water. Six important rivers empty into the Sound and drain important valleys which constitute the gateways from the back country. Here are found extensive flat areas on which the cities are built.

The City of Bellingham is located near the mouth of the Nooksack River; Everett, at the mouth of the Snohomish River; Seattle, at the mouth of the Duwamish River; Tacoma at the mouth of the Puyallup River; and Olympia, at the mouth of the Deschutes River. No city is built at the mouth of the Nisqually River.

At the mouth of the Duwamish River the flatlands of Seattle were reclaimed, and a large industrial area was created with harbor and waterway frontage provided, all at the south end of the harbor, perfectly landlocked from prevailing storm winds, except an occasional "Northwester". It is here that many of the citizens thought the development of the Port should have been concentrated and ocean piers constructed.

These piers would naturally have followed very closely in design the piers built at Smith's Cove and at the East Waterway. The adjacent areas were available for small and large factories, and this arrangement would have lessened the congestion of freight shipments, now experienced.

Building the piers in this flat area would have lessened the overhead maintenance and left the immediate city water-front for the mosquito fleet and coasting vessels. Many other factors of economy would have resulted. Three of the four transcontinental lines enter Seattle from the south and one from the north. Thus, the location of the piers in the south end of the harbor would have resulted in a single line of railway to handle freight at this point, instead of the three lines now obliged to handle a large part of their ocean freight to the north and less protected area. The movement of freight along the water-front from south to north, as at present, creates considerable confusion which is intensified when ocean vessels dock at the central front.

While the Port owns and operates the twelve various developments they are not operated at a profit, but at a loss. All this loss is borne by taxing the property lying within the district. The taxpayer derives some benefit, of course, because of the increased shipping with modern and adequate facilities for handling it. This district also comprises water-front property, privately owned, which is taxed to support a competitor.

Charles Evan Fowler,* M. Am. Soc. C. E. (by letter).—The very considerable part played by the writer in the formation of the Port of Seattle, causes him to read with much interest of the complete success of this municipal undertaking. As a member of the Harbor Committee of the Seattle Chamber of Commerce, the suggestion was made in 1911 of forming an unofficial Seattle Harbor Commission. About fourteen organizations appointed members, and these with the Mayor, the City Engineer, and the Corporation Counsel composed the body which planned the Port of Seattle, and secured the passage of the State law authorizing such legal municipal bodies for

* Cons. Engr., New York, N. Y.

any of the ports of the State, comprising either the entire county in which the port was located, or such portion of the county as might be set apart for the district which was to be subjected to taxation for creating the port properties.

The Committee that drew the law, consisted of Corporation Counsel Scott Calhoun, the late A. O. Powell, M. Am. Soc. C. E., and the writer, who believed the district should be greater than the city and less in size than the county, in order to keep it out of local politics. When the Port was organized, it was as the entire County of King, and notwithstanding this, it is pleasant to record that most of the members during the past fifteen years have been free from political influence. The writer, as Acting Chairman of the Engineering Committee of the unofficial Commission, during most of the formative period, gathered information from all over the world, and made trips to Portland, Ore., San Francisco and Los Angeles, Calif., Chicago, Ill., New York, N. Y., Baltimore, Md., and Washington, D. C., in search of data as to methods of organization and construction in use in the various ports.

This Committee also made plans and estimates of cost of sea walls, piers, warehouses, and all the appurtenances of a port, and it was upon these data that the first $6 500 000 was fixed for the initial units. The Committee favored one large concentrated terminal, preferably at Harbor Island in Elliott Bay. The first official Commission of the Port of Seattle was very fortunate in having as a member the late H. M. Chittenden, Brig.-Gen., U. S. A. (*Retired*), M. Am. Soc. C. E., and he as first Chairman was also in favor of a concentrated terminal. However, local politics did have a say and, as a result, part of the port improvements are on the East Waterway, part on the old water-front of the city at Bell Street, and part on Salmon Bay, or on the Lake Washington Canal. Later, the great concentrated terminal at Smith's Cove was begun, and the full development of this has dwarfed the smaller scattered units, which now only add to the cost of administration.

The smaller units, however, serve the separate districts well in providing space for the vessels in the Puget Sound, coastwise, and Alaskan trade, and the fishing fleet. While the business of the port proper is not a great factor in the growth of a port city, it is likely that these small units are more effective in increasing local business, than is the large terminal at Smith's Cove, where exchange is made from the ocean ships to the rail lines. The City of Seattle should be able to answer much better than the older ports, just how much the meeting of ship and rail lines has to do with the making of a metropolis, but in so doing full value must be given to the lumber and Alaskan trade, and to the business carried by the great fleet of smaller vessels plying the waters of Puget Sound.

This is work for the statistician and the port engineer that will be of great value in the future development of coast cities, and in the furtherance of the commerce which passes through them. Certain it is that the great ocean commerce of the future will be found on the Pacific, and this will add in untold measure to the land commerce west of the Mississippi River.

Paper No. 1681

BASIC INFORMATION NEEDED FOR A REGIONAL PLAN*

By Harold M. Lewis,† M. Am. Soc. C. E.

With Discussion by Messrs. Russell V. Black, George F. Unger, Arthur A. Shurtleff, Hale J. Walker, Joseph W. Shirley, Guy Wilfrid Hayler, William Bowie, Howard Strong, Charles W. Eliot, 2d, U. N. Arthur, Charles Wellford Leavitt, Harland Bartholomew, Donald M. Baker, Harry J. March and Harold M. Lewis.

As the concentration in cities has increased and the size and complexity of the individual city have grown beyond anything that could have been foreseen a few years ago, it is only natural that the scope of planning has also increased. Starting with a concentration on the civic center, planners enlarged their activities to the comprehensive city plan; then they studied the environs and grouped together two or more closely related communities in the regional plan. The State of New York has made studies for a State-wide plan and articles have been written in regard to a National plan. The writer has been asked to describe the type of material that should be assembled as a basis for determining the elements of a regional plan.

Most of the published information on city and regional planning gives the conclusions and details after the plan has been completed, or describes methods of co-operation or publicity necessary to carry out such projects. A description of the basic data required and the form of presentation is likely to be considered a matter of routine work which is probably standardized and almost surely uninteresting. When a large regional planning project is undertaken, however, the collection of this material becomes so huge a problem that it is well worth while to have it carefully planned and organized. A paper of this kind can only attempt to point out the "high spots" of the subject, it being understood that a large amount of subsidiary information

* Presented at the Joint Meeting of the City Planning Division with the American City Planning Inst., Philadelphia, Pa., October 7, 1926.

† Executive Engr., Regional Plan of New York and Its Environs, New York, N. Y.

must also be gathered. It is based primarily on an analysis of what has been accomplished toward developing a regional plan for New York and its environs. Although some of the steps described may seem to be unimportant details, most of them represent the result of careful experiment and, as such, should be of some value to the professional regional planner.

It seems desirable first to give some attention to the definition of a "regional plan". By a "region" is meant a group of separate communities which form a single metropolitan district with common interests. This, as a rule, will center about a large port or manufacturing headquarters. Obviously, the "plan" should comprise only those details which have some importance in the development or welfare of the entire region, or in the promotion of the orderly and efficient development of one of its integral parts.

Mr. Edward M. Bassett has defined the city or regional plan as "the determination of land areas stamped with definite characters by law", and points out that the community or region establishes its own plan through its legislative body or bodies. This is true of the legally adopted plan which will have positive control over future growth, but that must be preceded by planning studies which should be defined in greater detail. The late Nelson P. Lewis, M. Am. Soc. C. E., in a paper* entitled "Regional Planning" has stated that when he used this term he had in mind the following type of studies:

"Larger areas must be studied and instead of beginning with present centers and providing for expansion outward, absorbing one after another of outlying towns and villages, it is time to begin at the outer edges of a great metropolitan district, to study existing communities and strive to encourage the development of their centers, to create new social, commercial, and industrial centers, and strive to protect what is worth saving from being drawn into the vortex at the big center and absorbed bodily by it, with no line of demarcation and with no barrier to the steady outward movement of population."

The writer would suggest the following definition:

"A regional plan is one for the co-ordinated physical growth of a group of communities forming a single metropolitan district, based on the most desirable and efficient development of the whole region."

A summary of the type of data required is necessarily largely a list of headings, but is important to those who are organizing a regional plan. The following classifications are essential: (1) Physical; (2) economic; (3) social; (4) legal; and, (5) financial.

A combination of graphic, statistical, and descriptive presentation is required. The physical survey is the largest and most complicated undertaking, as it includes the preparation of those maps on which the planner must base the details of the regional plan. It might be called a survey of existing conditions, both visible and officially mapped. What is included under this heading and the form in which it should be presented will be described in considerable detail. The material required under the other four headings will only be very briefly outlined. This does not mean that they are unimportant, but they are largely supplemental. Each type of investigation

* *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 1326.

can be expanded into many sub-headings, some of which may lead the investigator far afield. Each should be tested by the following questions:

1.—Should this appear in a final report?
2.—Is it essential in order to arrive at conclusions that must be incorporated in the final report?
3.—Will the expense of obtaining it be practicable and justified?

The Regional Plan of New York and Its Environs is a pioneer project in its immensity. Started in 1921, it did not reach until 1925 a stage where it was felt that surveys and the gathering of data should be subordinated to planning studies. Much information has probably been obtained that will remain buried in the files. As there was no past experience of a comparable project to serve as a guide, this was unavoidable. Other communities can save time and expense by profiting from the experience in New York. Smaller and less complicated communities will probably not require as many types of information as have proved most useful in studying this particular problem. The Committee on a Regional Plan of New York and Its Environs was organized by the Russell Sage Foundation, which is a National organization with National interests. It was justified, therefore, in doing considerable research work along such lines as:

(*a*) Highway capacities under different conditions.
(*b*) Recreation space requirement standards.
(*c*) Length of haul of motor vehicles and transit lines.
(*d*) Standards of population and housing density.
(*e*) Variation in riding habit on transit lines.
(*f*) Model plans for a neighborhood unit.

It is hoped that some of this information may be of value to other communities. It must always be used, however, with due allowance for a difference in living conditions, habits, etc.

The main sub-headings under each of the five types of studies referred to are as follows:

Physical Survey.—

1.—Topography, boundaries, and other such basic physical features as influence the plan.
2.—Population—distribution, density, and rates of growth.
3.—Communication facilities:
   (*a*) Highways;
   (*b*) Transit—rapid transit, trolleys, and motor buses;
   (*c*) Transportation system—somewhat arbitrarily defined as including the railroad, waterway, and airway systems.
4.—Parks, parkways, and other open spaces.
5.—Sanitation—water supply, sewerage, and refuse disposal.
6.—Port and industrial development (will overlap with communication facilities).
7.—Miscellaneous, including such as:
   (*a*) Zoning (land uses established by existing zoning ordinances);
   (*b*) Land values;
   (*c*) Location of public buildings;
   (*d*) Power supply facilities.

Economic Survey.—A study of the history of the principal industries within the region should determine:

1.—Trends in location.
2.—Probable space demand in the future city.
3.—Probable future relative importance.

Social Survey.—

1.—Housing.
2.—Recreation.*
3.—Schools.
4.—Public health and sanitation.*
5.—Correctional institutions.

Legal Survey.—

1.—Ascertainment of city planning powers of the various political units.
2.—Study of new legislation needed to carry out the regional plan.

Financial Survey.—

1.—Cost of public improvements and methods of assessment.
2.—Distribution of funds available.

The first item to be determined is the area to be studied. This may vary greatly for different regions. It should be large enough to include all those communities, the business and recreational life of which are linked with the principal business center. It should include any of those suburbs from which an appreciable number of commuters travel daily to the business center. It should extend far enough to take in all industrial plants which are directly served by, and linked with, a common port. It should also contain those larger recreational spaces which are within easy reach by rail or automobile of the city or suburban dweller. The area studied in the New York Region corresponds roughly to that within a 50-mile radius of New York City Hall. On the north it extended approximately 60 miles, on the south, about 40 miles, and on the east all of Long Island was included, although it extends about 110 miles from the center of New York City. As a general rule, the area of a regional plan may vary between that within a 10 or 50-mile radius from the metropolitan center.

Maps of the entire region should probably be prepared on at least three different scales. These maps might be defined as follows:

1.—Regional table maps, by which is meant such maps as can readily be prepared and studied on an ordinary drafting table. On a scale of 1 in. = 2 to 3 miles.
2.—Regional wall maps. On a scale of 1 in. = 1 mile for a very large region, and perhaps on the scale of 1 in. = ½ mile for smaller regions.
3.—Detail sectional maps. On a scale of 1 in. = 2 000 ft. for large regions, or about 1 in. = 1 000 ft. for smaller ones.

Where particularly difficult problems require a local study, larger maps must be prepared of the areas concerned, on scales of 1 in. = 100 to 1 000 ft.

Each of these classes of maps should contain different types of data presented in different forms.

The so-called table maps should be merely outlines on which a single type of information should be shown. On such maps should be presented popula-

* Items 2 and 4 will necessarily overlap with the "Physical Survey."

tion statistics, existing railroad, rapid transit, and waterway systems, parks and parkways, and all the material necessary to study the regional aspects of all the items covered by the headings listed under "Physical Survey."

The regional wall maps will serve primarily for group discussions of the main elements of the regional plan and for exhibition purposes. They should contain the principal topographic features (in the New York District, which has elevations from sea level to more than 1 600 ft., 100-ft. contours were sufficient), the principal communication and recreation facilities, and one main feature which should be strongly emphasized. In the New York study, these maps were about 10 ft. square, and it was found desirable to have one of them to emphasize each of the following features:

1.—Highways.
2.—Railroads, including the main rapid transit systems.
3.—Parks and parkways.
4.—Sanitation, including water-sheds used for water supply and the location of sewage disposal plants.
5.—Land uses.

An excellent method of using these maps for planning studies is to have them covered with a transparent celluloid coating after all the existing features have been added. This coating can be worked upon in water or oil colors, crayons, or a soft pencil, and proposed facilities can be tentatively added in this way. Such information can be wiped off with a wet or oily rag and revised at will without any damage to the map beneath. The coating also acts as a protecting covering.

The detail sectional maps might be called the base maps of the regional plan. They should show in considerable detail the topography, street system, streams and waterway systems, transportation systems, parks and parkways, political boundaries, pier-head and bulkhead lines, and principal existing land uses. It is upon such maps that details would be worked out after their importance was determined from study of the regional wall maps. From them final sectional maps might be reproduced at smaller scale for publication. It has been found that these maps are not very suitable for discussion at conferences, as such discussion is likely to be sidetracked on detail locations which would not be apparent on maps of smaller scale. The regional importance of any proposal cannot be readily grasped unless it is on a map all parts of which can be readily seen at one instant. The 2 000-ft. scale maps prepared of the New York Region formed a map about 18 by 20 ft. in size when assembled. Such a map is effective in an exhibition, but is too large to use as a basis for serious discussion.

It was made up of enlargements from twenty-three of the standard Government topographic sheets. They were prepared at cost for the Regional Plan Committee by the U. S. Geological Survey and corrections in the shore lines, railroads, main highways, and larger park areas were incorporated. They were printed in three colors, with a few copies without the contours, some of the latter being printed in non-photographic blue. All but the outer edges of the region were covered, and as the Government sheets, 1 mile = 1 in., were the only ones available at uniform scale for a large part of the territory

outside New York City, there has been considerable local demand by official bodies and individuals for copies of the sheets. Part of their cost, therefore, has been recovered by the sale of some of the copies.

Three complete maps are being prepared on copies of this base map. Each map includes six sections made up from four (in one case, three) of the 2 000-ft. scale sheets. These maps are about 6 by 7½ ft., which is about as large as can be readily used. Joining these maps with additional sections for title and legend, respectively, the 18 by 20-ft. rectangular map already referred to, was obtained.

The first of these maps showed existing land uses classified as follows:

Industrial areas.
Principal business areas (in communities of more than 25 000 population).
Close residence development.
Parks and parkways of more than 25 acres and forest and water supply reservations.
Golf and country clubs.
Cemeteries of more than 25 acres.
Large public institutional properties.
Aviation fields.

} Shown by same color with different symbols superimposed.

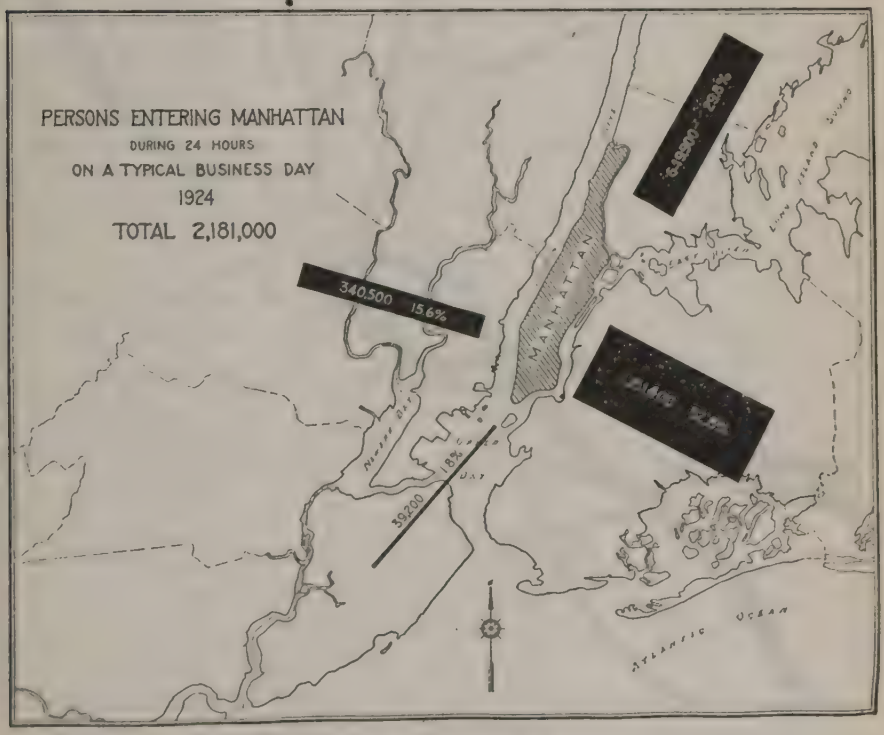

Fig. 1.—Study of Passenger Movement.

The classification of the first three groups was largely a matter of judgment and was intended to show the type of use which predominated in any

particular area. Airplane maps and oblique views were found to be very useful in the preparation of this map, and it was constantly revised as more complete information was obtained. It was necessary, therefore, to use colors that could readily be changed, and flat tints, obtained by rubbing in powdered school chalk with a piece of chamois, were found to be very satisfactory. They can be readily removed with an ordinary soft eraser.

The second map was a composite of all proposals for communication facilities of regional importance (as shown, for example, in Figs. 1 and 2) which seemed worthy of serious consideration, including those put forward by other bodies and individuals and developed by the Regional Plan Staff. This was found invaluable as a basis of discussion of the relative merits of highway, railroad, transit, and waterway projects.

FIG. 2.—STUDY OF FREIGHT MOVEMENT.

The third map has been called the draft regional plan and is a first attempt at co-ordinating all proposals for land uses, communication facilities, waterfront and port development, sanitation, etc. It is necessarily complicated,

but it has been found essential to present all such proposals on the same map so that they can be properly co-ordinated and their interdependence understood. It can be considered as the final major step in the accumulation and presentation of basic information. Conferences and discussions will surely lead to many changes in such a map, but if the work to this point has been carefully and thoroughly done the main elements of the regional plan should need only minor changes.

An important consideration in collecting the large amount of material required for a regional plan is the form in which it will be prepared for office use. It is easy to lose a large number of valuable data through filing. It has been very helpful to prepare photostat copies of uniform size of all important maps and bind them in logical sequence. When a particular study is nearing completion, folders have been prepared in letter-size form, which include copies of maps and diagrams relating to a specific subject and descriptive text in typewritten form. From this shape the material can readily be prepared for publication in monographs or bulletins. For the studies other than the physical survey, the material should be prepared in the same letter-size form, but in these cases it will be mainly descriptive, although maps and graphs should be freely used.

Even if the regional planning organization is an official one, a large degree of co-operation between different municipalities is essential for its success. When the organization is an unofficial one, its success depends entirely on such co-operation. It is important, therefore, that a large amount of the basic information be published early in a form readily understandable to both the laymen and the local city planners. For an unofficial body, definite suggestions may well be omitted from the first publications. If the survey material is forcibly presented, the different communities will be assisted in arriving at proper details of a regional plan. Preliminary publications may include the following:

(1) Monographs setting forward the material collected under the main headings of each of the different surveys. These should be largely pictorial, with maps and graphs that can be readily understood by the layman. (In city planning projects such reports may also contain the details of that part of the final plan which bears on the particular phase of the problem to which the monograph is devoted. Excellent examples of this are the reports published by Pittsburgh, Pa., and Toledo, Ohio).
(2) Bulletins on specific problems urgent in importance.
(3) Progress reports designed to keep the various communities informed as to the scope of the work being carried on.
(4) A periodical publication, such as has been published in Pittsburgh and Los Angeles, Calif., may be useful in keeping contact with a large number of individuals.

This general description of the kind of basic information required indicates that a regional plan is complicated. In addition to all such information as can be put down in written or map form, there is also required an intimate personal knowledge of the region, specialized technical ability along various lines, and a wide general knowledge of city and regional planning principles.

These qualifications can seldom be combined in a single individual and regional planning is, therefore, essentially a group project. The eventual plan must be the evolution of a staff working in close co-operation and aided by the best expert advice available. It is necessarily a compromise between conflicting proposals and ambitions of the various communities affected. Although in its final form it may not seem best for an individual community, it probably will prove to be so, as only a well-rounded and balanced plan is practicable.

DISCUSSION

Russell V. Black,* Assoc. M. Am. Soc. C. E.—In formulating a survey program for the Philadelphia Tri-State District regional study many diverse points of view have been expressed. One man of professional prominence advises, "Stop gathering information. Make plans." Another, of equal prominence in his field, remarks on the superficial character of the survey program of the New York Regional Plan, which has spent nearly five years and approximately $750 000, largely in gathering data and getting acquainted with its region.

The Philadelphia District is operating on very limited funds. In the light of planning experience and personal judgment, its members cannot proceed to plan without first learning a great deal more than is now known about their region. On the other hand, they can afford neither time nor money for the collection of unnecessary data, and depending, as they do, on public support, they must show some planning progress comparatively early in the work.

Mr. Lewis has given much helpful guidance as to the extent of material to be obtained and as to survey and study procedure; but the speaker is disappointed in not receiving more specific suggestions as to basic information indispensable to the preparation of a workable regional plan. It may be that the field of regional planning is still too little explored and the problems of the many districts too diverse to offer any very definite general suggestions of scientific approach. However, it would seem that, compelled as they have been to blaze absolutely new trails of survey and research, the several regional planning projects which have made noteworthy progress, must have made some recognizable errors; must have gone up some "blind alleys"; and that, were they to do the work over again, they would go about it somewhat differently. It is this experience which the Philadelphia District would find so valuable and which it has hoped might, in some way, be made available.

From brief experience, two or three conclusions in this matter of survey making have become evident. In the natural development of regional planning from city planning, it is questionable, as Mr. Lewis has described it, if the tendency to "follow the leader" has not led many planners to collect a great deal of thoroughly useless information. In the early and quite experimental age of city planning, men, new to the field, groped about for a formula and some sort of foundation with, and upon, which to erect their future cities. They conceived that certain groups of information might be valuable, and formulated a survey program accordingly. There is some evidence that present methods have not advanced far beyond those first efforts, and that surveys still hold a little of the old chaff that could well be discarded.

The regional plan should not concern itself with matters of purely local character. Local administrations are naturally somewhat jealous of their prerogatives and can usually handle their affairs to better advantage than any outside body. The plan should be limited in its application to those problems and development projects which involve two or more political jurisdic-

* Chf. Planning Engr., Regional Planning Federation of Philadelphia Tri-State Dist., Philadelphia, Pa.

tions, and for the solution and conduct of which no other machinery exists. A Regional Planning Federation, as an agency for the promotion of sound planning, might encourage the proper provision and distribution of neighborhood playgrounds and school grounds; but matters of such local moment should not be made a part of the regional plan. Likewise, it might be a function of a Federation, in furthering the general welfare of the region, to encourage a proper alignment of minor streets, a good width of lot, or the proper distribution of neighborhood store groups; but, again, these things are not a part of a regional plan. Such a plan involves determining the broad uses of land, the completion of a system of connecting and trunk highways, regional and intercommunity parks, regional water supply, the purification of streams, the conservation of natural resources, the broader phases of transportation, co-operative sewage and drainage, and other matters demanding the joint effort of two or more political sub-divisions. It follows that physical data, collected to serve as basis for a regional plan, should be in scale with its purpose, and that, by keeping this scale constantly in mind, a great deal of useless material can be eliminated.

In the field of economic and social survey it is more difficult to know where to stop searching. Too much cannot be known about the laws that govern the conduct of the human race nor of the foundation and controlling forces of an ever-changing economic system. At this moment, every one is pitifully ignorant of the degree to which the modern great city is inherently fundamental to the nature and progress of mankind and the degree to which it is simply a diseased overgrowth. Until more is known certainly of what this phenomenon of city growth is, decentralization of population cannot be adjudged as even desirable; much less can it be attained through present feeble efforts. This is the sort of knowledge needed in order to direct the destinies of great metropolitan areas; but it is the kind of knowledge that requires much more painstaking research than present-day planning organizations can afford in time or money. Fortunately, the knowledge gained in these directions in one part of the country, and to some extent, the world, is almost equally applicable in every other part. Supplemented by a familiarity with the local social and political structure, the general background to be obtained from present-day observation would probably provide as good a sociological basis for regional planning procedure as can be found.

In developing a program, local regional planning has been divided, somewhat roughly, into two steps: Step (1), preliminary, getting acquainted with the region, making tentative suggestions as need may demand, and feeling out and developing public opinion; and Step (2), laying down the master plan, piece by piece, and as based on an exact knowledge of existing conditions and present and probable future needs.

Step (1) is usually attended by small funds and large public skepticism. It must be conducted, not only with the idea of making sound progress, but equally with the object of gaining public attention and approval. A great deal of information, of little purpose other than to awaken public interest, must be collected and appealingly presented. This period is largely educational, with first efforts bent toward pointing out general existing conditions;

the sorry situation resulting from lack of earlier planning and the possibilities of planning for the future. The material collected for Step (1), while necessarily insufficient as a basis for definite planning proposals, should, nevertheless, be such as to serve as a foundation for the more detailed information to follow.

This refers, largely, to physical surveys which might include the topography of land, as given by the U. S. Geological Survey; the distribution and relative density of population, defined by minor civil divisions for several preceding census periods; the larger existing parks and playgrounds, cemeteries, and other potential open places; principal waterways; steam railways, and electric interurban lines; aviation fields; general sewage disposal facilities and character of water supply; extent of public service—gas, electricity, and telephones; other similar classes of data; and, perhaps most important, the broad use of land, including indication of the forest areas, farm lands, open suburban development, sub-divisions not built upon, principal business and industrial areas, large parks, private recreation areas, and large institution grounds.

This should provide sufficient basis for a fairly comprehensive understanding and statement of the condition and needs of the region. Coupled with a reasonable familiarity with the social and economic status of the region and with an appreciation of the bearing of existing legislation, this much of a survey should permit of tentative planning proposals and the first roughing out of the plan. What the schedule of procedure in making these tentative proposals might be, and whether or not the preliminary survey, as outlined, is to be completed before any of the planning studies are undertaken, depends on local necessity. It would seem, however, that at least this much of a picture of the region should be finished before very much planning is done.

Step (2) would involve more specific recommendations and the laying down of a workable skeleton plan with a considerable degree of exactitude. The gaining of public support is no less important at this stage of the work because, without the sympathy and co-operation of public officials and the sanction of the taxpayers, nothing can be accomplished; but the engineering and planning factors must be given more thorough consideration. There should be available at this phase of the study an aero-photographic map of the entire region at a scale not smaller than 2 000 ft. to the inch. There should be an accurate topographic map, in a scale ranging from 1 000 ft. to 200 ft. to the inch, depending on the nature and probable intensity of development of the locality. Each factor of the plan, such as sewage disposal and drainage; water supply; rail, water, and air transportation; highways and bridges; and parks and other recreational areas, would require its special consideration, although closely co-ordinated, detailed, and studied. Perhaps this phase of regional planning should ultimately be directed into the hands of a permanent official or semi-official body, functioning to execute the plan and to keep it adjusted to changing needs.

Such a program (especially Step (2)) is costly, but regional planning is an important undertaking which, if effective, must guide billions of dollars worth of public and private development projects. It holds the possibility of

saving many times any possible engineering or planning costs. Done wisely, no other single instrument offers as great an opportunity for the advancement of the general welfare. Ill-considered and superficially done regional planning holds almost equal opportunity for injury. It deserves, and must ultimately have, all needed public funds and the best engineering, economic, and sociologic thought of the time.

GEORGE F. UNGER,* ASSOC. M. AM. SOC. C. E. (by letter).—It is of great interest and value to have a paper presented on basic information needed for a regional plan. Many cities are growing so rapidly that they are over-reaching their present boundaries, thereby creating a decided influence on the adjacent territory and extending activities to various political sub-divisions, all of which have a common interest. This necessarily involves a treatment of the larger area in the broad sense of regional planning, and when presented to the planners of a metropolitan district, it immediately suggests the formulation of some definite outline of procedure.

The Niagara Frontier Planning Board is significant in that it was created in a way differing somewhat from other regional planning bodies. Legislation was obtained, giving it an official status and providing for a method of financing with public funds, the District included being the political subdivisions of Erie and Niagara Counties. This seemed to be the territory containing communities whose interests are common and whose commercial and recreational life is closely allied with the principal business centers. Subsequent to this legislation, funds were appropriated by the respective Boards of Supervisors, for carrying on the work. The Board consists of twelve *ex officio* members, designated by law, including the Mayors of the six cities of Erie and Niagara Counties and three members of the Boards of Supervisors of each county. The thirteenth member is chosen by the Board and acts as its Chairman.

The area which constitutes this District is about 1 556 sq. miles, extending from Lake Ontario on the north, to Cattaraugus Creek on the south, the Niagara River and Lake Erie on the west, and the county lines on the east, covering a distance of 60 miles north and south and 25 miles east and west, and containing 6 cities, 22 villages, and 37 townships.

Several commercial and industrial centers are located within this District, Buffalo being the largest, with Niagara Falls next, at a distance of 18 miles northwest. Tonawanda and North Tonawanda lie midway between, with Lockport in the northeastern section and Lackawanna bordering on the southern boundary of Buffalo. A portion of Canada contiguous to the Niagara River and lying to the west is also considered in close relationship to this area and planning is being developed to connect it with proposed structures crossing the Niagara River.

The District is divided, by the topography of the land, into four distinct natural sub-divisions: First, the table-land at the north, bordering on Lake Ontario, and extending with a gradual rise in elevation to the Lewiston Escarpment. This section is known as the "Niagara Fruit Belt," being devoted

* Chf. Engr., Niagara Frontier Planning Board, Tonawanda, N. Y.

largely to fruit growing, but with extensive general farming. At the escarpment, the elevation rises rather abruptly from an average of 400 ft. above sea level on the lower table-land to another elevation of 600 ft., running gradually to the south over a considerable area about 800 ft. In this second section are the six thriving cities and a network of railroads, highways, and navigable waters, and within which the tremendous development of the region is largely confined. The third division comprises rolling uplands with elevations from 800 to 1 200 ft., devoted to the dairy industry and general farming; while the fourth division, the extreme southern portion of the District, is fairly mountainous in character, rising to an elevation of 1 900 ft. above sea level. Although some portions of this hilly country are not easily accessible, it contributes liberally to the food supply of the District and also affords recreational facilities, forest preserves, and natural scenery.

While the outline made for obtaining data in this District does not conform exactly with that presented by Mr. Lewis, it carries the same general provisions. It is essential, also, to determine how the information that is collected is to be used in preparing a regional plan.

An accurate base map was first prepared on a scale of 1 in. to the mile, made from the U. S. Geological Survey Sheets, showing highways, railroads, waterways, parks, boundaries of political sub-divisions, and contours at 100-ft. intervals. The size of this map is 42 by 72 in. Base maps of the District were also prepared on a scale of 1 in. equals 2 miles and 1 in. equals 4 miles. Both these scales were used for mapping statistical data in relation to population, valuations, highways, transportation, and traffic. Maps of the cities and villages were prepared on a scale of 1 in. equals 600 ft. and of townships on a scale of 1 in. equals 2 000 ft., these being used for the purpose of more detailed studies in regard to the various communities.

The function of this Planning Board is not only to study the District as a whole, but to devote considerable attention to community planning as well, organizing local planning bodies to carry out the work of their own political sub-division. Due to the fact that this District has only been organized for about a year, most of the time has been spent on the physical survey, mapping the data in regard to topography, boundaries, population, highways, transportation facilities, parks and parkways, water supply, and sewage disposal. This information has been assembled in such a manner and extent as to enable some definite recommendations to be made on problems that have already been developed and require immediate consideration. Detailed plans have been prepared for the purpose of making some of the necessary developments.

Because of the National and International reputation of this District, visited by more than 1 000 000 tourists every year, great importance is placed on the scenic wonders as well as the other available natural resources which include water power and waterway transportation.

One of the most noteworthy projects recently planned, is that of a Regional Parkway System, which will ultimately be developed along the Niagara River. There is located in the Niagara River an island of 28 sq. miles, called Grand Island, lying adjacent to the most rapidly developing section of the District. A straight line drawn from the center of Buffalo to the center of Niagara

Falls, passes through the middle of this large undeveloped area. It seems very desirable to connect this area with the mainland. The construction of two bridges and a highway, crossing diagonally across Grand Island, will shorten the distance between Buffalo and Niagara Falls about 4 miles. It will then be possible to develop a parkway, about 6 miles long, on the western side of the island along the Niagara River. This parkway can be made to connect with the New York State Reservation at Niagara, and the parkway system laid out in and adjacent to Buffalo, thereby forming not only a link in the State Parkway System, but affording a beautiful driveway between the two largest communities. It will ultimately be extended northward along the Niagara River from Niagara Falls to Lake Ontario and southward through Erie County, passing to the east of Buffalo and connecting with Allegany and Letchworth State Parks.

Another project of regional importance recently completed is a highway bridge known as the "Peace Bridge," across the Niagara River at Buffalo to Fort Erie, Ont., Canada. The American terminus of this bridge is in one of the large city water-front parks, which is connected by parkways with the Buffalo Park System, while the Canadian terminus joins a parkway about 25 miles in length, extending northward along the shore of Niagara River to Niagara Falls and Queenstown, where bridges now cross to the American side. The New York State Parkway previously mentioned, is planned so as to make a river drive from Lewiston to Buffalo, comparable with the improvement so admirably carried out by the Park Commission in Canada.

It is impossible in this brief discussion, to elaborate on the work done either in preparing for planning this Region, or the inestimable value of the data already obtained. As the work of gathering the necessary information proceeds, it will be found that the paper presented by Mr. Lewis, will be a guide in obtaining results more efficiently than heretofore, and that other regions will profit greatly by the experience of the planners for New York and Its Environs.

Arthur A. Shurtleff,* Esq. (by letter).—This paper is sufficiently complete to be considered a good example of the kind of data which the engineer of to-day should collect for a great metropolitan area. Some data which at present are considered novel, will become, in later years, a matter of routine. Water supply and sewage disposal were novelties seventy-five years ago. Electric service was a novelty recently, and good motor traffic accommodation is a novelty now.

The writer hazards an opinion regarding one of the new problems that city planners will be forced to consider during the next two or three decades. By that time, it is to be hoped, the accommodation of vehicular transportation will have become fairly commonplace. Architectural excellence undoubtedly will be more general then; and better living and working conditions may be expected. Standardization of these more perfect things, however, will tend to create uniformity, which, on a vast scale, will become objectionable in itself.

* Landscape Archt., Boston, Mass.

Objectionable uniformity is something more than that which merely bores. It is a uniformity which becomes actively oppressive when repeated endlessly, mile after mile, no matter how complete or how attractive the objects may be in themselves. Beginnings of depressing uniformity of excellent things are to be seen in the central portion of the City of New York, and of less excellent things in the Everett-Chelsea-Somerville Districts of Boston, Mass. These depressing uniformities hurt the pleasantness of cities and, to that extent, threaten the continued earning power of the vast sums of money invested in great metropolitan regions, and they hurt the spirit of men.

The era is passing when a great city can hold out unique attractions of a compelling kind to the dweller in country districts. There was a time when great cities were maintained, in spite of heavy death rates, by the influx of families and workers from villages and farms seeking the city on account of its novelties, shelter, culture, entertainments, and its opportunities for social intercourse and employment. To-day, that situation is slowly tending to reverse. The urge from the great cities toward the suburbs and toward the villages is becoming stronger with the development of cheap transportation, with the growth of large isolated industrial plants, with the general provision of schools and hospitals, and with the facilities for ready construction of homes equipped with "modern improvements" of extraordinary completeness. Opportunities for recreation in natural surroundings are also acting as a strong urge toward the towns.

Parks have been built in cities to provide an opportunity to enjoy recreation in rural surroundings. However, parks in great metropolitan cities are gradually assuming a new and exceedingly valuable rôle quite aside from recreation spaces. The mere existence of areas of open ground covered with trees and grass is becoming an enormous asset in breaking up the monotony of great city areas. In most metropolitan cities, strips of vacant private land still remain between the smaller integral cities and towns and give these centers sufficient local separation to save their individuality from complete eclipse in the great fabric of buildings and streets. When town after town becomes closely knitted to its neighbor, as, for example, the Dorchester-Roxbury District, of Boston, and the Brooklyn region, of Greater New York, the entity of villages and towns becomes lost. The resulting monotonous repetition of street upon street and building upon building appals the human spirit and cannot be ameliorated by perfection of transportation, excellence of architecture, street trees, or perfect housing and attractive employment, because each of these good things tends toward its own endless repetitions.

The time is fast approaching when metropolitan regions must include in their budgets monies for the maintenance of large areas of open ground distributed in long strips or winding bands throughout the built-up area to relieve monotony of this kind, quite aside from the recreational value which the ground or the landscapes, contained in such strips, may possess. Vast appropriations for metropolitan thoroughfares are common. Expenditures as great, or greater, for the acquisition of open spaces required to safeguard metropolitan areas from depreciation in value, through an intolerable increase

in monotony resulting from too continuous up-building, are destined to become as common.

In coming years engineers will devote much time to the mapping and classification of vacant lands on the outskirts of cities and towns which are being absorbed in metropolitan districts. Much study will be needed to decide what land shall be saved for permanent strips or bands of open ground; its extent; its relation to the topography of hills and stream courses and low-lands; its contact with adjacent boundary streets and transportation routes; and the most favorable time for its acquisition. Evidently, these strips must be wider, or closer together, in cities which lack varied topography than in those the sites of which are naturally diversified.

The purpose of these costly public acquisitions will be the same as that for which even greater sums are being spent in private enterprises for the mere embellishment of office buildings, stores, factories, and residences; namely, to secure attractive appearance. In these times, not to secure attractive appearance in great private undertakings, means the risk of jeopardizing all the money invested. Mere structural strength, convenience, and comfort are not enough to meet the approval of the public.

The same approval must be reckoned with in great metropolitan areas. Mere convenience of transportation, beauty of buildings, excellence of light and air conditions, absence of confusion in building heights and uses, opportunities for amusement, recreation, and employment, will not be enough to satisfy the man who is enmeshed too completely by walls and streets. He will demand freedom from depressing monotony, or he will go where he can find it, readily and cheaply, in the small city or town the call of which is becoming clearer and stronger each decade.

Metropolitan areas need the most intelligent study and watchfulness which men can apply to them to prevent this call from becoming destructive in its consequences, either to the great treasure of money and culture which is contained in them or to the human beings, counted by millions, who depend on the city as the environment of body and spirit.

Hale J. Walker,* Esq.—In looking over this paper one is impressed by the scope of the outline. Every kind of necessary survey information would certainly find its place somewhere in the various and broad sub-heads.

A definition of "open spaces" would probably be as follows: All types of land, public, semi-public, and private, for the most part not built up in the third dimension, which gives to the region permanent breathing spaces. They have been described by some city planners as the "lungs of the city". Under "open spaces", information should be gathered, giving the location of all public lands, such as parks, parkways, and recreational areas, institutions (Government, State, County and City), town forests, airplane landings, waterways (rivers, lakes, ponds, creeks, swamps, reservoirs, and their catchment areas), and the location of public utilities requiring open space.

In gathering survey material the tendency has been to collect information on all public open spaces and to neglect semi-public and private open spaces.

* Town and City Planner, Cambridge, Mass.

Included under this heading then, will be information giving the location of semi-public and private open spaces that promise permanence, such as private schools and colleges, hospitals, sanitariums, cemeteries, churches, institutions, golf courses and country clubs, boat clubs, airplane landings, fair grounds, historic monuments and sites, commercial amusement parks, professional baseball fields, and swimming pools. There should also be noted that region of large country estates which could be made an effective open space by zoning. Some of the larger industries also furnish this type of open space. A large acreage is often required by gasoline and oil storage companies, furnishing an open space of sorts, but still a factor in the calculation of population density and in determining the character of future built-up areas. Information collected under the other sub-heads may also furnish material for open spaces—existing or proposed.

The topographical plan shows the basic physical features, such as mountains, lakes, forests, and other areas with strong topographical characteristics difficult of changing by the hand of man and particularly adaptable for park use. The mapping of population distribution also bears a direct relation to this subject. There might be added under this heading a collection of data on soil conditions and the mapping of existing agricultural lands. Agricultural belts and wedges have been recommended by city planners as breathing spaces for a large city or metropolitan region. Perhaps since, at present, city planners have no power to zone land to agricultural use, this type of open space may not seem very permanent. Nevertheless, the planner, in some cases, should consider land particularly adaptable for agricultural purposes as an open space, and design his region so as to discourage sub-division and to encourage truck gardening and agricultural pursuits. In designing agricultural land for this purpose, perhaps more intensive development of the area can be held off until it can be legally adopted for agricultural use.

The question of control of private open spaces makes the use of this information a somewhat hazardous problem in the design of a region. Of the list of private open spaces, colleges and cemeteries seem to be the most permanent. The first might fall under Mr. Lewis' heading, "Recreation." The latter holds a doubtful position. It might be considered as a park, but properly it falls under the heading of sanitation. There are instances in California where cemeteries have been re-designed for park purposes. A new type of cemetery is also being designed with park drives, gravestones and monuments being prohibited, so that the finished product is essentially a park. It is not uncommon to find park systems in Eastern cities linked up with cemetery drives.

Scope of Planning Proposals.—The collection of survey material for a certain region will be influenced and guided by the aims and purposes of the designer or designers. Preliminary investigations will bring out the needs of the region and, to a certain degree, the extent of the planning proposals. The scope of planning proposals covering the general topics which are normally included in a regional planning program will guide the collector of survey data so that there will be less chance of gathering data "which will remain buried in the files".

The following outline was prepared for a county regional plan:

SCOPE OF PLANNING PROPOSAL.*

I.—Planning Services.—

(*a*) Preliminary Investigation:

A field investigation or local survey, by the planner and his associates, of the physical features, economic factors, social conditions, customs, and public opinion of the county, county seat, other towns and cities, and adjoining region.

(*b*) County Planning:

(1) Circulation: Lines of communication.

(*a*) Highways:

Comprehensive Highway System: Main highways (State and County); secondary roads; minor or local roads; special drives and boulevards; bridges.

Transportation: Buses; bus stations; trucking; trucking terminals.

Suggested Road Improvements: Widenings, extensions; new roads.

Highways and Road Sections: Roadway widths; planting spaces.

Highway and Road Intersections: Study of important highway and road intersections.

Study of Special Problems in Relation to Highway Traffic.

Development of Highway Views.

Highway and Road Decoration: Lighting equipment; trees and shrubs; paving of roadways; removal of unsightly poles, wires, and signs.

(*b*) Railroads: The Place of the Railroads: Tracks, main lines, local lines, belt lines; stations—passenger, freight; grade crossings and grade eliminations; relation to present and future agricultural, horticultural, and industrial output.

(*c*) Water: Harbor and waterway terminals.

(*d*) Air Terminals: Selection of sites; requirements.

(2) Allocation of Areas for Appropriate Uses:

(*a*) Industry: Type of industrial development to best interest of the county; most appropriate areas.

(*b*) Areas for Colored Population: Present locations; probable future needs.

(*c*) Development of Water-Front (Ocean, River, Creeks, Ponds, or Lakes): Public and private use of shore land; residence; recreation; industry; commerce.

(*d*) Regulation of Land Sub-Division: Methods of securing proper development; acceptance of plats.

(3) Open Spaces:

(*a*) Parks and Parkways: Development of Parks and Parkways: Water-front parks; bird and game sanctuaries; neighborhood, or community parks;

* Covering the general topics which are normally included in a regional planning program. The scope of the proposal, of course, would have to be modified to some extent to meet local conditions.

(3) Open Spaces (*Continued*):

large parks, incorporating natural features as woodland of the region; connecting parkways and boulevards; promenades; park connections; small open spaces.

Linking up Parkways with City Systems.

Correlation of Open Spaces.

The Effect of Parks on Land Values.

(4) Schools:

(*a*) Standard Requirements for School Sites: Grade schools; junior high schools; senior high schools; agricultural schools; special schools and colleges.

(5) Recreation:

(*a*) Requirements of Permanent Population: Possibilities in Recreation: Playgrounds; county golf courses; athletic fields; swimming pools; beaches; piers; sailing and motor boating.

(6) County Building Sites:

Location of Buildings Important to the County.

Advantages of Grouping of County Buildings.

Possible Sites for Administration and Resort Buildings, such as county court house; county auditorium; agricultural hall; county library; branch libraries; county fair grounds; county agricultural experimental stations; county institutions, alms, etc.; county fish hatcheries; aquariums; county jail; county dock; county railroad shipping centers; citrus exchange; municipal cultural centers for farmers.

II.—Zoning Services within the Area of Jurisdiction.—

(*a*) Preliminary Investigation:

Field investigation by the planner and his associates of the present use of land, density of population, height of structures, and public opinion of the county.

(*b*) Zone Plan:

Use Districts: Business; industry; residential built areas; agriculture.

Height Districts.

Area Districts.

(*c*) Zone Ordinance.

III.—Report.—

Typewritten report, with illustrations, setting forth the recommendations and supplementing the studies and plans. Overseeing printing of report for distribution.

IV.—Schedule of Plans.—

(*a*) Existing Conditions Map:

Showing the following: Highways; roads; parks; parkways; schools; playgrounds; public property; railroad facilities; industrial areas.

(A record of existing conditions at commencement of work and basic map for planning studies.)

(*b*) General Planning Study:
Outlines in a broad way the planning proposals.

(*c*) Preliminary Zone Study:
Preliminary districting for various uses of land, height of buildings, and area to be built upon.

(*d*) Study of Major Roads and Highways.

(*e*) Highway and Road Sections:
Suggesting appropriate widths of roadways, walks, and planting strips for the various types of streets.

(*f*) Zone Plan:
Showing proposals for use of land.

(*g*) Major Roads and Highways Plan.

(*h*) Parks and Recreation Areas Plan:
Showing all parks, parkways, boulevards, playgrounds, and park connections.

(*i*) Comprehensive Regional Plan:
Master plan of all proposals. Guide to all future developments.

(*j*) Sketches of Details:
Selected sketches necessary to supplement the general plans.

Joseph W. Shirley,* Esq.—It is evident that the author has given the subject of the requirements for a regional plan much real study, and has completely covered all the essential points. This is highly desirable.

Most cities are not so fortunate as the City of New York in having an organization such as the Russell Sage Foundation, which has been planned to conduct this and other similar investigations. In the majority of cities one great difficulty is to arouse public interest in a study of this kind and to secure funds, either by private subscription or from the public treasury, with which to conduct the investigations.

In the preparation of such a report, great care should be exercised that it be made in a practical, common-sense way, readily understandable to the layman who is not familiar with technicalities. It should not be filled with scientific matter. Furthermore, when the whole problem is presented, its immensity should not be such as to stagger the public and make it hesitate to carry out the recommendations. Another feature not to be overlooked is the item of time. Every one will admit the danger of continuing investigations over such a long period that when the time comes to act much of the information collected has already become out of date.

The data needed, as specified by Mr. Lewis, are highly desirable, but it does seem that each community must modify this information to serve its own needs, bearing in mind not only the appropriations required for the preparation of the report, but also whether the community can stand the expense in carrying out some of the ideals that engineers believe cities should have. After all, is not the public concerned with what is actually to be accomplished as a result of these exhaustive reports? So many cities have been "fed up" with elaborate reports on city planning, traffic, and other features that the

* Engr. of Plans and Surveys, Dept. of Public Works, Baltimore, Md.

inevitable outcome has been to shelve them after large amounts of money have been paid in their preparation. To put it plainly, it means to fit the plan to the pocketbook of the city.

It has only been within comparatively few years that the American public has been interested in city planning. Regional planning is justified by the results which have been obtained, even in these very few years, by proper city planning. However, almost as much missionary work will be needed to convince the community that it should not confine its plans within its present limits, as was necessary to interest it in a study of the area for its own immediate use.

For the collection of general basic data, it is fortunate for the people of this country that such an organization as the Russell Sage Foundation has been established. Much of the information gained by its exhaustive studies, a single community could not afford to collect for itself. The information concerning:

"(*a*) Highway capacities under different conditions
"(*b*) Recreation space requirement standards
"(*c*) Length of haul of motor vehicles and transit lines
"(*d*) Standards of population and housing density
"(*e*) Variation in riding habit on transit lines
"(*f*) Model plans for a neighborhood unit"

outlined by Mr. Lewis, could be accepted by every municipality making a regional study if this information is available to those who desire it.

One of the essential things which should be done by any city contemplating city or regional planning is to supply itself with a thoroughly reliable and complete topographic map. If the regional area is large, a map on the scale of 1 mile to the inch would serve very well. If that area is small, a larger scale map would be more desirable. The making of the proper kind of topographic map is expensive, but this is an expense which cannot be avoided. If there are no U. S. Geological Survey maps, or State maps, available the general map of the smaller scale can often be obtained at a relatively low cost from an aerial survey. These aerial maps can be enlarged and topography added in various neighborhoods as needed. In studies in Baltimore, Md., it has been found, where detail is necessary, that a topographic map on the scale of 200 ft. to the inch works out very well. This scale is small enough to place the situation on a workable size sheet, at the same time covering a large area. From this scale map, work can be carefully planned and many calculations made.

For information concerning population and future distribution of population the zoning maps of the city are very useful. In some cities, public service companies have compiled much valuable data. Many railroads have perfected plans for their future development which are kept under cover for obvious reasons. An effort should be made to secure the confidence of these companies by those conducting the investigation so as to gain this valuable information.

Let engineers bear in mind that results are wanted and that care must be exercised not to spend too much time in making preliminary studies and elaborate reports.

Guy Wilfrid Hayler,* Assoc. M. Am. Soc. C. E. (by letter).—This interesting paper opens up a wide vista of the scope and methods necessary for the successful completion of regional planning work. Regional planning is, as Mr. Lewis states, "a complicated piece of work", and the methods of one locality can not, and should not, be necessarily applied to another locality. Every city and every region is entitled to a personality of its own, and it would be deplorable to standardize cities so that they would be more dull and uninviting than they frequently are. While regional planning may be said to be physical in its groundwork and economic in its approach, there is also an underlying factor to be taken into consideration, that is, the recognition of the "soul of the city". This alone can give any plan "the punch" necessary to make it sufficiently appealing to the taxpayers who have to pay the bill.

The basic information needed for regional planning is necessarily limited by the amount of money that can be expended on research and the personnel of those engaged in the studies. Then, again, the treatment of the subject by an unofficial organization will be different from that of an official authority. From the point of view of research it might be doubted if an unofficial body could do as well as an official body, but there would most certainly be an advantage offered by the former in that it could explore into many unknown fields, initiate new methods, and display greater originality. From this point of view the methods of the New York Regional Plan seem likely to establish many definite features which any regional plans of the future will be obliged to consider. It is very fortunate that the New York plan is being undertaken by such an important body as the Russell Sage Foundation which is National in scope and has considerable funds to prosecute its work. This should stand out as a significant fact to other localities proposing to do regional planning work and proclaim to them that a large sum of money is really necessary and the most highly trained experts are required, if studies and recommendations for regional development worthy of the name, are to result. The greatest failure of city planning in America has been due to the large number of communities that have started on the work with insufficient funds and negligible personnel, resulting in apathy in a very short time and no appreciable record of progress. Unless energetic city planning bodies are operating throughout a region, an all-inclusive planning body for that region is faced with a herculean task. If cities do meet the regional planning body half way, it is surely possible to eliminate many municipal problems and devote the time and money to the better purpose of establishing the wider co-ordination. It is necessary to think of regional planning from this angle if any foundation is to be established for the basic information. Of course, it is assumed that such regional planning is proposed in regions that are fairly well settled and comprise at least one large town or city as a center and scattered towns or suburbs in its sphere of influence. Assuming then, that a reasonable amount of money can be guaranteed over a period of years, and that a number of qualified men are available to undertake research and planning work, the general basic principles can be formulated.

* Planning Engr., Regional Plan Assoc., Inc., for San Francisco Bay Counties, San Francisco, Calif.

The Regional Plan Association of San Francisco Bay Counties has been in existence since 1924 and operates in a district composed of towns and cities of a strong individual character with a surprisingly small civic outlook as the city planner sees it. It has, therefore, been a matter largely of pioneering, where the education of the people comes first, and with it, the grouping of those anxious to undertake the formulation of a wide comprehensive plan. Under these circumstances progress is necessarily slow, and internal city problems which should be outside the general scope of regional planning are first in consideration, owing to the fact that there are no local organizations offering the technical help required. This may be an inevitable situation and it requires some ingenuity to prevent the wider vision from being obscured.

Coming to the matter of finance which is a limitation to research and to anything else, the San Francisco Bay Regional Plan Association has been fortunate in securing the active co-operation of Mr. Fred Dohrmann, Jr., a well-known Pacific Coast merchant, who has undertaken to carry the financial burden until the work has been established. This period is now (1926) drawing to a close as the organization is establishing itself in the nine counties surrounding the Bay. This splendid piece of civic patriotism has enabled the technical groundwork to be laid, together with a commencement on base maps, survey reports, and the promotion of several features of a regional plan.

The work has been built up by establishing the sectional elements of the research required. These are: (1) statistical; (2) streets and highways and traffic; (3) transportation; (4) harbor and water-front; (5) industries; (6) housing; (7) public utilities; (8) public health and safety; (9) education; (10) parks and recreation; and (11) agricultural resources.

While in the main this is understood to be a physical survey, the economic and social sides will be covered in the detailed "working out" of the elements of each particular section, together with the legal and financial aspects. A regional plan may be said to be in essence the ideal plan, and it must be practicable, legally and financially as well as physically, to complete it satisfactorily. Laws, however, can be changed and will be changed if the authorities and the people see that it is to their advantage to change them and, in that sense, the legal side may be said to be of an ephemeral character. Finance, as it is involved in the cost of public improvements and methods of assessment, is also largely a matter of legal enactment once the reasonableness of the cost of improvements is recognized.

In the San Francisco Bay District the sub-divisions of research before mentioned are probably the minimum in extent and yet cover the area of regional development with the least waste of time and money in collecting, verifying, and putting into form the data and suggested improvements. There is no object gained in spending valuable time and money over facts and statistics that are not necessary to prove points at issue, because such facts and statistics are generally obtainable from their original sources by any one who may wish to use them. The writer considers charts embracing the main points of research to be studied as one of the most useful elements in developing planning data and would advocate the wide use of colored pencils on maps used in the field. In the hands of qualified men this will insure a cer-

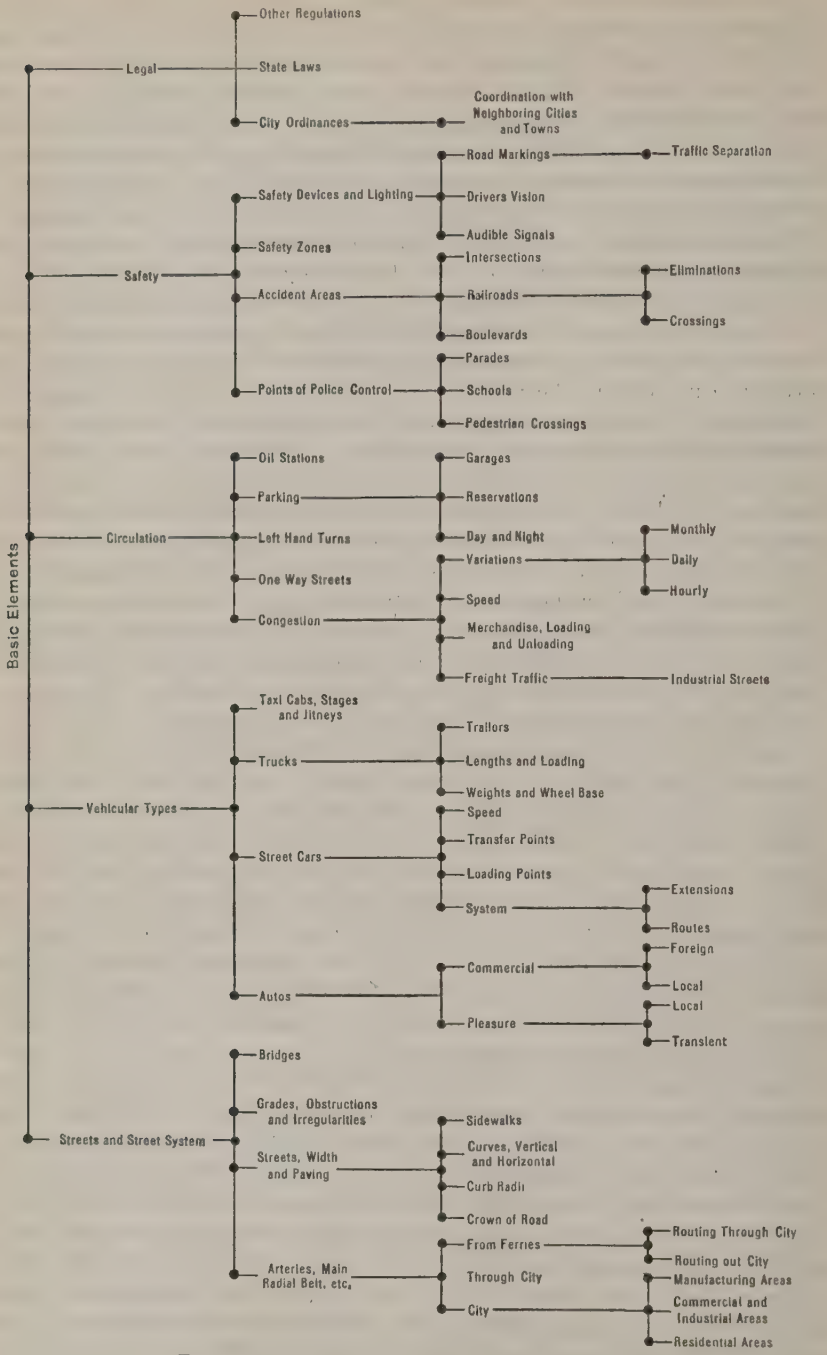

FIG. 3.—OUTLINE OF A CITY TRAFFIC SURVEY.

tain standardized method of gathering the data. When the latter reach the central office, they can then be readily transferred to base maps, office files, and special scrapbooks covering the various subjects.

The regional planner will probably be faced with the possibility of altering many existing maps so as to secure a uniform scale and he is then concerned with the best size of map to use. It is obviously impossible to lay down any particular size for this purpose, but the San Francisco Association has found it convenient to use a map measuring 4 ft. 3 in. by 3 ft. 4 in., covering the area within a 50-mile radius and drawn to a scale of 2 miles to 1 in. All smaller maps will bear some relationship in size to these foregoing maps. The technical details of map preparation have been so thoroughly devised by the organization responsible for the Regional Plan of New York that very little can be said to amplify them. However, as the information obtained will necessarily receive the attention of persons largely unversed in technical details, it is imperative that this fact should be kept in mind. This qualification also applies to the form in which charts of statistics are prepared, and it is desirable that these should be designed on as graphic a basis as possible. The foregoing might be said to apply to an unofficial organization preparing a regional plan, even more than an official body. A danger which must not be overlooked, however, is the stressing of a pictorial method without due attention to its accuracy; this should be avoided. Many misleading charts have been prepared from time to time, attempting to portray trends of development that have been little else than elaborate cartoons, rather than scientific explanations.

It is desirable that the basic information, as it is gathered, should be grouped in the political sub-divisions of the region where the least difference in boundaries has taken place over a wide period of years. This will prevent the overlapping of information and confusion of statistics. The best way to begin gathering this information is to prepare as large a number of maps as possible that will show the political sub-divisions of counties, towns, cities, and other administrative districts, and the variation of boundaries with time. Once this fundamental is established, an unassailable basis is made for statistics and contemporary conditions. As an example of a definite outline for attacking a problem, the writer has prepared what he considers are the fundamental considerations for a city traffic survey which will need little further elaboration to cover a region (see Fig. 3). Such an outline of requirements should be prepared for the study of each problem and in drawing them, a wide local knowledge on the part of some one is required to lay down, tentatively, the main points.

In conclusion, the writer would like to emphasize the element of time in all that appertains to city and regional planning. While there need be no undue haste, it is obvious that statistics and information, once they are gathered, rapidly become old and are affected by other elements that may develop from time to time. If they are to be of any use, and if the plan is to show itself as a live, wide-awake, aggressive piece of public work, time should be considered in every stage of the proceedings. If this is done the heavy labor of research will be felt to have achieved some reward and indeed the final success of improvements recommended will be much nearer fulfillment.

WILLIAM BOWIE,* M. AM. SOC. C. E.—The function of the surveyor is to make his computed positions, his maps, and his plans useful to other engineers. His province is to supply exact knowledge of the terrain, in place of approximations and guesswork.

They are facing a heavy responsibility who are studying the physical needs of modern cities and who are directing the enunciation of the principles which bear directly on a city's growth and on the activities of its citizens. Exact knowledge is no handicap to a city planner, even when he is dealing with such general questions as street and park layouts and suburban communications. The laws of urban growth and development are imperfectly understood, and it is possible that a close study of detailed topographic conditions will reveal influences to which much consideration must be given.

The fiscal ally of the city planner, the tax assessor, can be easily persuaded of the value of an accurate cadastral survey which will show, in convenient form, all taxable real estate and the improvements thereon. Many instances are known where the increase in the taxable real property, disclosed by an accurate and complete city survey, has paid for the survey and left a considerable margin. The city planner and the city engineer need not show, in dollars and cents, the value of an accurate survey to their own particular activities.

The problem then, for the surveyor, is to furnish a survey with its resultant maps, plans, elevations, and positions which will serve the purposes of the city planner, the city engineer, the tax assessor, and all the general engineering interests of the modern city.

HOWARD STRONG,† ESQ.—In the discussion of this paper, two extremes, perhaps, have been presented—one represented in a degree by the New York position; the other possibly by the Chicago method. The one would subordinate or even entirely disregard the various specific projects that may be before the region and would devote its entire attention to the studies preliminary to the making of a definite plan. The other seems to subordinate the surveys and studies in preparation for the plan and to emphasize the promotion of specific projects. There is a possible danger in either one of these extremes, even if, as in the case of the New York Regional Plan, finances are ample to go ahead with the making of studies and plans without regard to the attitude of the region.

If too much time is given to the making of the plan, and the actual planning accomplishment is entirely neglected for a number of years, it seems likely that the interest, enthusiasm, and support of the people in the region, upon whom, after all, depends the adoption of the plan, is likely to be lost. On the other hand, if too much emphasis is put on the project method, the picture is likely to get out of perspective, and the projects, themselves, will not be properly articulated in the general scheme.

It is certainly necessary to retain public support and, for that reason, some attention must be given to programs in which the people have an

* Chf., Div. of Geodesy, U. S. Coast and Geodetic Survey, Washington, D. C.
† Secy. Director, Regional Planning Federation, Philadelphia, Pa.

immediate interest. At the same time, the plan itself, which, after all, is the principal business in hand, must not be neglected. The only solution that will develop an adequate plan and, at the same time, will retain the interest of the people who must ultimately accept the plan, is a nice balance between the two extremes.

Charles W. Eliot, 2d,* Esq.—In Washington, D. C., the National Capital Park and Planning Commission is generally following the program laid down by Mr. Lewis in his most interesting paper; but there are two exceptions.

In the first place, he suggests that the first step in regional planning work should be the definition of a boundary. The Commission has carefully avoided setting any limits, and is going to avoid it as long as possible because it feels that the extent of the influence of the Capital City is a very indeterminate factor and something that will bear a great deal of study before any such limit is set.

In the second place, it has departed from the suggestions in regard to "open spaces". In Washington, a different set of indications are used from those suggested by Mr. Lewis. The idea has been to indicate areas withdrawn from urban occupation. That includes both private and public areas in very much the same way that Mr. Walker has outlined, but it is, perhaps, a little more accurate definition of "open spaces" than just those two words.

The City of Washington was very fortunate in the equipment that was available at the start for planning work. The U. S. Geological Survey, the U. S. Coast and Geodetic Survey, and the Air Service have made a great many studies and many maps of the Washington region. The basic maps, drawn to a scale of ½ mile to the inch are found to be entirely satisfactory. For more detailed studies, there are remarkably accurate maps of the District of Columbia at 400-ft. scale and general street maps at 1 600-ft. and 1 000-ft. scales.

In most regional planning work the studies are entirely separate from the city planning studies; but, in Washington, that is impossible, because the National Capital Park and Planning Commission has particular executive functions in the District of Columbia. It has the power and money to purchase land for parks and it has the guardianship of the "Highway Plan", which controls the platting of sub-divisions. Congress has seen fit to give it power to make regional studies, but it is forced constantly to meet immediate problems of design and planning within the District of Columbia. Although the attempt is made to keep the regional planning studies in a fluid state while data are being collected, the Commission is constantly having to make decisions in the District of Columbia that affect the regional plan. That is another reason why it is trying to keep the boundaries of its region somewhat indefinite because there is no knowing how far immediate decisions are going to influence the regional plan. Admitted that this method of going at the work is unfortunate—to have to be controlled by immediate decisions—that is the state of affairs.

Regional planners in Washington are grateful for the work that has been done in New York and particularly for Mr. Lewis' helpful suggestions; and

* City Planner, National Capital Park and Planning Comm., Washington, D. C.

hope, if they can get the co-operation of engineers, landscape architects, and all others interested in city planning, to be able to produce a plan, for the National Capital and the region around Washington, that will be a serviceable guide for the growth of that community and an inspiration for the remainder of the country.

U. N. ARTHUR,* ESQ.—Among the various outstanding problems confronting the great centers of population probably none is of greater moment than the development of a comprehensive plan. Regional planning, being still in its infancy, will measure its accomplishments by the basic principles governing the method of attack. Therefore, it is fortunate, indeed, to have the subject outlined as clearly and concisely as in this paper.

A finer opportunity is afforded for the planning of the large area of a region or district than that of city areas. This follows from the fact that, before any attempt had been made at scientific city planning, the area within the incorporated city limits was often largely platted and sufficiently developed to make impracticable any radical change in the system of major thoroughfares, parks, playgrounds, etc., while, for regional work, large areas are often open and susceptible of being properly planned to care for the various factors essential to the growth of the community.

While there can be no question as to the wisdom of supplying the various types of data suggested by Mr. Lewis, it might be well to emphasize the necessity of securing the basic physical, or land, facts of the area before any concentrated effort is made to produce a regional plan.

The three fundamental factors with which a community of any size has to deal, are: (*a*) The land it occupies; (*b*) the people that dwell in the land; and, (*c*) the social and industrial development. The other factors influencing the study and development of the plan are: First, general information; second, provision for making changes easily; and, third, means for accomplishing the final object—the plan.

The willingness with which planners often accept general information as sufficient for planning purposes has been a principal source of criticism. Often the weak points in a finally submitted plan are exposed to the attack of critics who claim that all planners are dreamers and that money expended on the study and development of a city or regional plan is money wasted. The exigencies of the case often require that the broader the extent and scope of the planning operation, the more generalized is the information secured. Such information, spread too thin, means vague information, which is frequently deceptive and leads to the development of plans that are impractical and expensive and often cast doubt on the honest intent and purpose of the planner.

It is a truism that, in most cases, the sites of cities and present centers of population were not selected because the physical surroundings were adaptable to easy development, but because of the existence of important cross-roads; or because of the transportation facilities afforded by navigable rivers; or because of natural harbor and port facilities. Such situations often have

* Chf. Engr., Pittsburgh Planning Comm., Pittsburgh, Pa.

immediate surrounding topography of the most rugged nature. It seems, therefore, that, in the first analysis, basic information is the securing of physical facts relating to the land—geodetic, geologic, and topographic. It is true that at the initial conception of most planning undertakings, ample funds have not been available for securing the engineering data so essential to the proper and economic completion of the work. However, if those data were properly evaluated and their importance recognized, in most cases, provision would be made for assembling them as a part of the planning program and as the logical first step toward real planning progress. The first fundamental consideration with which any community has to deal, is the land it occupies. It is not only the first, but it is perpetual. Bridges and viaducts may be built across rivers and valleys; hills may be tunneled; extensive grading operations may be carried out; but regardless of the magnitude of these engi-

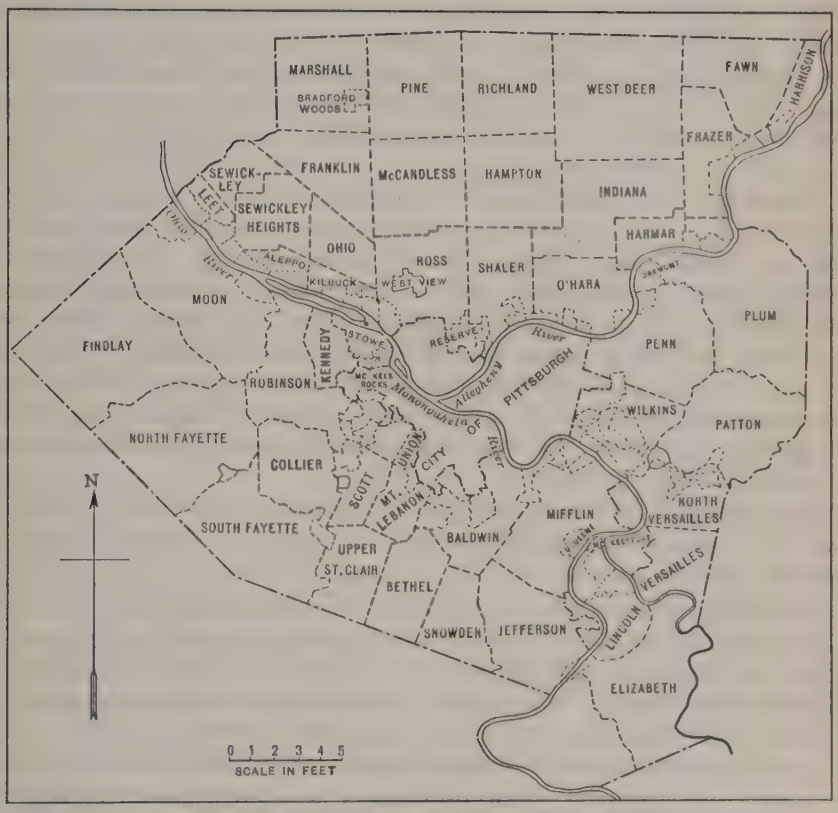

FIG. 4.—MAP OF ALLEGHENY COUNTY, PENNSYLVANIA.

neering feats, the terrain is altered only to an insignificant degree. Whatever be the location of the site, that it remains. The social, economic, and industrial development of the location and the chances for the existence and happiness of the population depend exclusively on the logical and scientific development of the site.

The basic physical, or land, facts are, and always will be, unavoidable. If they are ignored during the planning stage of any undertaking, they will be encountered during the construction stage. Disregarding these facts results in experimental building, and the structure (street, bridge, viaduct, tunnel, public building, sewer, etc.) that does not satisfactorily meet the physical conditions is inevitably replaced by one that does. Frequently, the cost of relieving one situation that has become insupportable is more than sufficient to have paid for securing basic data to serve the whole region.

As a specific example, illustrating both the necessity for, and economy to be gained by, a regional plan, the speaker believes no better case can be cited than is afforded by Allegheny County, Pennsylvania. This County has an area of 732 sq. miles. Within its boundaries are 4 cities, 70 boroughs, and 51 townships, many of the latter having legislative functions similar to those of the boroughs. The City of Pittsburgh is approximately at the geographical center, and being the largest and oldest of the municipal corporations, dominates the regions, many of the boroughs being simply dormitories for the city. (See Fig. 4.) The need for a regional plan has been felt for many years and various suggestions for accomplishing the co-operative solution of the municipal problems affecting this area have been proposed.

The City of Pittsburgh, under the direction of the Department of City Planning, began a comprehensive geodetic and topographic survey in 1923. The city survey was planned to control an area of about 100 sq. miles, or roughly twice the area within the corporation lines. The survey, however, was planned so as to permit of indefinite expansion. After the work was well under way the Allegheny County authorities, appreciating the fact that the need of basic planning data was not limited to the City of Pittsburgh, but was equally essential in carrying out the extensive construction program of the County, entered into a contract with the City to extend the survey to control the entire County.

This survey is of a somewhat unusual character and embraces the essential information needed for a regional plan. The general schedule adopted provides for the following:

1.—Precise triangulation extended over the metropolitan area. The stations of this triangulation average about 1 per square mile in incorporated or built-up territories, and about 1 for every 2 sq. miles throughout the remainder of the county. The accuracy of the triangulation is such that the probable error of any distance will not exceed 1 in 100 000.

2.—Precise traverse amplifying and making usable the results of the triangulation. The stations of the traverse are being well "monumented" and referenced. They coincide, as far as practicable, with existing property monuments. The traverse will have an accuracy represented by a limiting closing error of 1 in 20 000.

3.—Precise levels with bench-marks established on permanent structures along the routes and on traverse and triangulation monuments.

4.—Topographic sheets of the city area on a scale of 1 in. equals 200 ft.

5.—A property map of the city area on a scale of 1 in. equals 50 ft. This is to be the base map for all departmental information where dimensions are required.

6.—A wall or desk map on a scale of 1 in. equals 1 000 ft., compiled from the data shown on the large-scale topographic maps.

Topographic Survey.—Description.—The topographic map, which is being made of the Pittsburgh Area, is a definite and valuable result of the survey. On it are shown to exact scale and position all streets, roadways, curbs, retaining walls, steam and electric railroads and bridges; public, semi-public, and industrially important buildings; as well as streams, lakes, etc. The conformation and elevation of the surface of the ground are shown by contour lines. From the topographic map grades may be accurately computed, drainage areas may be scaled within a fraction of an acre, and excavation quantities computed. The Pittsburgh map sheets are published on a scale of 1 in. equals 200 ft., with a 2.5 and a 5-ft. contour interval. The datum plane for contour elevations is mean sea level, thus placing the maps on the ultimate datum plane and agreeing with Federal, State, and other maps.

The publication scale of 1 in. equals 200 ft. was adopted as best fitting the conditions imposed, which are:

1.—The map scale must be large enough to indicate clearly and accurately all the information desired.

2.—The scale should bear a definite relation to the accuracy of field measurements, and, since the majority of the positions are located by stadia, and stadia distances are dependable only within 1 ft., the scale should be such that distances may be plotted and scaled to the nearest foot.

3.—The scale of the map must be small enough so that the area covered by any one map sheet would be of such size that ordinary district improvement projects may be covered and studied upon it, without the necessity of assembling and matching the various adjoining sheets.

4.—From an economic standpoint it is desirable to keep the scale as small as possible, in order to decrease the cost of the field work and of reproduction.

While the scale of publication is 200 ft., the field scale, on which the maps are sketched in the field, is 165 ft. The purpose of this is the possible increase in accuracy of scale by the reduction, which is a part of the photographic process of publication, and the sharpening of lettering and other cartographic details and consequent improvement in appearance of the final published copies. It is of further advantage to make the field scale as large as is consistent with stadia methods for the purpose of making enlargements. For instance, it is possible to make a better photographic enlargement to a scale of 100 ft. by using an original copy on a scale of 165 ft., than would be the case if the original were on a 200-ft. scale.

Map Projection.—In deciding on the system of projection to be used on the map sheets, there were four conditions to be considered:

1.—The projection must be such that the maps will always be in correct orientation; that is, the boundaries of each sheet should always be true north

and south, east and west, in order that the true azimuth or bearings of any line may be quickly scaled from the map.

2.—The projection should permit of practically indefinite expansion.

3.—In order to be joined correctly and easily to other maps, such as those published by the Federal Government, State, Interstate Commerce Commission, etc., the boundaries of each map sheet should be some even value of latitude and longitude, these values being co-ordinates based on the North American datum.

4.—For ease and simplicity of ordinary distance, bearing, and position computations, the maps should have superimposed upon them a rectangular system of co-ordinates.

Reproduction.—After completion, the field sheet is reproduced in four colors. Cadastral information is shown in black, contours in brown, drainage in blue, and public property in green. The reproductions are to exact scale within the limits of paper expansion, and registration is correct at all points, the allowable registration error being 0.01 in. Two hundred copies on light-weight paper of these four color reproductions are printed on the initial order. In addition, ten copies are printed on "lenora" cloth for use in binding in atlas form. It is also expected that several copies will be secured showing the cadastral information only.

Estimates.—The estimated unit costs for the completed survey are, as follows:

Triangulation:

City area.....$350 per sq. mile, including monuments and computations.
County area.....$300 per sq. mile, including monuments and computations.

Precise Levels:

City area.....$70 per lin. mile, including the setting of benchmarks and computations.
County area.....$60 per lin. mile, including the setting of benchmarks and computations.

Precise Traverse:

City area.....$100 per lin. mile, including monuments and computations.
County area.....$90 per lin. mile, including monuments and computations.

Topography:

City area.....$1 800 per sq. mile, including reproduction.
County area.....$1 500 per sq. mile, including reproduction.

Charles Wellford Leavitt,* M. Am. Soc. C. E. (by letter).—Any one not familiar with the difficulties that have attended the gigantic undertaking of "planning New York and its environs" will find it almost impossible to compare this project with anything in regional planning taken up elsewhere, as there is no gauge that can be used to compare New York with any other city. Mr. Lewis has endeavored to stress this point with which he is perfectly

* Civ. and Landscape Engr. (Charles Wellford Leavitt & Son), New York, N. Y. Mr. Leavitt died on April 22, 1928.

familiar, but it cannot be emphasized too much for the reader. The paper very properly endeavors to give a clear idea of what basic information is to be secured.

The question arises as to what difference there is between a regional plan and the ordinary development of a city's growth under a mayor, common council, boards of water, sewer, health, streets, parks, buildings, etc., directed by a city engineer, with his various departmental assistants who, until very recently, have directed the growth of the cities of the world.

It is possible to infer from Mr. Lewis' paper that, the "basic information" having been secured, there is contemplated "research work" upon the various items under which this basic information has been classified and which in the past might properly have been studied by the city engineer. The fact is that while some information has been gathered by various city departments, as to sizes of water and sewer pipes, sanitary measures, street widths, park areas, building heights and strength, and fire-proofing, yet information is lacking as to whether it will be better to carry water in large mains to different satellite communities and there distribute, or to add to them from time to time, and some day be confronted with the necessity of scrapping the whole system and starting off afresh, which is an expensive method. In these old records, there was not a sufficient knowledge of future drainage and sewerage necessities to make it possible to plan the whole region with confidence, and to build what was immediately required, with assurance that, in the future, the work done would all come together and make a permanent system that would take care of any growth.

Each community acted independently; each section of the metropolitan center solved its individual problems; with the result that most all the work done will prove inadequate for the future and a whole new system must be built at great cost; and so on through the parks and building departments, the streets and highways, the docks, transit lines, areas set aside for manufacturing industries, business, residences, etc.

In Europe, and in America's older cities, these troubles were not so apparent, because the growths were slower and frequently pipes were worn out before they had to be enlarged; but park areas did not grow of themselves nor did streets become wider; and as early as 1910 the people became aware of the facts, and their interest became fixed upon research to determine how, in the future, they might avoid waste and provide for the comfort of city dwellers.

City engineers are usually overworked with many details of daily importance and have not the time and are not given the facilities to delve into the future or to determine what may take place in 50 to 100 years. Here, then, is where the city and regional plan will show an economic return to a county region, or a city, by securing the necessary power to plan ahead and make it possible to use the land for the purpose to which it is best suited.

This will take time. The first step is to collect the basic information, which can only properly be done by some one with experience and knowledge of what is needed. The second step is to interest the various official bodies contained within the region to be planned; third, to bring these official bodies

to a point where they will work together for the common good; and, fourth, to form an organization that will endure indefinitely either to carry out the plans, or to change them to meet any new conditions that may develop in the region's growth.

With such a program definitely outlined, and with a director versed by experience in what is and what is not needed, this basic information may be gathered, classified, and used to advantage. Most undoubtedly it will be well worth while for any community with a rapid growth, or which may anticipate such a growth in the future, to have available this basic information. On the other hand, the amassing of information that cannot be classified, or that cannot be made available for use either because of its volume, or the manner in which it is collected, may prove a veritable menace. Often it tends to confuse and discourage the ruling bodies, which may properly, if they do not understand the plans and program, roll them up and put them out of the way.

The great danger in collecting basic information for a regional plan is in getting too much and not being able to digest it into a clear workable plan that will carry its own conviction.

Harland Bartholomew,* M. Am. Soc. C. E. (by letter).—Regional planning is the logical and inevitable outgrowth of city planning. While an ever-increasing application of the principles of city planning may be expected in towns and cities, there will also be increasing need for the application of definite technique and scientific principles in regional planning. Difficult as is the preparation, adoption, and execution of a genuinely comprehensive city plan, of far greater magnitude and complexity are the difficulties of regional planning. In this initial stage of work it would be most unfortunate to attempt to specify means and methods too closely. This is probably the most complicated of the structures created by Man.

It is most fortunate that the initial undertaking of regional planning in America by the Committee on Regional Plan of New York and Its Environs has proceeded without some preconceived objective in view. The divisions of the work, that is, physical, economic, social, legal, and financial, are each important and necessary. The extent to which basic information could and should be secured is as yet impossible to estimate. It will be limited in each particular case by the nature and comprehensiveness of the project and the funds at hand. Unfortunately, there will probably be few projects undertaken with the breadth of view and with the resources that have been available to the New York organization.

It is quite probable that subsequent regional plans will sacrifice comprehensiveness for specific accomplishment in such fields as streets and highways, in transportation, or in parks. This will be productive of practical knowledge and results in individual instances, the summation of which will develop definite technique. It will increase current knowledge of the character of basic information of all kinds needed for a complete regional plan.

Mr. Lewis' paper is an excellent summary of the present knowledge of the subject of office technique growing out of his experience in the New

* (Harland Bartholomew and Associates), St. Louis, Mo.

York work. If one were to single out a specific subject for discussion, it might be the question of a base map. The inadequacy of existing maps of particular regions is complete. They just do not exist. In Washington, D. C., as in New York, for instance, it was found necessary to resort to the sheets of the U. S. Geological Survey and with the co-operation of the latter to bring existing information up to date and at a workable scale. The 2 000-ft. scale map used in the New York studies is very desirable and will undoubtedly become more or less standard. The U. S. Geological Survey has just completed a new survey of the Los Angeles, Calif., region at this (2 000-ft.) scale, which is exceptionally good. Where the Geological Survey sheets are not available, or are not up to date, there is an initial and well-nigh insuperable handicap on the work of starting a regional plan. There is even an astounding lack of good topographic maps in cities. One of the by-products of regional planning, as of city planning, will be more and improved topographic maps.

The scope of this subject is inexhaustible. Mr. Lewis includes in his "Physical Survey," "Population—distribution, density and rates of growth", and also mentions that special inquiry has been made of "Standards of Population and Housing Density". This information is of particular importance and should be augmented considerably. To what extent it has been considered in the New York study Mr. Lewis does not indicate, but this will doubtless be found in present or future reports of the Committee. Here, the economic and social surveys overlap the physical. Ultimately, regional planners are going to find out how widely they can disperse a given population (or congest it for that matter) and produce a condition that is both socially desirable and economically sound. This is "basic information" of the greatest importance.

Donald M. Baker,* Assoc. M. Am. Soc. C. E. (by letter).—The author has classified the various types of information necessary for the development of a regional plan as: Physical, economic, social, legal, and financial. He has also outlined an excellent program of securing this information. Emphasis has been placed, however, on the physical data necessary and detailed descriptions are given of the methods of collecting and filing it.

Engineers who are connected with planning work are often apt to place too great emphasis on the physical aspects of planning and not enough on other aspects, particularly the legal and financial. Too many plans and planning reports consist, almost in their entirety, of a physical plan with no discussion of the legal and financial methods of attaining the plan.

Use of property within the planned area can be governed by proper zoning, proper streets and traffic arteries through undeveloped territory may be secured by sub-division control, and housing can be regulated, but the necessary public agencies must be set up with adequate powers to carry out this administrative work. Improvements, such as new or wider streets and parkways, park areas, rapid transit and other transportation lines, can be made, but proper proceedings must be initiated for these improvements, rights of way and easements

* Cons. Engr.; Member, Board of City Planning Commrs., Los Angeles, Calif.

acquired, money must be raised for the payment of costs, and the costs must be prorated on an equitable basis.

Much regional planning work is now done in an advisory way through associations supported by private contribution or the assistance of municipal bodies, but ultimately planning work must be done in each locality by a body with legal authority to enforce adherence to the adopted plan. All States have more or less different laws granting authority to administrative agencies relative to planning work, and Court decisions in each State differ, as do local conditions. Any physical plan outlined for a locality must take these into account, and must also include suggestions for new statutes or necessary changes in existing statutes in order that the proper planning body may be created with adequate authority. Courts are rapidly awakening to the urgent need of planning and are adopting a sympathetic attitude toward the exercise of the police power in connection with it. State legislatures as well as city and county governing bodies are realizing more and more the imperative necessity of proper planning and of agencies to administer the work, and it is now much less difficult to obtain satisfactory legislation and sympathetic Court decisions than it was a decade ago.

Planning includes not only the laying out of developed areas and the providing of facilities for future population, but also the correction of existing mistakes and conditions resulting from uncontrolled settlement and development. The latter phase often results in the necessity of acquiring property, rights of way, or easements through condemnation, as well as the need of construction work.

Laws in many States, by means of which public improvements must be authorized, are relics of the "horse-and-buggy" days, when the several years required to complete a right-of-way condemnation proceeding was of no moment, and when the costs of improvements and their allocation were simple and not burdensome. The type of improvement was left to the judgment of a few property owners who paid the bill, and who were not in a position to determine whether such type fitted in with a well co-ordinated plan or with the use to which the improvement was to be put. It is just as important that improvements, once they are decided upon as necessary, should be expeditiously carried out and not wait years for Court awards in condemnation as it is that they should be of a type that fits in with a proper plan or that they satisfy the use to be made of them.

Any plan, city or regional, should include a thorough study of improvement laws and should suggest amendments or new laws which will satisfy present-day conditions, and this work should be done at the same time that other investigations are being made and physical data collected, because it sometimes takes a few years to obtain new legislation and have it tested in the Courts.

The entire theory behind the American system of taxation is that payment is made in proportion to the benefits received, and in paying for public improvements resulting from planning, the benefits may be divided into two classes: Those applying to the property directly affected by the improvement, thereby tending to enhance its value from an income standpoint, and personal benefits

reflecting on residents who might use the improvement, but whose property is so far removed from it as not to have its value appreciably affected. In short, benefits are specific and general, with no sharp line of division.

It is sometimes hard to classify, in a city or regional plan, those improvements that are "nice" and those that are "necessary". There is, however, always such a thing as inability to pay for an improvement. When the cost of improvements becomes an excessive burden on property owners, it may result in evils to them and to the community greater than the existing ones that made the improvement necessary.

In the "horse-and-buggy" days it was a simple matter to assess the benefits resulting from any public improvement. In general, they were either borne by the entire community, or by property immediately contiguous to the improvement. Nowadays, principally on account of the advent of the automobile and other improved forms of transportation, much study and investigation is necessary to assess equitably the costs and benefits resulting from any improvement.

The creation of a park in a neighborhood enhances, very greatly, the value of the immediately surrounding property for residences or apartment houses, but the man living 5 miles away and possessing an automobile is only 15 min. ride from it and probably uses it in a physical sense as much as the man living across the street. The opening or widening of a major traffic artery may be a positive detriment to property owners living upon it, from the standpoint of noise and dirt, and still be a benefit to them and to owners over a large area due to the convenience it affords them in reaching places of work, recreation, or pleasure.

Any improvement, such as a direct traffic artery or a rapid transit line, which brings a place of residence from 15 to 20 min. nearer a place of work, may add several hundred or even several thousand dollars to the value of a single piece of property, and all property so benefited should contribute toward the cost of the improvement. However, the method of payment should be adjusted so that it can be handled by the property owner and still allow him to reap some substantial benefit after he has paid the bill.

This discussion is given not in criticism of the very excellent outline of physical data to be obtained in formulating a plan, but in an effort to emphasize the fact that there are other types of data and other lines of research just as necessary in preparing a regional plan. Since planning work seems to be offering a considerable field to the Engineering Profession it is important to call attention to the importance of other than the physical aspects. Every engineer who has had any contact with public improvement work is more or less familiar with the legal and financial aspects of it, and it is usually far easier for him to understand them than it would be for a lawyer or financier to comprehend the physical and engineering aspect of planning, and therein lies the engineer's opportunity of correlating the three.

HARRY J. MARCH,* M. AM. SOC. C. E. (by letter).—The author deserves great commendation for the comparatively exhaustive and highly clarified presentation of a seriously complicated subject.

* Chairman, Executive, and Engr., City Planning Committee; Chairman, Board of Appeals, Buffalo, N. Y.

Regional planning has to do with the physical harmonizing and co-ordinating of all the various utilities and resources in the affected area. At the same time, because of its very nature, it causes naturally more or less conflict of persons, ideas, and plans. This is particularly so where glory or money is being dispensed. The various major and minor civil divisions composing the region have their respective officials who are more or less jealous of their prerogatives, not to speak of duties. The regional plan must not unduly trespass upon the respective plans of the units, but must correlate and coordinate them. Therefore, basic data must be obtained and impressively presented, so that it will be compelling in interest and objective.

While in this modern age it is recognized that communities are dependent, one upon the other, even if some of them are remotely separated, the insatiable craving of humanity for something different, whether it be in season or out of season and whether its immediate environment be favorable or unfavorable, has caused illimitable unrest and untold strife. The regional planner should first ascertain the existing and potential resources of the several communities within its scope, irrespective of the resultant glory of one community as compared with another, or the profits and benefits accruing therefrom. There must be community team work for effective success.

The life of the several communities must be systematically controlled. Any resources found lacking for the reasonable life of any community should be supplied, if not too prohibitive in cost. In other words, the life of the community should be as well-rounded as that of the individual. There should be varied housing, varied business, varied industry, varied educational and cultural pursuits and varied recreations and diversions.

Large intervening open spaces, which afford the breath of life, as it were, to the adjoining communities, might well form the division area between communities whose specific interests are different, but whose general interests are common.

Planners should know thoroughly the products which may best be developed on the lands within the region, as well as the potential resources of the waters in terms of commercial transportation, power, or recreational phase. For instance, in the portion of the Niagara Frontier Region north of the Lewistown Escarpment, there exists a fertile soil readily adaptable for the larger fruits, peaches, apples, etc.; the middle area, or that to the south of this area, has soil conditions that are favorable for sheep farming and dairying; the southern area is valuable for the smaller fruits, grapes, etc. These several areas partly encircle the large ones of varied industries at Niagara Falls, the Tonawandas, and Buffalo, which are respectively supplied by intervening housing and business areas. The writer desires to stress at this point the great advantage of resources available for the development of the communities, because, with the flagging of one industry, there may be an increase or acceleration of another that is entirely different.

All these conditions constitute the make-up of the self-contained community and produce an enviable economical result that cannot be surpassed by a region lacking varied resources and facilities. The regional plan must be so

comprehensive in its scope and compelling in its benefits that the individualized communities will subordinate their selfish interests to those of the comprehensive and economic interests of the whole region.

In the development of regional planning, the basic information to be procured should be that incident to landscape engineering, supplemented by landscape architectural considerations.

In the procurement of data, there perhaps is no better medium than that of a regional planning association for publicity purposes and that of a regional planning board for the technical work involved. The Niagara Frontier Planning Association and the Niagara Frontier Planning Board are typical examples of the effectiveness of such bodies. These organizations have developed an inter-community spirit worthy of emulation, and their members are looking forward to the attainment of some big objectives which perhaps could be obtained in no other way.

HAROLD M. LEWIS,* M. AM. SOC. C. E. (by letter).—The discussion on this paper indicates that regional planners are subject to two rather opposite faults—on the one hand to gather much more information than will prove useful, and on the other hand to obtain too little data in regard to existing topographic conditions. Somewhere between these two tendencies there must be a mean which will combine thoroughness with efficiency. Mr. Black has expressed a disappointment that more information was not given concerning the types of basic information that will not prove essential for future regional planning surveys. The writer would not recommend that other regional plan organizations should spend as much time as was spent in New York on special research work in general and somewhat theoretical problems. He believes that the Committee on Regional Plan of New York and Its Environs was justified, for two reasons, for spending as much time and effort as it did. In the first place, while the Committee was working on a single region, it was financed by a foundation with National interests, the primary work of which is research; and, secondly, at the time when the studies were started, there was little published material available on such subjects. Today, the condition is quite different. A large amount of information on the various standards of highway capacities, recreation use, population and housing densities, and community developments have been published within recent years. Much of it appears in the *Transactions* of the Society.

Mr. Leavitt referred to the "menace" of "the amassing of information that cannot be classified". It has been attempted to provide against this in the New York studies by publishing ten regional survey volumes which will be a classified reference library of basic information relating to the New York Region. Based on this material there will be published two additional volumes dealing with the conclusions and proposals as they relate to the Regional Plan.

Several of the discussors have stressed the need for early official co-operation and for speed in arriving at specific conclusions. The writer believes that such procedure is highly advantageous and can be followed more and

* Executive Engr., Regional Plan of New York and Its Environs, New York, N. Y.

more in later regional plan activities. In the New York studies, which were started in 1921, it was necessary to "sell" the idea of regional planning in a district where State and municipal boundaries and rivalries made it exceedingly difficult. It would probably have been impossible to establish any degree of official co-operation at the start within a region which contained parts of three States and was subdivided into about 425 different political units. It was essential to get together a large amount of material before any attempt at such co-operation could be made.

To-day (1928), the need and justification of regional planning is fairly well recognized, and other regions can undertake similar activities with a considerable advantage over New York. This does not mean that they will not have to collect information under the various survey headings suggested, but that they should be able to make much better progress in compiling and making available such material.

It is important that basic survey information, particularly when gathered by a non-official organization, should be prepared for publication at the earliest possible date. In New York, this was done in the hope that when placed in the hands of local communities and planning bodies it would guide them indirectly toward a correct solution of their own problems. By deferring the publication of a comprehensive plan, it developed that many of the proposals which had been studied by the Regional Plan Staff were taken up by and received the local backing of different political units within the New York Region. It is believed that many excellent projects have been advanced toward consummation in this way, that might have been opposed if presented at an earlier date under Regional Plan auspices.

Basic information, such as collected for a regional plan, should prove useful for both regional and local purposes. It is impossible to draw any distinct line between information that is only essential for one scope of planning. The development of general principles of local application can be considered as regional planning. Their specific application would generally be local planning, although an example might well be given in a regional plan report to demonstrate their use. It is important, as Mr. Black has stated, that the regional plan "should not concern itself with matters of purely local character".

Mr. Shurtleff's plea for the reservation of open spaces adjacent to built-up areas is very timely. The writer believes that they are needed not only to "relieve monotony" and to prevent "depreciation in value", but also because intensive building cannot be carried out over large areas without causing an impossible traffic burden on street systems already fixed by existing developments, and creating excessive costs for the necessary systems of rail transportation. Buildings of large bulk, therefore, must be balanced against extremely low buildings or open spaces.

Mr. Eliot has urged that the boundaries of a region be kept flexible. When the writer stated that the "first item to be determined is the area to be studied", he did not mean to imply that its boundary should be inflexible, but only to state that before making a map of a region one must decide where he is to stop his map. The boundaries should be placed far enough out at

the beginning to include all areas for which basic information will be required. As the work progresses more detail studies can probably be restricted to a smaller area.

The importance of the legal and financial surveys has been emphasized by Mr. Baker. The Legal Division has been a very important part of the New York Regional Plan Staff, but most of its investigations come under the head of special studies and planning details, rather than basic information. The financial problem in a regional plan is more a matter of guiding expenditures along efficient lines than of finding new sources of revenue. It should be studied primarily with the aim of preventing the waste of public funds rather than of finding methods of increasing the normal capital expenditures.

Paper No. 1682

HOUSING AND THE REGIONAL PLAN*

By John Ihlder,† Esq.

With Discussion by Messrs. James Ford, Benjamin H. Ritter, Bernard J. Newman, Bleecker Marquette, W. C. Rice, E. M. Bassett, Frank B. Williams, U. S. Grant, 3d, and John Ihlder.

The great American novel, the coming of which we used to discuss with such animation, has not been written and probably never will be, for a novel must have location and must picture, with fidelity to detail, individual characters as well as groups of characters. This necessary detail inevitably makes it sectional, provincial, differentiates its people and its atmosphere from the people and the atmosphere pictured in another novel equally good, equally true, the scene of which is laid in another part of the country, or which deals with a different group of people. These differences will cause Americans of other sections to disclaim both books as representative of America as they know it, although to foreigners, both books may seem typically American. We, close at hand, see most clearly the differences of detail, accept subconsciously the likenesses; they, farther away, miss the detail and see only the broad likenesses.

Thus, it must be with regional planning and the housing that is to develop as regional planning becomes accepted practice. The broad likeness that will be characteristic of regional plans and the housing for which they provide, will lie in acceptance of the proposition that they shall provide adequately, even generously, in terms of open spaces, of sanitary equipment, of "modern" conveniences; that they shall be based on the well-known but, fortunately, never clearly defined "American standard of living"; fortunately, because

† Mgr., Civic Development Dept., Chamber of Commerce of the United States, Washington, D. C.

this standard is ever changing, ever rising. Other nations may accept present standards, seeking merely to modify them so that they may be tolerable; other nations may calculate closely on economies which they believe the hard conditions of their life force upon them—definitely discard, for example, water-borne sewage and a sewerage system, not only because of cost of installation and operation, but also because of loss of fertilizing content which they believe they must have for their farms. Americans, however, who are coming to reckon farm productivity in terms of bushels per man, while other nations reckon it in terms of bushels per acre, will base their plans on the health, efficiency, and more abundant living of the population rather than on the amount of money not spent for a sewerage system or an imported or manufactured fertilizer. Water carriage of sewage may go into the discard, but not until a better method of safeguarding human well-being has been found.

Inside such broad American characterization, however, regional plans will doubtless take on many differentiating characteristics due to sectional habits, traditions, resources, and climate. Consequently, in a paper like this, dealing with the subject for the whole Nation, one must paint in broad strokes, describe objectives in general terms that are subject to infinite modification in their detailed application, and give approximations rather than exact measurements.

To engineers this may seem an indication of loose thinking, but knowledge of the fact that a 7½-ft. ceiling height may be adequate in Maine, whereas a 14-ft. ceiling height may be good economy in Southern Florida, gives the writer courage to persist.

A house is not a commodity of uniform sizes and character. Its variations are infinite, although they all fall into fairly clearly defined classifications. The use of each of these classifications will be affected by the regional plan if that plan proves effective in guiding metropolitan or regional development. Consequently, an outline of a regional plan from the housing point of view is necessary, if subsequently housing is to be fitted into it understandably.

Regional Plan Outline

The metropolitan region may roughly be defined as the area within commuting distance of the central or mother city. It may be an area about one or two cities of small or medium size, as well as that about a large city. At present, it may contain only one or two units of really urban character, the remainder of the region being residential suburban. If it does not have other urban units now, it will acquire them later as the population increases and neighborhood business districts develop. Moreover, in this day, when every chamber of commerce is seeking factories, and when factory managements are thinking in terms of industrial distribution, it is almost inevitable that the metropolitan region outside the mother city will develop industrial districts. Consequently, provision must be made in the regional plan for both industrial areas and commercial areas, in addition to residential areas. These, normally, will grow into separate towns, and, unless preventive measures

are taken, they ultimately will merge into one great city, as Philadelphia, Pa., and its satellites have done.

Philadelphia has developed much as the regional planner would have a city develop, except that adequate provision was not made for traffic and that the separate communities were not kept separate by adequate intervening open spaces. The original City of Philadelphia with its mill satellites, Kensington and Manayunk; its factory satellites, Nicetown and Tacony; its residential satellites, Germantown and Chestnut Hill, each separated from the others by open areas, the brook valleys preserved instead of being filled to make uncertain sites for the foundations of buildings, would have been a more pleasing city than it is, with its interminable streets filled with monotonous rows of houses. By the same token, the Philadelphia of to-day is a more pleasing city, with such access as it has to the open country, than it will be if its present streets stretch out and out until they join those of Chester and the other satellites that have succeeded to the opportunities once offered to Kensington and Germantown.

How Urban Units Are to Be Separated

The metropolitan region of the future, therefore, will be planned to contain a number of distinct urban communities which will be enabled to preserve their individuality by surrounding open areas. In part, these will consist of parks, some formal, such as Fairmount Park which to-day separates Philadelphia from the main-line towns, and some natural parks or forest reserves, such as those now being acquired by Boston, Mass., Chicago, Ill., and other cities. Park land alone, however, will not be enough. So much open space is required for the proper ventilation of cities that a considerable part of it must be devoted to productive uses that will pay its way. Cities like New York, N. Y., and its New Jersey neighbors, and the great congeries of cities that are growing up about San Francisco Bay have been blessed, largely against their wills, by open water spaces that seem to some persons far larger than are required—just as in the past with some cities, it was thought that certain streets were too wide, only to find to-day that they are not wide enough. It would be difficult to over-estimate the economic value of the breezes from the water that blow through the streets of New York and the Bay cities.

Awakening to the advantages which Nature forced on some fortunate cities, we shall provide adequately for the new kind of harbor that is coming with the airplane. We doubtless shall, under stress of necessity, calculate carefully how small an air field may be, how high the surrounding buildings may be permitted to rise, in order to bring the air harbor as far in town as possible so as to minimize change in existing values. As the railroad induced river towns to turn their backs on the levees so the airplane may induce them to face in a new direction, and those towns which make the most adequate provision are likely to reap a benefit.

Air harbors like water harbors, however, will prove inadequate to the purpose, and other uses, such as truck gardening and farming, will be found for these open areas.

How Urban Units Are to Be Connected

Isolation, however, is not an objective in the regional plan. Each of the urban units in the region must be readily accessible from the others, more accessible than the upper east side of New York from Riverside Drive. Water routes, rail routes, air routes, and main or arterial highways will be carefully planned so that each center in the region may be easily and quickly reached from every other center. Remembering that by far the greatest daily travel of an urban population is between home and place of employment and that in such cities as New York or Chicago, with their overgrown central business districts, where vocations that have no direct connection are jumbled together, the working population must pass twice daily thousands of buildings that have no possible part in their lives, the waste of time, effort, and money becomes obvious. Although like businesses instinctively tend to group themselves, and thus simplify the transport problem of the workers after arrival for the day's work, these employees still waste much time every morning and evening in passing the buildings of other groups and the dwellings that house the employees of these other groups. The regional plan will reduce this waste by segregating vocational groups more effectively and will bring the homes and workshops of each group closer together. The need of occasional intercourse between representatives of different groups will be met by express routes, rail and highway—perhaps in the near future, air—between the urban centers in the region.

The better segregation of vocations, which can be secured by intelligent regional planning and zoning instead of depending on the blind instinct that has guided in the past, will bring the home and the work closer together and in smaller urban units. As a result not only will time of travel—to-day worse than wasted because of crowded cars that sap the rider's strength and vitality—be reduced, but the character of the dwelling may be improved because more space will be available.

Transit Routes as District Boundaries

The transit routes that tie the urban centers of the region together will largely form the boundaries of residential districts. Along parts of these routes, especially at the intersections of arterial highways, will be minor or neighborhood business districts, containing neighborhood stores, banks, moving picture theatres, etc. Within the space they bound will be a residential area large enough to support one or more schools, playgrounds, small neighborhood parks, a branch library, a community center, churches, so that children at least will have small occasion to cross the busy main traffic streets.

These main traffic streets or arterial highways are one of the most interesting of the problems that confront regional planners. Their primary function is to carry traffic from center to center within the region or to more distant destinations. How they should be designed, what width should be secured for rights of way to provide against future needs, whether they should contain facilities for rail as well as for road vehicles, are questions outside the scope of this paper. It is necessary, however, to point out that they will carry not

only a heavy volumn of traffic, in some cases a constant stream of traffic by day and a considerable and increasing amount of traffic by night, but that they will carry heavy vehicles. The increasing weight of trucks and buses has become a matter of public concern. Admitting, what seems to be the fact, that while the large truck and bus make for economy of operation for their owners, they at present cause great expense to the community as a whole and to property owners along many of their routes where they are permitted to range at will. Street paving that would carry passenger cars for years goes to pieces quickly under their pounding which also cracks the walls of dwelling houses, and which, together with their noise, seriously depreciates the value of whole residence districts. The main arterial highways apparently must be designed and built to carry vehicles that will some day be excluded from residential streets.

The old theory that every street-car street was potentially a business street, was a poor one and was based on inadequate experience. Inadequate as the basis always was, it is becoming every day less adequate. Not only are merchants realizing that the string business district can not compare with the compact district; not only are buses that operate on parallel streets applying the same argument to those parallel streets, but the public is learning that business can never occupy all the frontage on street-car streets. Recent studies have indicated that, outside the principal down-town shopping district, not more than 5% of an area will be occupied by business.

If this is borne out by further studies, it seems that the frontage on the main arterial highways of the region must in large part be devoted to other than business uses. Attempts to develop such frontages to residential use are not proving permanently successful, even for multi-family houses. The inhabitants of multi-family houses object less to noise and movement than those of one-family houses, but even they are beginning to find that noise and movement can be increased to such a degree as to become intolerable. Thus, although the non-business frontage of these arteries may be zoned for multi-family house occupancy, even such dwellings will have to be given protection if they are not to be blighted. The suggestion the writer would offer is that in addition to the ample right of way for traffic purposes, the community shall take possession of strips on either side of the traffic artery. These strips should be parked, and on each side of them should be a minor street serving the dwellings. The dwellings should then be set back, to provide for two screens of planting between them and the traffic highway. The park strip might be so wide that when business expansion can utilize it in part it will provide suitable sites.

This may seem extravagant but it will prove less costly than the slow and spotty development of property abutting directly upon a main traffic highway and the inevitable depreciation of such dwellings as may be there erected.

City Facilities and Neighborhood Facilities

Housing cannot be considered adequately apart from facilities offered by the city or community and their accessibility. To the wage earner distance from place of employment translated into terms of money for means of transit

and time or effort is of greater importance than to those whose means are greater and hours of work shorter. To every one, however, the waste involved in needless daily travel is an economic loss of moment unless it can be transformed into a strength-giving, or health-giving, or inspiration-giving factor. The well-to-do man who drives from a pleasant home to an office near a parkway, may well find this interval an asset, but one who must travel morning and evening in a closely packed subway train is almost sure to find it a distinct liability.

The best means of transit yet invented is that one, reminiscent of days before the horseless carriage, known as "shank's mare." For the normal man a half hour's walk, especially if it can be along a pleasant route, is a good prelude to a day of sedentary or indoor labor. Next, perhaps, comes the bicycle, for this too involves exercise. Then, come vehicles that give their occupants the benefit of sun and air, and last comes underground transit. As the old-fashioned, outside, iron fire escape, now happily disappearing, was a confession of failure to construct buildings properly, so the subway is a confession of failure to construct cities properly. There is room enough in the United States for all to live above ground except the miners. Such failures, forcing people to patronize crowded or sub-surface vehicles, have a direct effect on housing by compelling a choice of two evils—these means of transit, or an inferior type of dwelling nearer the place of employment.

Although access to place of employment is usually the chief consideration, access to schools and to places of recreation, are of some importance. These merge into facilities offered by the neighborhood which is the area that, ideally, lies between main traffic streets and all parts of which are within easy walking distance of home even when home is part of a district of widely spaced, garden-surrounded one-family houses. Here will be the grade schools and the playgrounds for small children, perhaps a High School, or at least a Junior "High," for the older children, a library, or a community center, and a neighborhood playground for adults, and churches—set in grounds large enough to permit their expansion without violating the area provisions of the zoning code. Most congregations seem to be pessimistic of their future, yet instances are known of churches having had occasion to expand and their officers had no hesitation in asking that a rule made for the benefit of the community and the protection of their neighbors should be suspended in order that they might escape the penalty of lack of foresight or lack of faith.

Within the region and its units, thus broadly outlined, the problem is to fit housing so as to give the people of urban America the greatest possible facilities for living abundantly.

A Few Assumptions

In order to summarize the subject, several assumptions will be given, as follows:

1.—It is desirable to decrease the speculative elements in housing and to increase the investment element until the first has been reduced approximately to the vanishing point and the latter has

become controlling. This means that values should be stabilized. Stabilization of house values is dependent on stabilizing the character of the neighborhood and in this stabilization regional planning, supplemented by zoning, is essential.

Conceding the great part that speculation has played in producing the dwellings of America, it must also be admitted that it has played as great a part in destroying them, in blighting whole sections of cities, in promoting rapid transition that lowers housing values so quickly that the investor has withdrawn from a large part of the market, leaving it to the "home owner" whose controlling motive is sentiment, in deteriorating construction until the buildings erected to-day have a much shorter expectation of life and a far higher expectation of repair and maintenance costs than those of our fathers and grandfathers, and, most important, in leading to the acceptance of dwellings inferior in type. From the one-family house it has led to the multi-family house and has gradually squeezed and cramped this lower form of dwelling until a large and increasing part of the urban population lives in one, two, and three-room apartments. These multi-family dwellings are popularly supposed to have investment value, but experience is showing that the rapid obsolescence of a multi-family house often prevents its being rated as a high-class investment. From the social point of view its destructive effect on family life is a matter of concern.

2.—The preservation of the family—meaning parents and children—is essential. The population of voting age may be everything that candidates for public office tell its members they are, but its life and its work would lose significance if there were no children to carry on. With the children lies the whole future. Consequently, children are of first importance. As the house is the shell in which the family functions, as it exerts a constant influence in moulding and shaping the family, even in determining whether or not there shall be children, the question of housing should be approached from the point of view of the well-being of children.

3.—The one-family house with generous open spaces about it is the best house for a child. Consequently, every effort should be made to promote the erection, to protect the continued existence of such houses.

4.—While the one-family house is the most important type of dwelling, there is a legitimate demand for other types, ranging from the two-family house through the so-called multi-family house and the apartment hotel to the hotel. This demand must be met, but because these socially inferior types of dwellings with their possibilities of land overcrowding and cramped living quarters can under-live the one-family house and drive it out, just as Oriental labor can under-live and drive out white labor, it must be restricted to certain specified sections of the community and must be strictly regulated so that it will provide the essentials of wholesome living—light, air, room space, sanitation—for its inhabitants.

Classification of Urban Population

In urban communities there are several easily recognized groups for each of which housing provision should be made. First and much the most im-

portant, because with them lies the future, are the families with children or expectation of children. They call for first consideration. They themselves may be divided into two classes. First are those who are fairly permanently located in the community, whose interests and fortunes have been and will be bound up with those of their neighbors and fellow citizens. They are the most valuable element for they have developed or can develop a lively sense of community responsibility. Less valuable, but more in need of assistance, is the second class, composed of families which, because of the nature of the bread winner's work or because of the temperament of father or mother, frequently move from city to city. They range from high salaried officials of large corporations, army and navy officers, professional men and women—civil engineers, social workers—to the automobile tramps who have become an interesting and puzzling phenomenon of modern life, whose younger children have never known a more stable home than the "flivver" and whose importunities are increasing the burden carried by charity organizations. Even those among this second class who are best placed economically have a difficult problem in providing homes for their children in these days when the choice lies between buying a proper house or renting an apartment.

In the first group it will be noted that families with "expectation of children" have been included as well as those with children. There is a great deal of talk about giving the young married couple a shelter that will just fit their present needs, assuming that when the expected happens they will move from their furnished two-room flat to that idyllic vine-covered cottage where love traditionally abides. Considered as a matter of pure economics, there is much to be said for all this, but while sound economics should be the foundation of living, pure economics is a sterile soil which will not produce an adequate crop of babies. Marriage, the family, is an adventure. Reason it out too coldly, balance economic items too carefully, and the young couple will grow to middle age, still living in their apartment, still thinking first of their own safety, their own comforts. Then the Nation may well ask why it was taxed to provide for their schooling, to protect their health, when they have been unwilling to pass on the heritage they received. The first home of the young couple should be at least a promise of its future home, should have in it the room, the play-yard that every day ask when the expected is to arrive. This may be economic waste, but the greater part of the joy of living consists of what cannot be strictly justified on the score of pure economics; it may be beyond the means of many young married couples, but it is an objective to be approximated as closely as we—and they—can.

Next to be considered, because they have not shirked but have rendered their service to society, is the group composed of those who have reared their children and sent them out into the world. The home that sheltered them when all the family were together may now be too large, too much of a burden. Many will continue to maintain it because of sentiment, but others will desire and should have a more convenient shelter. Their problem is not met by old folks' homes, however those may be disguised by luxury. Perhaps the nearest

approach to a solution is the occasional multi-family dwelling where through some happy circumstance of management, tenant leadership, or a common dining room, the inhabitants mingle for a time in the evening, and the older people have opportunity to maintain some daily contact with younger people.

Then come the unattached individuals who form the tragedy of civilization, often not recognized by its victims until they reach middle age. Their variety is so great, class merges into class so imperceptibly that it is difficult to classify them definitely. They range all the way from the well-to-do bachelor who lives at his club and thus has the casual social intercourse with his fellows that fills so many of the odd moments of contented living, the lack of which reduces living to periods of conscious effort interspersed with periods of loneliness; from the two spinsters who have joined forces to fight off loneliness and who live together in a little apartment, through those forlorn ones who inhabit boarding houses—a form of housing now apparently on the decrease—hotels and rooming houses—a form of housing now apparently on the increase. This great army is recruited from the youth of the land who venture forth in search of fortune. Its veterans are those who fail to make a family harbor. The problem of the unattached, whether it be the well-known "homeless man" who patronizes municipal lodging houses, or the wage-earning woman, whether it be the raw recruit or the veteran left-over, is one that has not yet begun to be solved in spite of the voluminous literature dealing with fragments of it—perhaps because this literature does deal with fragments only instead of with the problem as a whole.

Classification of Houses

For the population that is to be housed in a carefully planned region there is choice among the following types of dwellings:

One-family houses (one family occupying the whole house from cellar to roof.): Detached; semi-detached; group; or, row.

Two-family houses (one family above the other) subdivided as previously described.

Multi-family houses (ranging from the building in which every apartment is equipped for housekeeping, through that where a common dining room supplements or supersedes the housewife's efforts, to the hotel where cooking in an apartment is strictly forbidden.) Detached; group; or row.

Somewhat apart from any of those mentioned are the boarding house and the lodging or rooming house. These are not a distinct type of housing, but are merely the result of opportunist attempts to utilize the waste resultant from lack of city planning and a housing policy in the past. When the day comes that there are no more blighted districts, no more cast-off dwellings, the boarding house and rooming house, as they are known to-day, will disappear, their places being taken by houses designed for the purpose. Instead of a shame-faced dilapidation, recalling better days, they will evidence the self-respect of those who accomplish what they intend to do.

With this classification of houses; with a clear understanding of the function of each class; with a regional plan, zoning regulation, and an intelligent

distribution of centers of employment so that there will be ready access from home to shop; with a stabilization of the character of neighborhoods and, consequently, of house values, and, not least important, a clearer recognition of the value of space, both inside and outside the house, but part of the same domain so that alterations and improvements may be made, it will be comparatively easy to develop a housing policy designed to serve adequately the needs of the population.

Each individual has conflicting desires among which he must choose. Each might prefer to live in the White House, not because of an ambition to be President, but because the house has the desirable characteristics of a family dwelling; it is spacious and set in a very pleasant yard large enough for children's play and even contains a tennis court, and, in addition, it is most accessible from its tenant's office which is easily reached by his chief business associates, and, to add excellence to excellence, to satisfy the other head of the family, it is cheek by jowl with the principal shopping district, within a block or so of two theatres, and within easy reach of the others. In short, it would seem to be ideal. Certainly, as Lincoln is reported to have observed, most of its tenants desire to renew their leases.

Although this combination is provided for Presidents, most families have to make choices. If convenience of access of department stores is more important than home or children, an apartment near the center of one of the larger urban units or along one of the arterial highways is selected. If we no longer have children or expectation of them, a similar choice may be made, although some recent sub-divisions give reason to hope that it will be possible to find a small house of five or six rooms, attractively designed and located in a pleasant neighborhood, thus doing away with the present hard choice between an eight to ten-room house and a five-room apartment. If there are growing children a one-family dwelling will be chosen, a little less accessible from the centers of work and amusement, but compensating for this by giving neighbors who have the same chief interest and who have a greater tendency to "stay put" long enough for the development of family acquaintance, parents with neighbors' children, as well as the horizontal acquaintance of apartment-house populations which tends to follow the line of age groups.

The greater stabilization of the character of neighborhoods will encourage investment in rental housing by increasing the life expectancy of the individual house. It will lead to the wider use in one-family house districts of services now characteristic of multi-family houses. Stabilization which reduces the speculative factor in real estate, which turns attention to permanent investment values, should result in creating again the estate or company that owns or manages a considerable number of one-family houses, for these depreciate, become obsolescent less rapidly, cost less to maintain and, provided they have open space about them, are more readily kept in step with "modern improvement," than are multi-family dwellings. Some of the finest dwellings are one-family houses built 50 or 100 years ago. Some of the old one-family house districts after a period of decadence have come back strongly. Few multi-family dwellings have maintained the standing of their

youth until reaching their majority, and none, so far as the writer knows, has ever come back after it once lost prestige.

Probably this has been due chiefly to misplacing. They have themselves spoiled many neighborhoods and, in time, have suffered from the deterioration they caused; or they have been injured by the invasion of business. In a planned and zoned region these causes should be removed. There will obviously be space enough so that the temptation to land-overcrowding will be reduced. There will be system and order so that each type of dwelling will have that place best fitted to its purpose. Zoning does not imply a series of girdles about an urban center, but it does imply an arrangement in relation to traffic and traffic facilities. The regional plan will guide the development of traffic facilities, types of dwellings will be placed in accordance with their need of these facilities, and zoning regulations will prevent the placing of an inferior type in a district where it does not belong.

DISCUSSION

JAMES FORD,* ESQ. (by letter).—This paper is the ablest discussion of the civic and social aspects of housing in its relation to the regional plan that has come to the writer's attention. It shows clearly the paramount importance of making the regional plan contribute to human welfare and civic progress. The author outlines specific ways of escape from the present deplorable tendency to let selfish interest dominate public interest.

In America, ugliness and unsightliness in industrial and residential districts, and noise and inconvenience in traffic arrangements, have become so common that they are taken as matters of course. There is no reason why access to the amenities of life should be the exclusive right of the well-to-do. If the highly trained minds of the Engineering Profession can be applied with equal force and skill and practical judgment to the problem of providing better homes and better neighborhoods and better community life for wage earners, America will make over its industrial districts so radically that they will be a source of justifiable pride.

Mr. Ihlder points out effectively that the next generation should be the object of chief concern. Progress and America's contribution to world civilization rest with them. They are largely the creatures of their environment and cannot far transcend it. The drab, monotonous, unkempt, crowded, treeless, industrial quarters of American cities can hardly produce enthusiasm for public service or good judgment as to what constitutes civic interest. Housing conditions that make for wholesomeness in home life and respect for government are, therefore, necessary and the regional plan is clearly the first point of attack.

Sunless, unventilated, crowded homes produce irritability and low vitality, if not actual ill health. The detached dwelling, placed with careful consideration of orientation, makes it possible to have sunlight and cross ventilation in each room and provides for adequate privacy and control of the factors of home life. It also makes possible the home garden and the safe home playground. It can provide relative freedom from the dust, noise, and accident danger, which characterize crowded residential districts. It unquestionably provides larger opportunities for self-development on the part of parents and children. The home ownership, which it makes possible and which, for the majority of the population, is advisable, contributes to civic interest, for the home owner ceases to be a nomad, puts down roots in his neighborhood, recognizes community and civic interests, and bends his energies to the improvement of his neighborhood and of his city.

Carefully considered regional planning, as outlined by Mr. Ihlder, will, in time, make these values accessible to all. There are few civic measures more significant than this.

BENJAMIN H. RITTER,† ESQ.—The author has outlined the basic principles of regional planning, which must be observed in any metropolitan district if housing is to be developed and maintained on a sound basis.

* Executive Director, Better Homes in America, Washington, D. C.

† Executive Secy., Pennsylvania Housing and Town Planning Assoc., Philadelphia, Pa.

Surely all will agree that adequate open spaces surrounding accessible individual homes with sanitary equipment and modern conveniences, are the primary requisites of good housing. As indicated, this requires the proper distribution of population over a given area. Therefore, the outstanding need of any region, from the housing standpoint, is the adoption of a practical plan that will facilitate the conveniences of the home and prevent congestion and overcrowding of the land.

In the absence of plans, regulations, and possibly some of the necessary equipment in the past, many centers of population have been allowed to become overcrowded to the extent of 100 to 700 persons per acre. These conditions are not limited to Manhattan Island, or to any large city. They are found even in the small mining towns of Pennsylvania. Such practices have resulted in what has been termed, very fittingly, "the American blight." Unquestionably, the time has come when the authority vested in municipal governments must be exercised to check and control this injurious form of city growth.

The problem does not seem so complex when it is realized that in the United States there are 50 metropolitan centers, each with a population of 150 000 and more, scattered over 3 000 000 miles of land, most of which is habitable. These centers with their surrounding territories represent the country's metropolitan reservoirs. Knowing where the reservoirs of people are and the topography of the land surrounding them, it should be more or less easy to determine the flow of population and properly to provide for it.

The machinery for handling this job is in the making. No one ventures to say that it is perfect, but the various experiments made with it, and the many new parts patented during the past ten years, convince one that it will be effective. Its successful operation will depend on the willingness of individual urban communities to co-operate as a unit under the guidance of some form of a regional organization.

To make it effective and carry the proper weight, it seems that membership in this regional organization should be by election or administrative appointment from the various municipalities concerned. A nominal fee for attending meetings might not be out of order. This board with its complete data and maps, showing the general layout of the region, elevation of territory, incorporated villages, transportation lines, present use of land, the location of industry, commerce, and residential districts, open spaces, population density, and curves of population growth, will be in a position to direct the proper development of the region, preserve the individuality of the small towns, and yet enable them to carry on their various public activities as one large unit.

A properly laid out street and road system will serve as a reliable guide for future sub-divisions and platting of land. Parks, playgrounds, club houses, shops, stores, and all the complex equipment of a modern city can be located with a definite economical relation to each community center as well as to the district as a whole. This will encourage regional light, power, gas, water, and sewage systems, in addition to many other community enterprises, both public and private. It will tend to reduce the cost of supplying necessary

conveniences to suburban districts. With the coming of the automobile, motor-bus line, and adequate suburban streets and transportation lines, isolation will give way to united communities with all the advantages found in any city plus a more delightful home environment. This will give rise to incentives that bring about the proper decentralization of people and will make it economically possible for families to live in homes of better selection.

Even now, the doors of the suburban districts are opening to thousands of middle-class families even if the bread-winners must continue to work in the city. It remains the duty of each incorporated unit in metropolitan regions to safeguard this movement by protecting all residential districts with proper zoning regulations. Likewise, it is the obligation of government to see that sufficient space for industries is reserved in some of the resident districts, so that employment may be provided for those who may wish to work near home. Here, again, a guiding hand for the metropolitan region is of greatest importance, for it may be just as necessary to advise a municipal unit what not to do, as it is to advise it what to do.

It must be realized that industrial plants and even a variation of housing accommodations are just as necessary as individual homes. One cannot survive without the other. A properly regulated factory or an office building may be just as essential to one locality as a hotel or an apartment house is to another. The complexity of modern life will not permit any of these factors to be overlooked. The manner in which they are correlated will determine the future housing in metropolitan regions.

Bernard J. Newman,* Esq.—The author, looking out over an expanse of slum waste in American cities presents a vision by which, if consistently held, home life may be changed so that it will produce the man power needed to maintain the supremacy of the nation. Large areas in American cities are a waste to-day. There is no justification for herding tens of thousands of families in congested centers. The inhumanity of it is apparent. The social loss is measurable. In Philadelphia, Pa., for example, more than $28 000 000 are spent annually to care for defectives, dependents, and delinquents. That is not a foundation, but an annual expenditure of public and private charity for the care of the waste product of urban living. Under the right program, of which planning is a part, much of it can be salvaged for capital expenditures.

The paper assumes that the fundamental note of all city or regional planning is human welfare. Through highways are recommended; parks, parkways, and recreational centers are suggested; the unification of sewer systems is proposed; and common sources for regional water supplies are advocated, not as technical engineering problems, but as adjuncts to serve man in the various aspects of living.

The author has implied that the regional planner is more than a technician with an engineering problem before him. His technique, based on the fundamental principles of his profession, is essential to the solution of his problem, but it is secondary to its object, namely, the layout of the area for constructive

* Managing Director, Philadelphia Housing Assoc., Philadelphia, Pa.

communal service. If this is accepted, the logical deduction is that any regional plan proposed is defective if it is not evolved from a concept wherein the human side of communal life is of more concern than the mechanical aids toward its expression. Such mechanical aids are not thereby minimized in importance, but are properly subordinated to their place as aids. In other words, the physical city as it is to-day is of no value except as it is a place in which man may live, work, or play. The hollow echoes of abandoned mining towns stir only historic interest. Their street plans, business areas, and housing are of merely academic significance. Man has forsaken them. Cities are concerned with physical expression, solely because of suitability or non-suitability to meet the every-day needs of those who there live, work, or play. Manifestly, in their planning or re-planning, the object of prime importance is that they may serve man in each of his major interests with the least restraint or injury. If they do not so serve him, then the logical and the practical thing to do is to control all future urban development or re-development so as to avoid past mistakes.

In determining the significance of all that comprises an urban area and in planning for its utilitarian as well as its artistic expression, the fact must not be lost sight of, that the preservation of family life, which the sociologist declares is the unit of all social life, is of fundamental and primary importance. In short, highways, transportation facilities, parks and civic centers, are not entities in themselves, but are correlated units, obtaining their real value from the service they render to their community. To the extent that their construction or placement is unsuitable, or produces a problem in any other phase of communal life, they are subject to remedial action; to the extent that their planning or promotion fails to take into account this inter-relationship, they are faulty. There is an interdependence between the physical expression of the city, in its provisions for industrial and commercial needs, and those other aspects of such physical expression manifest in residential areas and the social needs accessory thereto.

This fact has not received adequate consideration in city growth. If it had, there would be little need for legally expressed regulation for zoning; multiple housing would not have gained headway; there would be no such widespread areas of slums; cities would not be so concerned with population "bigness"; and there would not be such concentration of land values with all the attendant increases in the cost of production and government. In like manner there would not be so many sectional plans concerned with getting a business population into or out of a business center. Things as they are would not be considered fixed, with attention given to alleviatory plans which, as in the subway in New York, or the loop hazard in Chicago, often serve to accentuate the problem.

This thought must be kept in the foreground of all proposals for city development advanced by the city and regional planner. Has it been so kept? The speaker does not think so. It has been subconsciously accepted, but there is little evidence available in proposed plans to justify the belief that it has been an ever-conscious companion of the planner's thoughts. For this

reason, therefore, it is very pertinent to analyze the place of housing in the regional plan.

Mr. Ihlder has very properly pointed out the illogical development of cities to-day with land loads, in building and people, that have placed heavy burdens on family life, with a slum virus that has not only menaced communal health, but destroyed the industrial efficiency and commercial resources of hundreds of thousands of workers and their families. He has challenged the practicality of congested business districts and concentrated industrial areas. He has emphasized the necessity for decentralization, pointed out its feasibility, and outlined means whereby the present trend may be expedited through satellite communities, interrelated with, but separated, geographically and physically, from the parent city. As a natural corollary, he has indicated the compelling necessity for suitably planned and adequately supplied housing accommodations.

Cities are not fixed entities, but units, breaking down in spots by natural processes through the withdrawal of industries to more suitable sites and the migratory practices encouraged by business concerns chasing each other to more strategic centers of trade. A constant process of wedging in and drawing out is written in the records of the decadence, alteration, or demolition of buildings in all older areas. A financial district may remain static in a city like New York and the insurance district change, or the insurance district may have sent its roots down and the financial district changed, as in Philadelphia, but there is constantly going on, in all American cities, that illusive maneuvering for the "best" locations, which is conclusive evidence of faulty planning. The greatest loss is to the home life of the people, which is ruthlessly encroached upon. The dwelling, in which such home life is centered, loses some of its desirability. Its occupants, in order to preserve those attributes of home life most prized, are forced to move to other areas farther away from centers in which they trade or labor. Regional planning, therefore, offers the opportunity to reverse this mistaken policy, especially in new areas. In the almost virgin territory outside large cities it can plan for those satellite communities which are practically complete entities in themselves, but are so connected with the parent city by highways and transit facilities that the ultra-cultural advantages offered by the latter may be available to the former. In such satellite cities, interrelated and co-operating with each other for the economic operation of service needs, will be found the antidote to the lure that over-populates urban centers while depopulating rural areas. There, adequate housing can be established and protected without loss to or encroachment on industrial or commercial life.

Mr. Ihlder has outlined the essential elements, industrial and commercial, cultural and recreational, that are needed in such smaller communities, and has emphasized the feasibility of providing satisfactory home environment with space in and about the dwelling to serve family needs. Decentralization is the keynote. Its popularity cannot be questioned in the face of the present higher rate of growth of suburban towns as compared with the cities to which they are adjuncts. The trend is that way, but it needs wise directing in order to obtain for the future citizen the best results. The practical difficulty, under

present land-development practices, of maintaining the necessary isolation from the parent city is remedial. The suggestion is made that intercommunity parks separate geographical boundaries and that, by low land cost, agricultural belts be established which, because dedicated to agricultural use, cannot rise to the prohibitory land values accompanying other forms of development. The speaker doubts whether there can be any insurmountable legal disqualification to the establishment of such community safeguards. The processes involved to secure them are: By voluntary gift of civic-minded property owners, or landlords and others interested, of land for park purposes, specially designated for all time for such uses; by municipal purchase, especially of areas where land costs are lower; by excess condemnation when boulevards or transit lines tap undeveloped districts; by zoning; by prior designation of use, as practiced in small park and street platting in Philadelphia, prior to the actual taking title thereto by the municipality, so as to forestall the erection of private structures with an attending higher condemnation cost to the local government; by preferential tax rates and assessments of land according to city, suburban, or farm use; and similar methods which have been adopted where public control over land has been exercised by towns and cities.

The author has discussed many phases of the part that housing plays in the regional plan. The major contribution he has made is his emphasis on the need to expedite a movement already under way and to guide it so as not to create a flock of evils in new centers similar to those so costly in the old. He clearly sees that the promotion of housing betterment in urban centers must always labor under the handicaps of faulty planning, or lack of planning, of the past and although relief can be secured, nevertheless compact construction dooms family life to be satisfied with less than the normal advantages essential to wholesome living.

Bleecker Marquette,* Esq. (by letter).—This scholarly paper goes to the root of the housing problem. There can be no question in the mind of any one who has had experience in this line, that there are no arbitrary city boundaries that can confine within their limits the housing problem of a city.

The importance of the proper allocation of industry and homes for workers is quite properly stressed. It is desirable to eliminate, at least to some extent, the severe strain on the vitality of workmen in the long period of unnecessary travel to and from work. Few people have any real conception of the ill effect of the terrific hustle and bustle of modern city life. The fact that mental disease is found to be uniformly more common in cities than in rural areas is enough to justify careful study of ways and means of decreasing the strain of modern city life.

The writer is not discouraged with the possibilities of regional planning, but it will take a great deal of effort and much education before the attainment of real progress toward Mr. Ihlder's ideal of locating industry and housing so that the amount of unnecessary time spent in travel will be cut to the minimum. Perhaps, some day, leaders of industries will see that they have much

* Executive Secy., Cincinnati Better Housing League, Cincinnati, Ohio.

to lose by locating in large cities, and will seek smaller communities where their workmen will have an opportunity to enjoy the amenities of living. At the moment it must be admitted the trend seems altogether in the opposite direction.

Mr. Ihlder presents a unique point of view when he discusses the difficulty of finding logical use for land adjoining main highways in cities. This is a great problem and will become a greater one. Certainly, business will never occupy all the properties along these highways. Zoning laws usually locate apartment districts adjoining them. Tenants of such apartment buildings are already beginning to recognize the disadvantages of the noise, dust, and commotion, and architects and builders are reflecting their objections. They are demanding that sites be provided for apartment houses away from main highways. The suggestion, made by Mr. Ihlder, that minor streets be laid out parallel with thoroughfares, separated from them by parked strips, and that apartment houses be constructed along these minor streets, seems worthy of consideration.

The housing of a city cannot be safeguarded without regional planning. That was learned early in the game, before anything was known about regional planning. Builders soon find that limitations are placed on the shack type of house in the larger cities, but that they can step outside the city limits and build just about as they please. The better the housing regulations in the city, the more temptation for "jerry builders" to carry on "beyond the pale". Nothing is more distressing than this to the person active in housing improvement in a community. Just as he has begun to bring about a reasonably satisfactory situation in the city, he finds himself confronted with a serious housing problem in the outlying district. This is exactly what has happened in Cincinnati, Ohio. The city has a reasonably good building code, and the housing regulations are now in the process of complete revision. It has perhaps as intelligent and conscientious enforcement of the regulations as could be asked for by any city. It has a good zoning law and a comprehensive city plan. In the meantime, while attention has been directed toward problems within the confines of the city, little slums have been growing up in the county. Some method of controlling the development of these areas is becoming absolutely imperative, and the regional plan is undoubtedly the way to meet the problem.

Cincinnati has eight distinctive satellites, several of which are nearly surrounded by the city. They are practically a part of the city life, participating in its benefits and materially affecting its welfare. Most of their inhabitants earn their living in the city, use the city's streets, and profit by practically all the safeguards of city government. They do not want annexation. A regional plan would help to make it possible to fit these satellite communities into the whole and to bring about a situation in which they will play a proper part in the city's life and in the maintenance of its government. A State law is already in effect which provides for the establishment of a county and regional planning commission. Forward-looking citizens interested in the proper development of Cincinnati regard regional planning as the next big forward step.

W. C. Rice,* Esq.—As Mr. Ihlder points out each regional plan will have to meet the conditions of its local setting. The speaker desires to indicate some trends affecting the Pittsburgh, Pa., Industrial District.

General Features.—The Pittsburgh District owes its general layout to its topographical features, which determined its location on account of water transportation. The railroads follow the waterways, giving the District its present formation in which the lowlands have been taken over by industry and the highlands by residential districts. Future development will continue along these lines, with the unoccupied lowlands being taken up by industries. The railroad connections available are now generally supplemented by an improved system of highways. Therefore, the main river valleys and the valleys of the larger creeks, in which railroads now exist, will form the industrial sections of the future Pittsburgh Metropolitan District. The highlands between these valleys form the logical location for residences and the sections that lie closest to the valleys should be considered as the best location for the homes of the operatives of the adjoining industries. The more remote highlands should be preserved for the more expensive residential developments and for parks and other public recreational features.

Facts Influencing Location of Residences.—This is influenced, however, by the demand for housing accommodations of those who are not directly concerned with the operation of the industries, but who serve the industrial population as a whole in the various commercial enterprises. It is also affected by those who, on account of an improvement in their economic condition and the diversity of occupations in the family group, are not located in close proximity to the mills where they work. The changing conditions in employment and the improvement in living conditions have been the great influences that have changed neighborhoods.

Proper Basis for Area Requirements.—The present practice of zoning on the basis of the family unit is not as logical as zoning on the basis of the individual. The classification suggested by Mr. Ihlder is not comprehensive or elastic enough to form a proper basis for a housing-control program. There are certain minimum requirements of area and volume per individual that govern, and if a reasonable limitation is made as to area per individual, the multiple house will lose the greater part of its objections. Ample area and street frontage would then be available, and the light and air space of the adjoining property owners would not be injuriously affected.

In neighborhood commercial districts, where the ground floors are used for business and the upper floors for residences, in addition to the minimum area per capita requirement, the lot should be of sufficient area to allow twice that occupied by business. For land located in the lowlands and which is obviously a future industrial site, the minimum requirements per capita should be considerably increased for the reason that these locations are generally not as healthful because of the prevalence of fog, smoke, and dust.

With these basic considerations determined, the early sub-dividers should be given wide latitude in laying out their property. Further development of

* Pittsburgh, Pa.

the property by houses would then be easily controlled by proper building code and fire protection restrictions.

Multiple versus Single-Family Houses.—The single-family house may not be the ideal one for a large industrial population. It is more expensive than the multiple house. If the speculative builder is eliminated and the cost of building construction continues at its present level, the opportunity of the individual to secure a single-family house ample for his needs will decrease. Then, if the accommodations are not furnished by the industries, doubling up of families and greater congestion than that which now exists, are bound to occur under the pressure of economic necessity. On the other hand, if the speculative builder is encouraged and controlled by proper building regulations and zoning restrictions, he will use proper materials in his buildings.

The housing of the Pittsburgh Regional District must depend more and more on the speculative investment builder and on the industries themselves. The growth of financial knowledge, the increasing mobility of people, and the changing ideal in the family will cause them to view with concern any tendency toward establishing themselves by a considerable investment in one definite place. This would tend to restrict their ability to take advantage of opportunities in other parts of the District or other sections of the country.

Some of the tendencies along this line, which must be recognized, are the greater investments being made in automobiles, radios, and similar facilities for enjoying life. Stocks, bonds, and similar investments, which do not require so much oversight on the part of the owner, are also gaining in popular favor. The prosperity enjoyed by the inhabitants of the industrial sections of this country—increased pay, shorter hours, restriction of emigration, and aversion to manual labor by the younger generation—are also dominant factors.

E. M. Bassett,* Esq.—City plan maps must be precise because they mark the different characters of parcels of land. The boundary of a park must be definite—a definite line; the boundary of a street must be a definite line; the boundary of a zoning district must be a definite line; so with the school site, a fire-house site, the site of a court house; and, also, with pierhead and bulkhead lines. It is the determination of those lines that constitutes city planning.

Open spaces between communities—how shall they be obtained? Mr. Ihlder has properly stated that they cannot be parks, because parks are an expense to a community and yield nothing by taxation. These open development spaces must be put to use, as flying fields, fair grounds, race tracks, country estates, golf courses, etc. They probably cannot be obtained through adjustment of taxation. A low tax rate will cause increased value, because the land is favored by taxation. With any low taxation there must be regulation of the percentage of land to be covered by buildings. Probably a 3% limit of cover cannot be attained through the police power because the Courts would decide that it was a "taking" and not a police power regulation. Perhaps these open development spaces can be taken by the State imposing an

* Counsel, Zoning Committee, New York, N. Y.

easement that will prevent structures occupying more than 3% of the lot. Such an easement could be taken by eminent domain. Owners of country estates dread the incoming of developments of 30 by 50-ft. lots. Some of these estate owners would not make claims for damages if the State imposed an easement of 3% cover on the land.

This country is the only one where the acts of legislative bodies can be set aside by Courts, and, therefore, citizens can only do by legislation those things that can be brought under the police power. If it is not possible to accomplish the result under that power, it must be accomplished by eminent domain, and eminent domain is expensive.

Frank B. Williams,* Esq.—This paper has inspired a quickened sense of the importance of the proper regulation of the region as a whole and has strengthened the belief that by itself regional planning, in the sense usually attached to that term, is insufficient for that regulation.

There are many reasons why regional control is becoming rapidly and increasingly necessary:

First.—With the growth of cities, urban population is more and more seeking the remoter suburbs. Population is thus increasing not only in the centers, but in the entire region.

Second.—Throughout the region, and not in cities alone as formerly, people are demanding urban facilities, and local officials are finding the problem of satisfying these demands, and reconciling them with those of other localities, more and more difficult of solution. Urban problems, now region wide, are almost impossible of solution by local effort alone.

Third.—Urban facilities in rural and semi-rural localities are bringing with them poles, billboards, filling stations, "hot dog" stands, and other nuisances, prevalent in cities, to escape which city people have gone to the remoter suburbs. There is a deepening feeling that, to-day, these conveniences can be furnished in the country without giving the offense which is often regarded as necessarily incident to them. This, however, can be done only by restrictions covering broad areas.

Evidently the planning of a region or any other area is not enough. The plan, to be effective, must be enforced. The growing importance and difficulty of regional planning is bringing to the forefront, as never before, this problem of the administration of regional planning, which in this country still awaits solution. In so far as such administration has been attempted it has been of two kinds:

(1) The jurisdiction of the city has been extended a certain distance over the adjacent outlying territory. This has proved to be both too much and too little. It is undemocratic to govern one community by the vote of another, and this practice will not be continued. Indeed, in the more developed parts of the country where regional administration is especially important, it is not feasible. Thus, Nassau and Westchester Counties, New York, will not tolerate any control over them by New York City. Because it is undemocratic, it seems

* Attorney-at-Law, New York, N. Y.

impossible, anywhere, to give the central city the planning powers over the outside land, which are necessary for a sufficient measure of control. For instance, no central city is allowed to zone outside areas in spite of the great need of harmony in the zoning of the entire region.

(2) Regional control is attempted by extending the boundaries of the central city. This extension, often greatly delayed by local interests, is never wide enough to give the regional control necessary, and if it were sufficiently extensive for that purpose, would unduly destroy local government, so necessary for efficiency and happiness; for, with all its faults, home rule, in large measure, is more advantageous than centralized control of local affairs.

There seems to be no immediate prospect of the attainment of effective regional planning administration in this country. Abroad such administration exists, and is obtained by State supervision of local planning, harmonizing local conflicts, and furnishing the incentive to local governments in their work. It is along this line, it would seem, that real regional planning must come in America. To some it seems contrary to the principle of home rule; but, in fact, it preserves home rule by giving just the proper amount of regional control without further interference with local government. Other systems fail by reason of ineffectiveness or excess; State supervision succeeds by keeping to the golden mean. Successful abroad, it will surely come in this country.

U. S. Grant, 3d,* Assoc. M. Am. Soc. C. E.—The speaker, whose practical work with city planning has only covered a few years, has been engaged in some regional planning which includes the National Capital, and some rather peculiar problems that have arisen there.

In the first place, it appears that city planners are likely to be too intent upon the problems of the moment, especially traffic and business problems; and that the urgency of a solution to these problems is very apt to lead any planning commission from the more general, and to the speaker's mind, more important, problem of planning for the future. Work on the two must go on simultaneously, and one cannot be neglected in order to take care of the other. Moreover, the more immediate problems demand attention and, therefore, are sure to be solved in the natural course of events, so that the really serious problem, which the city planning profession alone can appreciate and handle, is that of preventing too great a concentration of population, and the evils that come therefrom; that is, the problem of preserving the open spaces. Parks alone, and the high cost of securing them, even by exercising the right of eminent domain, will hardly save the situation for the present; although this may take care of it in the future, if some other way can be found to increase the available amount of open spaces to meet present needs.

A partial lien on open spaces used for other purposes certainly does indicate a legal method of preserving all the open space that is still left. However, there is another legal method of carrying out the combined operation of different authorities, as in the State of California, where a plan of flood control,

* Lt.-Col., Corps of Engrs., U. S. A.; Director, Public Bldgs. and Parks of the National Capital, Washington, D. C.

extending over nearly all the northern part of the Valley of California has been adopted jointly by the Federal Government and the State. Each has set up a board with authority to modify the approved plan to some extent, and each has passed laws by which plans inconsistent with the adopted project cannot be carried out. In the case of interference of this plan, with irrigation and other local projects, the proponents of the latter can, of course, have recourse to the Courts and show a damage which is covered by appropriation or assessment; but thus far this method of prevention has worked very well, and the Supreme Court of California has sustained the legality of the legislation. It offers a compromise measure which is immediately possible where planners have to deal, as they do in the region of which Washington is the center, with municipalities or States and the United States; and even in other cases, where separate States mutually agree upon some general plan for the preservation of certain open spaces, each contributing toward its cost an amount proportioned to the features in which each individual State is particularly interested. Each State would constitute its own board to carry out its part of the plan; and both boards, meeting together, could arrive at a mutual decision as to general changes in the plan, which were found in the interest of both sides. Within the limits of its own jurisdiction each State Board would then prevent any development inconsistent with the project during the period necessary to complete it, and increases in taxation of open spaces remaining in private ownership could be prevented, wholly or in part, as long as their open character beneficial to the public is maintained.

The question of the cost of parks is one that deserves more study than it usually gets. Those who come into city planning from the Engineering Profession are especially inclined to look upon parks as a luxury that is expensive and, therefore, something that should be dispensed with as much as possible. In many cases, especially where they are laid out after careful study, parks may actually result in an economy to the city in which they are placed. One park project, over which urban development would have been very much more expensive than park treatment, has been before the City of Washington for about twelve years, and is now (1926) nearing completion. The only possible loss to the city because of the park is the reduction in taxation due to losing the assessments that might have been raised on the property located within the park limits; but no such loss will actually occur because the increase in taxable values of the land adjacent to the park may be expected to equal the former value of the land taken, not to mention the benefits in traffic and other facilities which it offers. There is an actual gain of about $4 000 000 to the city in the cost of the park as compared with what it would have cost to make the usual street developments.

The open spaces must include, not merely playgrounds and small city square parks, but larger areas. The necessity for them is very much greater than it was, because the public has a much greater amount of leisure time to spend out of doors, for which provision has to be made. Twenty-five years ago the laboring man worked 10 to 12 hours per day, and his children began to work quite early in life. Nowadays, those children are still going to school at the age

of 14 and 15 during part of the year only, and then just a few hours of the day, and the working man himself has a considerable amount of leisure time during the day and in the evening. They cannot find a safe or satisfactory place for exercise on the streets, because of the crowded condition, and the parks are their only safe and sane recourse.

JOHN IHLDER,* ESQ. (by letter).—The writer has been fortunate—or unfortunate—depending upon one's viewpoint, in the discussors of this paper. With a single exception, each party to the discussion sees practically "eye to eye," so they leave nothing further to be said except by way of expressing appreciation for the greater emphasis and clarity they have given to points made in the paper, and for additional data, which the writer has found instructive and helpful.

The writer takes issue with Mr. Rice on two points—which really are one. Believing, as he does, that the family is the essential unit of society (the paper recognizes the fact that there are individuals who must be provided for), the writer cannot agree that the requirements of the individual form a proper basis for a housing program. Consequently, also, he cannot agree that "if a reasonable limitation is made as to area per individual, the multiple house will lose the greater part of its objections." To quote from the paper,

"The preservation of the family—meaning parents and children—is essential. * * * The one-family house with generous open spaces about it is the best house for a child."

Mr. Rice apparently believes that proper housing is fully provided if the house is sanitary and has adequate light and ventilation. The writer believes that this is not enough, that the predominant type of house must also be a home which makes adequate provision for children. Therefore, he disagrees with the statement of Mr. Rice that "the single-family house may not be the ideal one for a large industrial population." An industrial population has children.

It may be that under existing conditions in many American cities the wage-earners must live in two or three-room apartments, but that does not make these apartments ideal. Mr. Rice's supporting argument is that the single-family house "is more expensive than the multiple house." In that statement he raises a question which he does not answer, one which cannot be answered briefly because it involves many factors. One can say, however, that before the World War, when housing conditions were more nearly normal than they have been since, the rent of a six-room one-family brick house in Philadelphia was lower than that of a rear five-room unheated, walk-up tenement in New York, or that of an apartment in a wooden "three-decker" in Boston.

Paper No. 1683

CULTURAL OPPORTUNITIES IN REGIONAL PLANNING*

By Andrew Wright Crawford,† Esq.

With Discussion by Messrs. Henry V. Hubbard, James Sturgis Pray, Noulan Cauchon, E. M. Bassett, Jacob L. Crane, Jr., Charles Wellford Leavitt, Morris Knowles, Harold M. Lewis, R. H. Randall, C. H. Howell, Charles W. Eliot, 2d, Winters Haydock, Gilmore D. Clarke, Harry J. March, John Ihlder, and Joseph Barnett.

On his return from a tour through the Southern and Western States, Otis Skinner related that he had done numerous one or two-night stands in typical "Main Street" towns, with all the stale, flat dullness that one associates with that description. In nearly every case, however, some one asked him to play on the golf course, which he generally did; and he always found the delightful, charming loveliness, with all the beauty and abiding cheerfulness of Nature, which the well-kept swards and the long green vistas, required by the game, produce at every turn.

The introduction of golf has brought a cultural opportunity to the dullest, drabbest town that boasts a course. Golf courses are the anti-toxin of "Main Street". Doctors state that golf is prolonging the lives of many men, but, important as that service is, it seems surpassed by this observation of Mr. Skinner. Many individuals will echo an agreement, and give parallel citations of their own experiences. "Bangor" used to bring the recollection of terrible meals in a wretched station in a hopeless town; but now the name conjures the vivid picture of a river vista bordered by the tapis vert of the golf course, dotted with glorious New England elms.

Culture is assisted much by education, much by travel, much by reading, but it depends in large measure upon physical adjuncts. It is possible to

* Presented at the Joint Meeting of the City Planning Division with the American City Planning Inst., Philadelphia, Pa., October 8, 1926.

† Attorney-at-law; Secy., Philadelphia Municipal Art. Comm., Philadelphia, Pa.

conceive of a cultured man living in a town with no schools, no libraries, no playgrounds, no parks, no golf courses. But while one individual, like a "sport" in horticulture, might arrive and stay in such a place, it is not reasonably possible to conceive of such a town becoming a community of cultured men and women. The opportunity has to be present. Schools for the children, with the play space where they learn so much, libraries, churches, and community centers must be provided. Consider the charm of an ancient street of a New England town with great elms arching over it in cathedral forms. The mere thought suggests refinement. Cut every tree down and the suggestion is obliterated.

If the regional plan gives adequate locations for libraries, for common and high schools, for colleges, for universities—all on the educational side; if locations are plotted for playgrounds—preferably to be recreational playgrounds —although in crowded centers they must be largely pedagogical playgrounds; if the opportunity to get back to Nature for city people is provided through country parks in sufficient number to make it a frequent experience; if the regional plan gives sufficient examples of the plotting of street trees with as much care and particularity as the plotting of street conduits (be it noted that in some foreign countries the engineering plan always shows the locations of trees); if these things are done, then the regional plan will be of distinct service in helping to create the physical surroundings which are an important aid in the production of a cultivated community.

This is not all. If public structures, or structures extending over public property, like bridges of all types, signs, lighting fixtures, etc., are well designed, they will be at least as cheap as ugly structures. They will add to or detract from values of the neighborhood in exact proportion to their beauty. An ugly bridge seldom lasts out its life. The community gets rid of it before its expectation of life is run. An engineer who does not point that out to his client, when the latter wants him to design an ugly bridge (but which he calls "merely utilitarian"), fails in his duty to that client.

An investment in ugliness is as extravagant an investment as the directors of a corporation, the council of a city, or any group may make. If Washington, Paris, and Pasadena, show the money-making power of municipal attractiveness, how completely do Hoboken, Weehawken, and Manayunk demonstrate the sheer cost of ugliness. Effective regional planners, therefore, will see to it that over each and every region into which the regional plan reaches, some authority is recommended to be set up, like the State Art Commissioners or Art Juries—of which there are now about thirty in the United States—which will consist of men who will have the backbone to say to politicians seeking favors for important voters, that no ugly thing will be permitted to depreciate the values, financial and cultural, of their city, suburb, or country. An ugly bridge decreases all values around it, especially in suburban sections, and an attractive one increases that value.

In Philadelphia, the tradition of attractiveness in suburban development has become so strong that its suburbs have become world famous. Nevertheless, much could be done in this region to improve the architecture of the

smaller houses. In one or two foreign countries, "Bureaus of Building Advice" have been created, the function of which parallels for private owners (who purpose to build on private property) those of the public art commissions as to public buildings. Plans are submitted to the "Bureau of Building Advice" and it advises the owners as to the effect of the appearance of their buildings on the values and worth of the community. The owners do not have to accept the advice; but they do not care to have the advertisement that their buildings have been condemned by the "Bureau of Building Advice" and, consequently, they do accept the advice in many cases. It would be well, therefore, for the regional planning central group to recommend and then to secure the creation of such "Bureaus of Building Advice" in its community.

Fifty years ago individual parks were regarded as luxuries. Thirty years ago they were accepted as necessities, but parkways to link them into an organic whole were regarded as luxuries. To-day, parkways are regarded as necessities, and some automobilists would have us create super-parkways to give them super-opportunities for killing others as well as themselves.

It is assumed that the creation of an adequate park system, including the reservation of creek valleys, the preservation of places of natural beauty or historic interest, the acquisition of certain high plateaus in the region for public use and public enjoyment, will be accepted for what they are, as fundamental portions of the regional plan.

It is important, however, to refer to two points—one of which is obvious and more or less becoming the practice, but the other of which, curiously, has been lost to sight. Parkways should be regarded as traffic thoroughfares. Opportunities for the operators of motor trucks, as well as of pleasure vehicles, to drive, in the course of their daily employment, or on their way to or from work, through attractive thoroughfares, is one which is somewhat recognized, but not as completely as it should be. The idea that a park or parkway is somewhat the old-fashioned parlor—only to be used on Sunday when the parson comes for dinner after church—is one that should be completely discarded—the idea, not the parson. Motor-truck routes and motor touring-car routes should be devised for their every-day attractiveness and for every hour of the day. This means occasionally a slightly additional expense for width. It means hardly anything in the way of the development expense of the property; perhaps it really means a reduction of cost, instead of an increase, because property fronting on a parkway is more valuable than one that does not.

The second point that it is desired to emphasize in this respect is the one that has been forgotten. A practice has grown that is in direct contrast with the theory with which modern city planning in America was begun about twenty years ago. It was the basic argument for city planning then that one improvement to a city frequently was plotted, or designed, or conceived solely with reference to that improvement and without reference to the program of the city as a whole and the proposed order for other adjacent improvements. City planners insisted that this was wrong and that the entire problem should be considered together. Then zoning came along and many city planners lost

sight of their argument for comprehensiveness. Zoning systems, plotted without regard to park systems, are numerous. Zoners think that if they zone property in a certain way because it fronts on a park, that they have sufficiently recognized the park system.

One has yet to see a zoning plan in which zoning for use is made complete. If property is to be used for residences, business, or manufacturing, the zoning plan shows it; but if the property should be used for parks the zoning plan by itself does not show that use. Obviously, a zoning plan should suggest areas for public use in the form of parks or playgrounds, just as it should zone areas for private use in the form of single-family and multiple-family houses, commerce, or industry. Zoners have failed adequately to see the opportunity for living up to the principle for which the city planners began twenty years ago—of preparing the plan in its entirety.

In addition, however, an opportunity for parks in connection with zoning, has certainly not been emphasized. There is no reason why zoners should not frankly divide a commercial or a transportation industry from a residential district by the interposition of a public park. True, it may not be so acquired, but it should be submitted as a recommendation. In Philadelphia, there is such a natural division. The Midvale Steel Works lies in a valley and a suburban section of Southern Germantown lies just over the crest of the hill. The hill and the slope are occupied by Fernhill Park—53 acres in extent. Why should not this principle be frequently applied in zoning?

The opportunity is especially available in connection with regional planning. When a region is planned the opportunity for placing elongated, wide, or narrow parks as a boundary, with residences on one side and heavy or light industry or business on the other, is so obvious and the opportunity is so great that this paper will be considered worth while if it conveys this thought, plus Otis Skinner's observation of the cultural power of golf courses.

Sixty to seventy-five years ago, when American cities first began to acquire such parks as Fairmount Park, Central Park, Franklin Park, and Druid Hill Park—in Philadelphia, New York, Boston, and Baltimore, respectively—it was thought that just one big park was all that was necessary. When the writer became Secretary of the City Parks Association, in 1900, there was put into his hands a pamphlet by President Elliot, of Harvard University, on the question of how to get the people to the parks. It has been answered by taking the parks to the people in the form of small parks and the park system, by establishing, as it were, a central park and branch parks.

The same psychological change has occurred in connection with libraries. The great Public Library in Boston—great because of its beauty, not because of its size—was just in course of completion a little more than a third of a century ago. In that short space of time the need for taking the library to the people has been recognized, and every large city has built many branch libraries. Numerous American cities (Philadelphia among them) have recently completed or are completing great central art museums. They are absolutely important to the cultural development of the city; but equally important will be branch art museums throughout the region. The recognition of this psychology is just at the beginning. We had to take parks to the people. We

had to take libraries to the people. We equally have to take art museums to the people. Only within the last year has New York City opened its first Branch Museum, at 196th Street. The regional plan must, of necessity, if it is to be adequate to its cultural opportunities, plot the locations of a sufficient number of branch art museums to take pictures to the people as effectively as the branch libraries have taken books to the people.

It is suggested that the next generation will create branch universities. Imagine the University of Pennsylvania with eight or ten branches in the region within 30 or 40 miles of Philadelphia. It is not such a great advance over what has already been done, educationally, as it appears. In 1890, there was just one High School in Philadelphia. To-day, there are eleven High Schools and twelve Junior High Schools. In other words, the Central High School—a City College—is supplemented by branch high schools, some of the teachers of which think their own branches are higher than the High School. In some respects their thought is true. It would be interesting, or at least advantageous, to have locations for branches of institutions of higher learning in outer regions suggested by the regional plan. The first regional plan that does so will be regarded in the future as prophetic.

What is the opportunity of civil engineers in presenting on paper plans directed to the securing of locations in the region for the creation of cultural opportunities in all these different and diverse ways? What are the qualifications of civil engineers for the job? Well, it may be stated, in the first place, they understand construction; but only a few of them understand that construction is not design. Here is an illustration. If a plumber attaches three pipes to a main so that the water spouts from the other ends, he has not designed a fountain—he has constructed it; he has done the plumbing part. If an engineer builds a bridge merely sufficient to stand the traffic, he has not designed the bridge; he has only constructed it; he is only a plumber. If an engineer takes the trunk of a tree and makes kitchen chairs sufficiently strong to stand the weight of the cook, he has constructed the chair, but he has not designed it. An artist, taking another portion of that same tree trunk, will, by adding design to construction, produce a Chippendale chair worth $40 compared to the engineer's chair with a value of $4. Only those engineers who know design as distinct from construction should have anything to do with the regional plan. If that cuts out 95%, they can overcome the difficulty by studying design as distinct from construction. Again, such constructors can prevent other engineers from lacking what they lack by insisting that institutes of technology shall teach design to engineers, as well as how to calculate strength of materials, stresses, and strains.

Some civil engineers have felt justified in complaining of the injection of architects and landscape designers into city planning, because it seemed especially the field of civil engineers; but the civil engineers had the field entirely to themselves for the whole of the Nineteenth Century, and they have only themselves to blame that the public, weary at last of the drab, stupid, stale rectangularity of the checker-board cities which were all the civil engineers of a century produced, relegated them to the subordinate position of drawing the working plans for designs conceived by others. "By their fruits, ye shall know

them." And the public has judged of civil engineers as city planners by the Nineteenth Century gridiron. The end is not yet. A graduate of civil engineering asked the writer whether, as the result of fifteen years direct contact with the supervision of plans for bridges, he thought architects would supersede engineers as designers of bridges. The answer was that it depends on whether engineers learn to design—present trends indicate they would not—and that, with the astonishing advance in the determination of American cities to use Art as their daily servitor, the architects in another decade will have pushed the engineers down to the subordinate position of calculating stresses and strains for the plans of bridges designed by their architect-employers.

One had only to go to the Sesqui-Centennial in Philadelphia to see how Art has come into its own. If the Sesqui Art Museum and all it contained had been entirely removed, the whole exhibition would have remained a great art exhibit. Consider how the steel industry was most conspicuously represented. Jones and Laughlin, steel manufacturers, showed what? They showed what was essentially a notable work in sculpture. It could have been with advantage less literal; but the whole conception was fundamentally sculptural. That was the method of appeal to the public; that was the advertisement chosen by a great steel concern. In the housing of individual exhibits, every form of Grecian, Roman, and Byzantine architecture was used.

The mere engineer will become only a skilled workman unless he looks to design. What should those engineers, qualified by a knowledge of design, as well as of construction, for the job of regional planning—what should they study, what facts should they ascertain in order to be able to plan for the cultural development of an entire region? Chief traffic routes must be studied. Such mistakes, as that in New York, where Central Park blocks two vitally needed north and south routes, must be avoided. Opportunities along the traffic routes for the preservation of places of natural beauty and historic interest should be determined.

Obviously, the topography must be studied. A poor topography may require a somewhat larger area for a park system than a favorable one. The City of Philadelphia is fortunate. Such a deep narrow valley as the Wissahickon requires less area for the preservation of extraordinarily great natural charm, than a level terrain would have required. The percentage of the total area which should be taken for the park system necessarily will vary with the topography, with the character of the community so far as it can be predetermined by zoning, and with other elements. Ten per cent. is a principle which has stood the test of many years. Probably a good regional park system will approximate that. Larger playfields, covering 10 to 20 acres, should be plotted about 1 mile from each other, and the smaller playgrounds within 5 min. of each child's home. This, again, will vary in accordance with the expected intensity of residential development as forecast by the zoning system.

In connection with playgrounds, and harking back to Otis Skinner, the writer would emphasize the importance of pay-as-you-play golf courses, and, in addition, a method for making privately owned golf courses permanent in

their locations. Golf courses are open spaces. If completely permanent they would be open air parks, by which is meant parks which would be enjoyed by the public even if it could not walk over them. How can they be made as nearly permanent as possible?

It is submitted that if the golf club is willing to throw its course open to any member of the public who behaves himself and who pays the greens' fee, which averages from $1 to $3, that would be a sufficient justification, either for entirely exempting the golf club from taxes or for making the rate, say, about one-half the ordinary tax rate. In the City of Philadelphia there are three tax rates—the "city" rate, the "suburban" rate, and the "rural" rate. The suggestion is that taxes on golf courses, which are open to those who pay the greens' fee, should be either the rural rate or else that the taxes should be waived altogether. This would require legislation, but it would be a cheap means of increasing the permanent open spaces of a region. Within a journey of ½ or ¾ hour of Philadelphia there are more than sixty golf courses—which means there are sixty open spaces, averaging about 100 acres. If all these spaces could be made permanent by a stroke of the pen, it would be a blessing. Freedom from taxation would be a great incentive to a club to remain where it is. Otherwise, increases in values may not only make it desirable to move, but may make it imperative.

There is one other thought in this respect. If any golf club intends to sell its property, it ought to give some public authority about six months' opportunity to purchase it at a price equal to the highest price offered.

Zoning will also help to predetermine the natural location for school houses and libraries. If zoning, in its logical development, is finally sustained by the Courts, the needs of the region and of each section of the region in respect to thoroughfares, all sorts of public conveniences will be able to be forecasted, for fifteen or twenty years, with much greater accuracy than at present. Nevertheless, forecasts must be attempted through the familiar methods of studying the growth of communities by maps and otherwise.

In answer to the query as to the kind of investigation that should be made, in order to plan effectively for the cultural development of a community, so far as physical accomplishments can help toward that development, the items of calculation and of investigation are pretty much the same as in regard to the other elements of the regional plan. Growth of population, directions of that growth, topography, natural and artificial barriers, locations of railroad, rapid transit lines, traffic arteries, and secondary streets, all are to be included. It would be easy to take the ordinary list of divisions and sub-divisions of a schedule, and repeat, but to engineers it is unnecessary. Indeed, when one takes up one of the published summaries and sub-divisions presented for an ideal investigation, the effect is appalling. The investigator is apt to think that each particular head and sub-head must be investigated with equal meticulousness before he dare make a decision.

If to-day one could present a perfect plan for Metropolitan Philadelphia, twelve months later it would be not more than 97½% perfect. In four years, it might not be more than 90% perfect. Most big plans take at least ten years

to realize, and a regional plan will take thirty or forty years. A perfect plan to-day may not be more than 60% of perfection by the end of thirty years. Every city plan and every regional plan that is under way to-day can be convicted of too much meticulousness in the information sought. The time spent in investigating and getting minute details is so great and the value of those details is so negligible that a great deal of impatience with regional planning is justified.

It is necessary, therefore, to determine when all the really worth while investigation has been made, and all the information that is important has been obtained, but use much good sense as well as "horse" sense in determining that which is important. Hasty decisions are not advocated, but delayed decisions are strongly deprecated. These lists and tables of matters to be investigated have written over them on each page, in enormous letters so big that they are never seen, the words "Excuses for Delays". Refuse to emphasize the various points that might be investigated. The engineer can readily find such schedules, but when he finds them he should spend no more time than is absolutely necessary in answering each of them and should see whether genuine efficiency, not the meticulous kind so much preached and regrettably also practiced, does not dictate that many of them go uninvestigated. If a physician made every possible investigation that he might make in the case of each patient, his patient would probably die before he were a quarter finished.

It is important, too, to recollect that some of the modern gods may not prove immortal. Especially is this true of the god, Speed. To-day, speed automobilists have the public by the throat. All they have to do is to present an appeal against some kind of obstruction to infinite speed in order to have that obstruction wiped away. If a circular park at an intersection can be shown to delay automobilists 2 or 3 sec., weak-kneed city officials remove the circle. At the time of the Philadelphia Sesqui-Centennial, a Philadelphian took an educated Chinaman from the Exposition to a charming suburban home, ten miles out, going by a beautiful route. On returning, he told his guest that they would come back by the less interesting Lincoln Highway, because it would save 10 min., whereupon the Chinaman said, "And what will you do with it?" The automobilist, abashed, was unable to reply. Propaganda for speed is in sad need of "debunking".

A cultivated community may come accidentally, but it will come far more adequately and far more certainly if it is consciously planned. The ideals of one generation become the accepted realities of the next—sometimes sooner. In 1906 an intimate friend—the city editor of a great Philadelphia daily—referring to a project at which many were hammering away, said: "The Fairmount Parkway is a dream". In coming to the Convention of the Society in 1926 many used the dream of 1906.

Engineers are practical men and because of that fact the writer wants to emphasize this thought—that dreams are the most practical forces in the world. Engineers can be mere technicians or they can be much more. Remember that mere dreamers have accomplished far more than mere engineers. Why not be both engineer and dreamer?

DISCUSSION

HENRY V. HUBBARD,* ESQ.—The author emphasizes the idea of bringing the parks to the people. Every one agrees, but the process has its limits. Books can be brought to people because the book is the same whether one reads it in a great public library, in the branch library, or at home; but the essence of a big park is its bigness, and that cannot be brought to the people by distributing the same recreation area among their homes in small fragments. The playground and the little park can be brought to the people. The people must be taken to the big park.

Mr. Crawford speaks very truly of the desirability of zoning the region with due regard to the park areas. This principle should be applied also to the uses permitted in parks and parkways after they have been acquired by the public; that is, subsidiary uses destructive of their main purpose should not be allowed to invade the park areas. Landscape charm, reasonable quiet, and safety are essential attributes in parks and parkways. The cultural value of the parkways to the motor-truck drivers, whose welfare Mr. Crawford so feelingly bespeaks, would not be sufficient to compensate for the destruction which the noisy dangerous passage of the trucks would work in those qualities of the parkway which fit it for its main and essential recreational use.

As to the engineer's contribution to city planning, it should be remembered that the engineers of the early Nineteenth Century were fighting alone in the front line of the battle. There were at that time no art juries, no city planners, and no lawyers trained to give counsel to engineers and to help them in their difficulties; but even so they were not without their triumphs in the field of esthetics and of broad plan conception. Major L'Enfant, for instance, was an engineer.

As to the future of engineers in regional planning, it is plain that whoever lays out the broad conception of future community development, his work will be bad unless it is based on engineering knowledge; and, in any case, most of it will be built by engineers.

The main lesson of this discussion is obvious. For the fuller development of all the cultural opportunities of the city and the region, there should be fuller co-operation among all the professions involved; each profession knowing that it is only one wheel of the city-planning cart. The cart would not run well without that one wheel, but it would run still worse supported on one wheel alone. Many examples of effective common sense co-operation between professions in regional planning may be seen, and it will not be long before it will be a matter of course.

JAMES STURGIS PRAY,† ESQ. (by letter).—This topic opens up an enormous field. Mr. Crawford brings out effectively and suggestively many of these cultural opportunities. Culture may mean very different things to different

* Editor, *City Planning Magazine* and of *Landscape Architecture*, Cambridge, Mass.

† Charles Eliot Professor of Landscape Architecture, and Chairman, School of Landscape Architecture, Harvard Univ., Cambridge, Mass.

people—in short, anything from *Kultur* to refinement of taste. If the development or strengthening of the mental powers is meant; or improving or refining of the mind, the morals, the taste;* and not merely the culture and refinement of the few, but rather the advancement and uplift of the many; then, surely comprehensive, competent, and far-seeing regional planning not only offers unlimited opportunities for culture, but is essential to the most widespread culture. It is known that culture, proverbially, has bulked larger in cities, but cities have no monopoly of it. Some of the most truly cultivated minds are possessed by individuals who have spent their whole lives in the country, and some by those who have lived a large part of their lives in the wilderness, for example, John Muir. The region, the term as now commonly used for a great metropolitan area with a city center and extensive outlying suburban and rural districts, embraces both city and country. The whole strong aim and tendency of regional planning to-day is, not only to extend into the country as many as possible of the advantages long accruing almost exclusively to city dwellers but, also, to bring into the city all possible of the advantages of life in the country. This is far more important. All the opportunities for culture offered by the physical and human environment may then be provided by regional planning, for it is not necessary to except wholly even such as may be had only in the wilderness, since areas in a wilderness can be conserved by planning for their use; as, say, in the region of Geneva, Switzerland.

Any region will, of course, even without what is called regional planning, offer many of these opportunities. That is, it will offer these opportunities in ways limited either to certain classes of the population or to all classes in certain respects only, and within certain none-too-broad limits. However, great metropolitan areas to-day, without regional planning, offer also much, and in some ways more and more, that works powerfully against culture. Crowding without planning, and the speeding up of life of which large populations tend to become victims, operate against health; the lack of planning adequately for ease of circulation leads to colossal inefficiency and waste; and the thoughtless piling up of ugliness in many parts of these great areas certainly dulls the popular sensitiveness to beauty and deadens even the aspirations for beauty in environment. Culture may exist in a slum or in a deadly monotonous suburb or in the most repulsive industrial area, but certainly these conditions in themselves do not make for culture; yet normal humans, the uneducated as well as the educated, the simpler minded as well as the more sophisticated, are responsive naturally to beauty in their environment and particularly to beauty in its universal and its highest forms. Given sufficiently widespread understanding and will to co-operate in bringing about a better set of conditions in the city or region, there is every reason why not only living areas and recreation areas to which much attention to beauty is already given, but all working areas as well, should supply a vastly more beautiful environment than they do at present.

The control by regional planning of these matters, when it includes regional zoning, will increase these opportunities for culture in the following principal ways. True culture comes both from hard work and from times of

* Standard Dictionary.

relaxation and is, perhaps, like genius, one-third inspiration and two-thirds perspiration. Sound regional planning will go far to promote and assure public health and the general physical well-being of the people living, working, and playing within a region. It will bring increased alertness, sensitiveness, and greater sanity, and will give to the workers at once more power to draw culture from their hours of labor and more energy to devote their spare time to things that make for culture over and beyond what their regular pursuits may bring them. Therefore, sound regional planning spells greater community efficiency, and from this greater efficiency, result important economies of time and money, thus affording both more money and more leisure.

Assuredly, there is no occasion to emphasize here the tremendous gains in efficiency of life in a metropolitan community, which accrue from a comprehensive, well-organized plan for the whole area and in which the component districts are set apart for their respective dominant functions of residence, business, industry, and recreation; each such district is not just conventionally but really functionally planned with respect to sizes and shapes of blocks, as well as the continuity and cross-section of local streets. The whole is tied together by a comprehensive system of main thoroughfares—radial, diagonal, and circumferential. Nor is it necessary to dwell on the colossal economy from such efficient, comprehensive, functional planning. Nevertheless, it is important to note that, from these gains in efficiency and economy, there must come to the great masses of the people greatly increased opportunities for culture. For although, of course, neither increase of wealth nor added leisure necessarily leads to increase of culture, both greatly enlarge the opportunities for some of its highest, most precious forms. Nor is there need to urge that comprehensive, functional planning in itself produces the highest order of functional or organic beauty, the sort of beauty that results inevitably from the perfect adaptation of the form of an object to the use for which it is designed. All are familiar with the classic example of this: The clipper ship which, in the old days, was built for speed and the profit accruing from quick passages to foreign ports rather than for beauty, but which offers one of the most beautiful forms ever created by man.

Indeed, one does not have to go back to that time. The modern world is full of examples, such as the electric locomotive, the functional highway, the modern factory building, and the airplane.

Beyond this sort of beauty, there is still needed, through all planning and zoning, a conscious seeking for outward visual beauty of form, color, texture, and composition, such as can be supplied only by those specially trained to create it. While the mass of the people cannot be expected to unite readily in securing this beauty, it can be brought about through the leadership of the competent. When through competent far-reaching regional planning, beauty in regional environment shall widely prevail, will not the people who grow up and work and play amid these beautiful surroundings, be far more intolerant of all that is ugly than people are to-day? Will they be satisfied any longer with what is merely poor, mediocre, indifferent, uninteresting? Does not beauty beget beauty?

Is it not true, for instance, that, if or when Philadelphia, or New York, or Boston, or Chicago, shall realize a wide, comprehensive dream of beauty, the influence over the country and over the world for beauty will be beyond one's utmost power to imagine?

The more perfectly organized the physical plan of the area of a community for health, efficiency, and economy, the more the members of that community can accomplish within it in a given time by the same expenditure of effort or money, and so the more time they will have over for cultural pursuits—pursuits which both further culture in themselves and also indirectly increase cultural opportunities.

This, however, is not enough, because a regional plan is not truly efficient that does not assure the absence of ugliness and the presence of the maximum of possible beauty throughout its whole three-dimensional extent, from dignified uplifting building groups to the artistic design of street name plates and mail boxes. No such dream as this can be realized that is not based on comprehensive, systematic, unified planning of the region. Then, out of this realized efficient and beautiful regional environment can come, and will come, more freely than ever before and far more widely, opportunities for culture.

Noulan Cauchon,* Esq. (by letter).—Engineers should have as an indispensable part of their education, a serious grounding in the principles of design in art. Without it, it is not safe to allow them at large. Look at the resultant atrocities of the merely utilitarian which some of them have perpetrated on the unsuspecting democracy. Henry Fairfield Osborn makes clear in his recent trenchant restatement of the truth of evolution† that the physical evolution of man is the least distinctively human part of him. In his intellectual and spiritual side lies the great advance beyond the brute. The brute has all the adaptabilities for fitness to purpose in a given environment. Are people to be restricted to thinking in merely the three quantitative dimensions of which the so-called "practical" man (and the brute) is cognizant, or should they not soar in a fourth qualitative dimension of the intellect and the spirit and insist on events and intervals being acceptable on the more human basis—something better than brute bluntness to impressions of hunger and shelter?

As Mr. Crawford so well puts it, things beautiful cost no more than ugly expressions of buildings, bridges, and landscape. Let planners express Nature, which is Truth, in its myriad forms, in such a way that all, from childhood to maturity, may get close to it in school, playground, and park, in home, workshop, and council chamber, to draw strength and cheer and guidance on the path of progress, individual and collective—National. Also, civilization has advanced to the point where amenity has become a negotiable value to the most dense. An art jury is desirable for all communities as a source of helpful, constructive criticism and restraining influence on private and public aberrations.

A further thought which Mr. Crawford advances for consideration is that public amenities, parks and parkways, should come into the daily life of the

* Ottawa, Ont., Canada.

† "Science and Religion in Education."

people, be used to and from, between their homes and work, and that they be planned to create this condition. Some years ago, it was the writer's privilege to suggest that in a mountain park development the pedestrian pathways, in threading their way through the park, should be kept as far as possible away from the highways. Need one argue with trained minds on the cultural opportunities that lie within regional planning and of the necessity that it be comprehensive planning?

It is the civil power which is always "skinning" the engineer's estimates, generally leaving very little with which to develop things of beauty.

Mr. Crawford, in attacking the gridiron plan, has, in the writer, a staunch supporter. The gridiron is vestigial of prehistoric limitation to two-dimensional thinking; it has an inherent property of congestion. On the other hand, hexagonal planning, in a four-dimensional state of mind, has an inherent property of diffusing traffic. The plan, by analogy, must fulfill the principles of organic evolution, that is, be adaptable to circumstance, that its continuity must be nourished by fitness for purpose—the high purpose of good living conditions and the fulfillment of human life.

E. M. Bassett,* Esq.—Houses will back upon parkways unless there is an intervening street. A parkway has no street front because the owner of the parkway (city or State) can build a high wall or put up an iron fence along its edge. The reason is that a parkway is a park. The abutting owners along a parkway have no easement of access or of light and air over a parkway. It is well to keep that distinction in mind between a highway and a parkway. Parks should be zoned by municipalities for height and bulk. They can not be zoned for use, because all parks are devoted to recreational use, and only those buildings can be erected that are connected with recreation. If a school board begins to put up a school on a park area, any taxpayer can enjoin the board because it would not be a building intended for park use. In New York City, parks are zoned for height and bulk, but not for use. The zoning of a lot for a park would be wiped out by the Courts as soon as the property owner brought it to their attention.

Art juries can pass on beautiful designs for public buildings, and for buildings in streets and parks, but not for those on private property; at least in the United States. The reason seems to be that their's is the realm of æsthetics, and police power does not extend to æsthetics. Probably this is because the Courts conceive that they would have to depend on opinion evidence as to what was and what was not beautiful, and opinion evidence would vary so much that there would be no criterion. One expert might say that in a certain place a certain color was right and another would be equally sure that it was not right. In other words, the Courts in this country conceive that they cannot decide disputes regarding taste, and they look on æsthetics as a matter of taste.

However, it is proper and lawful to bring in the principle of design in city planning. For instance, the pyramidal buildings in Greater New York, that many architects like, are often considered beautiful. Part of their

* Counsel, Zoning Committee, New York, N. Y.

creation was city planning, and part was something else. They are mostly in the "two times" district on the zoning map; that is, the building can go up two times the width of the street on the property line, and then it must set back at the rate of one to four. The city planning part is to stamp on the land the zoning height district of two times. When the land is so stamped, it is for the architect to produce the building. If he would produce it in exact accordance with the set-back plans, it would probably not be a thing of beauty. It is the architect's ability to make a good design within the requirements stamped on the land that produces the beautiful building.

JACOB L. CRANE, JR.,* M. AM. SOC. C. E. (by letter).—Writing from the viewpoint of the professional town planner and referring to the statement in Mr. Crawford's interesting paper that the civil engineers had the city planning field entirely to themselves for the whole of the Nineteenth Century, it is true that the planning of streets and sub-divisions was carried out during that period largely by engineers and surveyors. However, the writer feels that "the stale, flat dullness" of "Main Street" towns and the "drab, stupid rectangularity of the checker-board cities" must be charged equally against the architects and builders who were responsible for the design and placing of the principal visual features, namely, the structures, and still more to the uncritical taste and frequently greedy haste of the American public.

The placing of the blame is not important except to realize that it is not only the engineers who need to be roused out of the easy habit of commonplace, hurried design. Further, the writer wishes to take exception to the reference to the "money-making power of municipal attractiveness". He believes that there is good reason for not continuously harping on the slogan that "beauty pays" in the campaign for a more satisfactory visual environment. As Mr. Crawford points out, the ugly ground plans and buildings are more rapidly replaced, while the beautiful objects continue to satisfy and are preserved. On the other hand, for the individual commercial enterprise, the ugly ground plan or building sometimes is actually most profitable to the individual concerned. In the second place, whether "beauty pays" is not the question. A visual environment, satisfying because of its loveliness, must be considered a justification in itself aside from its purely incidental dollars and cents value. Finally, the writer believes that planners can afford to be careful in their conception of what beauty really is. It has been easy for the zealous landscape architect to destroy the native picturesque beauty of a piece of marsh land, or a finely modeled hillside, or even an old abandoned gravel pit, by imposing upon them the neat and sophisticated design of the professional; and for the architect to spoil the structural feeling and silhouette of a building by too much ornamentation and, particularly, by too great ostentatiousness.

The writer finds that some steel bridges, industrial plants, grain elevators, and machines are among the most beautiful things created in modern life. And they are all the work of the engineer.

* Municipal Development Engr., Chicago, Ill.

Referring to Mr. Crawford's suggestion for "Bureaus of Building Advice", it should be pointed out that such bureaus are, in effect, established in a number of towns and cities in the Middle West. They are constituted as special citizens' or architects' committees. They operate largely by persuasion, but with a marked effectiveness.

Replying to Mr. Crawford's criticism that zoning plans do not indicate sites for parks, a legal zoning map cannot designate property for public use in advance of its having been taken for that use; and it is necessary to designate the zoning of all private property, even if some of it is recommended for park purposes on the general development plans, where such recommendations should properly be indicated.

The writer doubts the effectiveness of the suggestion that golf courses may be made permanent open spaces by remitting the taxes on daily fee courses. Such courses are ordinarily privately owned by an individual or a small syndicate as a purely commercial enterprise; and, while the remission of taxes would undoubtedly be appreciated by such a syndicate, they could not be expected to hold the land for semi-public use when the opportunity arrives to profit by a large increase in land value.

There is a cultural opportunity in regional planning which may be worth mentioning, namely, the extension of the citizen's imagination to include in his civic ideal, not only the territory within the legal limits of his city, but the entire interrelated and interdependent region. It is not easy to define a cultural opportunity, but in all city planning and regional planning work one of the greatest cultural effects seems to the writer to be the stimulation of the imagination and the broadening of the interests of the average citizen.

Mr. Crawford very well points out that the dreamers are entitled to the credit for most of the advancement, and one of the primary purposes of regional planning should be to make a dreamer, not only of the engineer, but of all members of the community. Great city and regional plans will eventually be the crystallization of the dreams of many men and women.

Charles Wellford Leavitt,* M. Am. Soc. C. E.—The author has said much with which all can agree without hesitation, such as the dignity of elms bordering streets in a New England village engendering culture. In one such village where the elms were cut down to provide greater width for a street instead of building a parallel relief street, the people will regret it for the next 200 years at least, if not longer. The dignity and beauty of the town are gone, and it is now ordinary, sordid, and like many other ugly towns throughout the United States.

Art commissions and juries are important, with Bureaus of Building Advice on the side; the value of parks, parkways, playgrounds, and auto-parking places are admitted without argument. Zoning is good and should include zoning for parks. Putting a park between the industries and the home is fine. Central and branch parks with connecting parkways undoubtedly is a great thought. Art museums are certainly cultural with or without

* Civ. and Landscape Engr. (Charles Wellford Leavitt & Son), New York, N. Y. Mr. Leavitt died on April 22, 1928.

the central structure and branch attachments; and a central university with little universities all around sounds like the acme of cultural phenomena.

The Philadelphia Sesqui-Centennial with all the art removed would still be the best advertised exhibition in the world—by a prize fight. It was wonderful, if not cultural.

What is meant by a "poor topography" is a question. Topography is topography. Engineers have to take it as they find it and do their best with it.

Golf courses are certainly a God-send in providing some light and air. A good meal is pleasant to remember, but not to be compared with a vista, or a tapis vert—if one is not hungry. Throwing private golf courses open to the public by the payment of a green's fee might cultivate the masses; but would it be cultural for the club members? It is doubtful. Yet the speaker would like to see all golf courses maintained as open spaces in the future. Should golf courses be exempt from taxes? In case the course be sold for profit or sub-divided, the total accumulated taxes with interest should be paid at the time of transfer.

Traffic study is cultural, for without this cultural activity people would soon be dead, not cultivated.

A city or regional plan is apt to be held up if an attempt is made to carry on as a whole, or in a full and comprehensive way. The speaker is heartily in accord with the idea of knowing what has to be done, but of not advertising the whole plan at once, simply one of the items to be accomplished, and when this has been secured to take up others until the whole city has been re-made, no matter how long this may take. A complete comprehensive plan is very apt to scare the taxpayers, the would-be developers of cities.

The city planner must be prepared to change the plan and keep it up to the best interests of the city, as ideas change frequently and very often for broader and better living conditions.

Does Mr. Crawford suggest that the decision be whether to speed or not to speed? If so, it will undoubtedly be "speed"; but speed made safe by, and with, culture. Probably the American will use the moments saved to go to a cultural movie.

The Fairmount Parkway was a dream. Through the persistent efforts of Mr. Crawford and others in Philadelphia, it was brought to a reality—a great achievement. The process of endeavor and achievement meant much culture. The parkway may still further cultivate if the city is governed by cultured officials. If not, the reverse may obtain, and this "culture" will be spelled with a "K".

No one has a greater respect for the designing talent of the architect than the speaker. It is regrettable that more engineers have not had greater training in the art of design and the sense of proportion which are so carefully studied by the architect. Some civil engineers, like some architects, landscape architects, city planners, lawyers, doctors, and plumbers, are not fitted for the job of designing a bridge, or a chair. However, the speaker must beg to differ as to the engineer being entirely lacking in the power to design. There have been many statements such as this. Consider the Brooklyn Bridge, and other

bridges in United States parks, in Spain, and in Italy, the Washington Monument, the Sixty Wall Street Building, New York, the engineering part of the Delaware River Bridge; and then, by comparison, notice some of the later East River bridges and their approaches in which the architects have had a hand. The public buildings in Philadelphia, the New York Post Office, and the Capitol Building in Albany, N. Y., are products of architects—it does not require more than amateurs to judge that, in these instances, the palm will fall to the credit of the engineer.

It matters not whether he calls himself an engineer, a landscape architect, a city planner, or an architect, if he but have the power of design and sense of proportion. An artist versed in the sense of proportion and design can easily be recognized by his work. It is deplored that many who write titles after their names, meaning designers, fall far short of being true artists.

If its leaders are cultured, America may fairly compete with, or surpass, in the development of its coming race, the best examples in Europe of cultured citizens and resplendent cities. If we are not able to recognize true artistic leaders, we will be following false prophets and the development of our peoples and the appearance of our cities will fall far short of those ancient Greeks and Egyptians of whose achievements young students love to cant. We should follow the artist, whether he be a Brooklyn Bridge engineer, a Major L'Enfant, or the architect of New York's beautiful City Hall—John McComb; and we should avoid the designer or planner who, though he may call himself what he will—architect, engineer, or otherwise—cannot produce anything better than some of the existing public structures which do not please the best sense of proportion.

By being critical and judging these objects for himself, whether he is professional or amateur, and by his efforts of seeing, observing, and careful analysis and criticism, an engineer will surely develop culture spelled with a "C".

Morris Knowles,* M. Am. Soc. C. E.—An apt illustration of culture in engineering is the Philadelphia-Camden Bridge. It is certain that there never could have been any controversy between the architect and the engineer on that bridge, else the result would not have been so successful as it is a great tribute to the profession and a notable example of the application of simplicity of engineering design. It is a production with which every one is satisfied.

After all there really is no need of a controversy. There are engineers who are good designers and also those who are poor designers, and there are architects in both classes. It is not a question of profession, it is one of personality; the criterion is whether the man himself has the ability to see beyond and through the things he is trying to do. It is not a question of whether he is an engineer or an architect, any more than it is a question of whether a lawyer can be a successful business man. Many engineers make successful business managers and many others cannot successfully handle their own affairs. Engineers do poorly to discuss this question from the pro-

* Pres. and Chf. Engr., Morris Knowles, Inc., Pittsburgh, Pa.

fessional angle. What they should do is to try and cultivate and stimulate culture in every one, be he an engineer or an architect.

HAROLD M. LEWIS,* M. AM. SOC. C. E.—Perhaps the reason both engineers and architects have fallen down, to a certain extent, in trying to arrive at the best solution of a modern city plan, is the great increase in the complexity of such plans. Mr. Harvey W. Corbett, a well-known New York architect, who has also had an engineering training, has said that the engineer deals in "facts" and the architect in "fancies", and that both are essential for the successful completion of a large modern building. The speaker believes this should be supplemented by stating that they both deal in design, based primarily on different points of view.

A combination of fact and fancy is still more essential in the development of a practical and adequate city or regional plan. The great size of large metropolitan centers has been made possible by improved methods of transportation, sanitation, and building construction. This has brought many new problems, with which the engineer is specially trained to deal. Carefully prepared and analyzed facts are necessary as the basis for any plan, but the successful regional planner must have broad vision and must be somewhat of an idealist. Engineers would do well to develop such qualities to a greater extent.

The future should not be merely an extension of past trends, but should bring opportunities for improved culture of the kinds referred to by Mr. Crawford. As the execution of a regional plan is based on a co-operation between local planning authorities, so should its preparation be based on the best that both engineers and architects can give. If such co-operation is successfully accomplished there is plenty of room for credit for both, where credit is due.

R. H. RANDALL,† M. AM. SOC. C. E.—It may appear at first that Mr. Crawford is just a trifle hard on the engineer, and that the outlook is dark, or even black. Somewhere, perhaps in the explanatory text on the back of the U. S. Geological Survey standard maps, there is a phrase to the effect that "culture, or the works of man, is shown in black". While it is good map practice to show the works of man (which are naturally and usually the product of the engineer) in black, the terms, "culture" and "black", are not synonymous, even by inference and as they are chargeable to the engineer.

Both engineers and architects have produced structures so ugly as to be actually limited in their usefulness. However, there is noticeable a present and increasing betterment in this respect. Mr. Crawford's paper should serve as a valuable incentive toward continued improvement in both engineering and architectural design; a reminder of what now and always needs to be done, rather than an arraignment for past shortcomings.

C. H. HOWELL,‡ M. AM. SOC. C. E. (by letter).—The author states that, "if an engineer builds a bridge merely sufficient to stand the traffic, he has not designed the bridge; he has only constructed it; he is only a plumber".

* Executive Engr., Regional Plan of New York and Its Environs, New York, N. Y.
† Pres. and Chf. Engr., R. H. Randall & Co., Toledo, Ohio.
‡ Designing Engr., The J. G. White Eng. Corporation, City of Mexico, Mexico.

However close to the plumber the construction engineer may be in Mr. Crawford's opinion, it is certain that some one designed the bridge. Presumably, it was a bridge engineer.

Webster's Dictionary defines the word, "design", as follows: "To produce a scheme or plan for the making of anything". Anything that is planned is designed, according to this definition, and Mr. Crawford is, seemingly, at variance with Webster.

The writer also submits, that the one outstanding example of non-rectangular city planning of this country, Washington, D. C., was the design of an engineer, L'Enfant.

Not all the "drab, stupid, stale rectangularity of the checker-board cities" should be charged against civil engineers. Some of the drabness, stupidness, and other terrors of the older parts of old cities are the results of, shall it be said, designs by architects? The writer believes the best engineering talent of the Nineteenth Century produced work comparable to that of the best architects and that the common or garden variety of engineering work was quite superior to the common run of architectural efforts.

The graduate, to whom Mr. Crawford referred, need have no fears about architects supplanting civil engineers as designers of bridges. Bridge design is a highly specialized science. No mere architect can afford the time to master it. If he does master it, he becomes an engineer. "The end is not yet"—except in dreams.

Charles W. Eliot, 2d,* Esq.—There is a great need for agreed definitions among planners and generally among the public as to what is a park or parkway and as to the proper functions of a park. Confusion concerning these terms has apparently upset Mr. Crawford. A parkway is not a boulevard; neither is it a traffic thoroughfare. The use of the Bronx Parkway in New York by large numbers of automobiles, traveling at high speed, does not make the parkway into a traffic thoroughfare. Perhaps Mr. Crawford only means that more thoroughfares should be wider and more attractive. That would be a great advantage, but it would not make them parkways. Is it not possible for the Society, or a similar organization, to put before the public in a forcible way, the differentiation between the purposes of different kinds of parks, and particularly the difference between a park and a semi-public, or other kind of open space?

Winters Haydock,† M. Am. Soc. C. E.—An interesting relationship may be discovered between the subject of Mr. Crawford's paper and an announcement in the public press, an announcement which undoubtedly is of great significance on account of its economic, sociological, and cultural implications.

The head of a large industry employing an enormous number of workers has announced that he intends to adopt a 5-day week. That announcement immediately raised a storm of protest on the part of industrial leaders throughout the country, a protest which was the greater on account of the prestige which the author of the announcement, Mr. Henry Ford, enjoys

* City Planner, National Capital Park and Planning Comm., Washington, D. C.
† Directing Engr., Dept. of City Transit, Pittsburgh, Pa.

as a successful pioneer in new fields. The plan was immediately denounced as being economically unsound.

For many reasons it is very improbable that any general change in the working week is an immediate prospect. However, would it not be very rash of any one to declare to-day that it is improbable that the 5-day week will be in the accepted order of things a quarter of a century hence? Suppose that it does become the order of the day? What will that mean? The problem is then immediately thrust on the city planner in a much graver aspect. Does not his responsibility then become as great as that of the leaders in education and in other cultural fields whose well-recognized responsibility it is to determine and make provision for the cultural requirements of the people? If this is true, is not one of the most important functions of the city planner and the regional planner the insuring for the future of facilities for the advantageous utilization of this growing leisure of the masses?

GILMORE D. CLARKE,* ESQ. (by letter).—This paper justifies the wide circulation it has received. Not only is it valuable for engineers, but for the fine arts as well. To-day, these professions have been brought face to face with tremendous problems in connection with the planning of regions, cities, and counties, and of all their component parts.

The problems cannot be solved by members of any one profession. The multiplicity of detail which enters into regional planning are such that no single profession can ever master it. Mr. Crawford brings the Engineering Profession to task for its accomplishments in connection with city planning in the Nineteenth Century. He states that,

"* * * they [engineers] have only themselves to blame, that the public, weary at last of the drab, stupid, stale rectangularity of the checker-board cities, which were all the civil engineers of a century produced, relegated them to the subordinate position of drawing the working plans for designs conceived by others".

This is true, but there are many engineers who now realize the necessity for collaboration with the professions of the arts, in order to effect results in the planning of areas and in the design of structures which will be more satisfying to others as well as to themselves.

A concrete example of collaborative work on the part of members of the professions of engineering, landscape architecture, and architecture, is the following: A Commission was organized in 1922 to prepare a park and parkway plan for Westchester County, New York, which lies just north of New York City between the Hudson River and Long Island Sound. The area of the county is about 500 sq. miles, the richest suburban area in the country. The working organization is made up of a Chief Executive Officer, whose title is "Chief Engineer", a Deputy Chief Engineer, whose duties have to do with engineering design and construction, and a Landscape Architect charged with the planning and design of park and parkway areas and the design of park structures. Architects are called upon to design all buildings which do not come under the category of "minor structures". In addition, there are

* Landscape Archt., Westchester County Park Comm., Bronxville, N. Y.

other departments, such as legal, land purchase, maintenance, and secretarial and accounting departments.

There has been no disposition on the part of the efficient engineers in this organization to complain of the injection of the landscape architect and the architect into this regional planning problem. As a matter of fact, they have welcomed these representatives from the arts, and the results of this co-operation are noteworthy.

In the matter of bridge design, the writer has had an interesting experience in working out more difficult problems with the Commission's structural engineer. There has never been any disposition on the part of this engineer to accomplish work in design that normally is in the field of architecture. The writer believes that, because the bridges designed for the Westchester County Park Commission are the result of collaborative effort, they represent the best there is in modern bridge design in the world.

Mr. Crawford holds out some hope that the engineer may some day become competent to design artistically—to be a "dreamer". The writer doubts it. The mind of the average engineer is trained to precision, to the definite practical working out of problems, to things concrete. Such a mind does not easily re-act to the artist's business of dreaming and imagining. What must be accomplished is to bring these minds together, for one individual to realize the shortcomings of the other, to the end that, when working together on a single problem, it will represent joint efforts and will produce the finest results.

Engineers are practical men, and it is hoped, for the sake of engineering, that they may remain so. Dreaming must be left to other souls; and then the dreamer and the practical man, by getting together and collaborating, will accomplish more than if the attributes of both were centered in one individual.

Harry J. March,* M. Am. Soc. C. E. (by letter).—Mr. Crawford has evidently not yet sensed the relative importance, first, of economic design, and, second, of pictorial design; or, in other words, first the work of the engineer and then that of the architect. There must be first a substantial structure that will serve the highest utility purposes and then let it be painted. The writer is not unmindful of the character of utility in the artistic design, but it is not an absolute necessity. To illustrate, he has in mind a landscape architect's dream of a development which, while beautiful in its effect, utterly disregarded economic traffic conditions. The architect had to be shown by the engineer the relative value of the traffic and the artistic phase, and he finally subordinated the latter to the former. There is a need to stress the importance of co-ordinating the work of the architect and the engineer. The architect should be more of an engineer and the engineer should be more of an architect. Co-ordination is the keynote of the whole development of regional planning as well as of municipal planning. Would that "the powers that be", controlling as they do the extent and intent of public improvements, could realize the value of such development!

* Chairman, Executive, and Engr., City Planning Committee; Chairman, Board of Appeals, Buffalo, N. Y.

This phase of the inter-relationship of the architect and engineer is an important one in the development of regional planning, particularly where bridges are to be erected and county parks or forest preserves established. Every one is quite familiar with the terms, "City Engineer", "City Architect", and "County Engineer", but one seldom hears of a "County Architect". The regional area in its development should bear the impress of the architect to the same proportional extent as the municipal area bears the impress of the City Architect. The idea could be best comprehended, perhaps, under the term, "landscape engineering", rather than "landscape architecture".

JOHN IHLDER,* ESQ.—It seems that in the case of boulevard, parkway, etc., the author and the speaker are talking or thinking of two or three different things, because they do not always supply the same definition to a word.

The increase of heavy truck traffic in American cities has become a matter of serious concern. It not only results in breaking up light pavements, but it is injuring neighboring property. In Washington, D. C., the walls of houses are being cracked, and there are also instances of window panes being cracked by the vibrations of heavy trucks. Something has to be done to regulate that kind of traffic.

Heretofore, apparently, city planners have considered it only from the point of view of facilitating traffic movement, in the case of parkways, by forbidding trucks. In Washington, trucks are now forbidden on the main arterial roads, such as 16th Street and Massachusetts Avenue, etc., the idea being that they delay the movement of lighter automobiles.

This, however, is only one phase of the problem. It must also be considered from the point of view of the character of neighborhood. The present prohibition in Washington is causing trucks to use the minor residential streets to the great detriment of the neighborhood. Should not city planners begin to consider the creation of a system of heavy traffic streets that will adequately serve trucking needs in the cities, and not simply prohibit and divert it from one street or road to another?

JOSEPH BARNETT,† ASSOC. M. AM. SOC. C. E. (by letter).—This is the day of specialists and in the nature of things, specialization will increase as time goes on. The sum total of human knowledge increases steadily, and it is becoming more and more difficult for the individual, in one life time, to learn, appreciate, and develop the ability to use even a small percentage of the information on any one subject. Therefore, whether the subject for discussion is regional planning as a whole, such as the laying out of a city, or a great park system, or whether consideration is being given to one of the details, say, the adaptability of a certain type of structure, it seems advisable to get different viewpoints on the subject. If each specialist has a proper appreciation and respect for the outlook of the others, pleasing as well as economical results will be obtained. Mr. Crawford uses the word, "designer," as if a dress or piece of furniture is under discussion. In regional planning the

* Mgr., Civic Development Dept., Chamber of Commerce of the United States, Washington, D. C.

† Chf. Draftsman, Westchester County Park Comm., Bronxville, N. Y.

functions of design must be divided. The designing engineer, landscape architect, and other specialists all have proper functions to perform.

The Bronx River Parkway, which is a part of the Westchester County, New York, Park System, is an excellent example of the results which can be obtained by co-operation. The bridges are an important feature of this development. To state that they could have been designed by architects alone would be just as untrue as to state that they could have been as successfully designed by the engineer alone. The fundamental structural designs for these bridges were made by the Designing Engineer. Not just the "plumbing" as Mr. Crawford calls it, the computation of stresses and strains, but the conceptions of proportions which made these bridges possible; the development of the solid section rigid frame with variable moment of inertia. Incidentally, on almost every bridge except one, the architect's name appears alone.

To blame all ugly structures of the past on the engineer is a refusal to recognize the fact that such structures were the products of the times. The people more or less controlled the funds for public improvement and any expense over and above the bare requirements formerly met with considerable opposition. Monuments, art museums, and city halls were generally excepted, but to place cut stone facing on a highway bridge of twenty years ago would have been considered the height of extravagance. The modern trend, however, is toward a greater appreciation of the esthetic value of those things with which people come in daily contact and this fact makes Mr. Crawford's paper timely indeed, because designers should keep just a little ahead of the tastes of the times. It would be an excellent thing if all civil engineers, especially those engaged in design, would read, carefully, Mr. Crawford's paper; but regional planning would derive just as much benefit from a similar paper illustrating the necessity of architects acquiring an appreciation of things engineering.

Engineers need not fear having architects called in to lend advice on the esthetics of structures on account of the cost because pleasing structures can be built at very little extra expense, provided the architect has a proper appreciation of the engineering aspects of the problem. Likewise, architects should not assume that engineers have no esthetic taste and that they persist in violating esthetic rules when insistence on extreme economy is not pressed on them. At times, engineers can improve the appearance of a structure very materially. The writer has in mind a case in which outlines for a number of bridges were laid out having intrados curves resembling ellipses. The architects properly recognized that multiple-centered curves would not be smooth, but when the designing engineer suggested curves following fixed mathematical laws instead of the free-hand curves at first laid out, the suggestions were rejected although fundamental clearances and heights were retained. After the first bridges were built they were found to have the appearance of sagging at the crown. On later bridges, mathematical curves were used with perfect effect. One of the structures was a two-span bridge

with different span lengths and by applying the same formula to both intrados curves, matched curves resulted. Incidentally, the formula used was,

$$\frac{x^{2.2}}{a^{2.2}} + \frac{y^{2.2}}{b^{2.2}} = 1$$

The slight variation from the true ellipse provided greater clearances at the haunches. This bridge is now finished and the intrados curves are probably the most graceful in this set of bridges.

Therefore, to obtain the best results in regional planning, or any allied project, it is not necessary to have the engineer learn architecture, or *vice versa,* but to teach each an appreciation of the other and the public an appreciation of both.

Paper No. 1684

FORECAST: THE REGIONAL COMMUNITY OF THE FUTURE*

By Thomas Adams,† Esq.

With Discussion by Messrs. Robert Kingery, Howard Strong, William J. Wilgus, Frederic H. Fay, William T. Lyle, Charles Wellford Leavitt, Morris Knowles, and Thomas Adams.

Introduction

The modern city is a product of science—applied to manufacture, to transportation, and to modes of living. It reveals in its conditions of growth that science may deflect the path of society and still do little or nothing to arrest the weaknesses that accompany the changes or movements inherent in human action. Yet the science that has brought about so much progress in the arts of industry and transportation, apparently could, if applied collectively on a wide community basis, make for better cities. It must be admitted, however, that whatever social progress may be attained, or expected, in this direction, by means of physical improvements, can only lessen and not remove defects in living and working conditions.

The complex dynamic forces that enter into the composition of the city may lead in the future along one of a thousand different avenues of growth. Who can calculate all the forces that might enter into one of these possibilities? Who can predict the periods and degrees of advancement and recoil, of action and re-action, of growth and decay, and, therefore, calculate their effect? Who can visualize how changes and innovations in individual and collective practice will operate to bring about new trends in growth; or in what measure and over what periods the government of the future will

* Presented at the Joint Meeting of the City Planning Division with the American City Planning Inst., Philadelphia, Pa., October 8, 1926.

† Gen. Director of Plans and Surveys, Regional Plan of New York and Its Environs, New York, N. Y.

be influenced by principle or expediency? These questions indicate how rash it is to try to picture what the future regional community will be like. Yet, it is worth while to weigh and investigate future possibilities and opportunities in the light of knowledge of facts and tendencies of community growth; it is worth while to attempt to create some practical ideal and try to guide communities toward its achievement.

William James has stated, "If shown a certain way, a community may take it; if not, it will never find it."

The function of the city planner is to show the community the way that leads toward the healthiest and most efficient pattern of town development. To do so he must first have developed in his mind an ideal pattern which he conceives to be within practical reach; and, second, have worked out the ways along which it is possible and best for the community to travel toward its achievement. Lack of this ideal for the community, or of an intelligent means of reaching it, and not technical imperfections, lies at the foundation of many failures in city planning and zoning.

It is the writer's purpose to give a general conception of the regional community of the future, based on the belief that the growth of the science and art of city planning, aided by the play of economic forces, will influence the direction and form of urban growth toward a higher and more ideal civic pattern and more rational forms of development. Before presenting this general conception, some of the conditions and problems of the modern city will be discussed.

Some Conditions and Problems of Modern Cities

The modern city does not differ from cities of previous times in regard to the underlying character and causes of its defects; changes have rid it of some evils and brought others to take their place. The large city has always suffered, in different forms, from congestion of building and traffic, from poverty and bad housing, and from the inherent selfishness of man in dealing with private property. Since these are the results of human tendencies, that do not change with time and circumstance, they will always be present. The conditions and problems of New York, N. Y., and Philadelphia, Pa., differ in character and to some extent in degree from those of thirty or forty years ago. The automobile has not made congestion, but has created new forms of congestion; and it is still possible to move about the congested centers of the great cities with more expedition and more agreeably than in the days of horse-drawn vehicles. The high building has brought new kinds of evils, but is not so unhealthy in some respects as the unsanitary building facing the narrow streets of medieval cities. Science has relieved poverty by providing man with more abundance of food and clothing, but in the great city the poorer classes still suffer from low standards of housing accommodations and bad environment. The control of private property is effected by laws that lag far behind changes in growth. In spite of all the lessons of the past, man is too slow in adjusting himself to changes of conditions. This is what is meant by lack of foresight in dealing with the problems of the city.

The conditions and problems of the modern great city that are exceptional, are the results of the unprecedented size and rapidity of growth of urban aggregations. For instance:

(1) Evils of congestion that were bearable in small areas, where development proceeded slowly, have created almost intolerable conditions when extended over large rapidly growing urban areas.

(2) Separation of the home from the place of occupation of the worker, desirable in some respects in the smaller cities, has intensified congestion and caused serious economic waste in the large cities of to-day.

(3) Lack of space for movement, light, air, and recreation in the crowded central areas of cities was not a serious problem when the country fields lay within walking distance; but in the big city that spreads its buildings over 1 000 sq. miles, or more, it is found to be the chief defect in its growth.

(4) Co-ordination of municipal action in matters of public improvements and utilities was hardly necessary when cities were small, of comparatively slow growth, and widely scattered; to-day, every metropolitan region is suffering serious injury from lack of co-ordination between its constituent communities.

It is evident, therefore, that the demand for regional study and treatment of large cities is in large measure the result of peculiarities of modern urban growth. In approaching the study of regional problems, the unknown factors are so many and knowledge of past growth is so illusive as a basis for planning for the future that scientific investigation will be of only limited value. The investigations have to be reinforced in a special degree by reason and common sense, and the price of developing a new experience and a new science will have to be paid.

Important Trends in City Development

Tendencies in connection with transportation by rail and highway within regional areas are all toward facilitating quicker movement and more efficient distribution. These tendencies will continue to promote concentration of large populations in urban regions. This concentration has of course a great economic value, and as long as it is not permitted to lead to congestion, it need not be injurious to health, safety, or general welfare. The causes of congestion, as distinct from an efficient degree of concentration, lie in the lack of proper control of land development; the support that is given by law to abuses of property rights; the lack of proper standards of density and height of buildings as a basis for zoning; and the lack of harmony between physical planning and zoning regulations. The greatest menace to the modern city is that it will persist in avoiding the removal of these causes and simultaneously develop its facilities for transportation and promote new sources of energy. These facilities and forces will produce good or ill in proportion as the concentration they cause will be well or badly regulated by law and planning.

Perhaps the most hopeful fact in the metropolitan regions of America is the extent to which land is being acquired for parks. It may be many years

before zoning of private property can be based on standards that will give cities ample space for freedom of movement and for light and air in buildings, and before it can be given a permanence that will make it really effective in preventing congestion; it may be still longer before areas of land in these regions can be zoned for agriculture and horticulture and made integral parts of the open areas of cities; but the movement toward acquiring large areas of land for permanent open spaces for parks and parkways has gained an impetus that is full of promise as a means of giving future areas of urban expansion a large degree of lung space permanently dedicated to public use and ever present as a stimulus to better balanced development.

In the future, the architect, the engineer, and the social investigator will take a broader view of city problems. Zoning has already given a lead to a new architectural conception of city building, and as a force in town development it is still in its infancy. Scientific developments in relation to electric power, production of metals, improvement of machinery, and transportation; needs of great urban regions in regard to comprehensive systems of drainage, water supply, and adequate open spaces; these and other things will bring the engineer and the landscape architect face to face with great concrete problems of regional development, and make them more expert in the art of regulating city growth.

If nothing else forces action of governments and communities to plan comprehensively, compulsion will come from economic necessity. Great cities to-day are within sight of the end of the financial resources available to meet their needs, a condition that has been brought about by the wastes and inefficiencies incidental to economically unsound methods of development which permit unhealthy and unsafe conditions both of over-crowding in the central areas and of under-crowding in suburban and rural areas.

New York's Problems and Future Growth

Data regarding present and future conditions and problems in the New York Region will be referred to briefly.

The area of the City of New York is 298 sq. miles, but the area regarded as appropriate for regional planning around the Port of New York comprises 5 528 sq. miles. This area is in three States and has more than four hundred separate units of administration. This indicates a geographical extent and a complexity of physical and social conditions that sufficiently proves how extraordinarily different the modern city is from anything in the past.

In 1900 the population of the New York Region was 5 384 734; to-day, it is more than 9 000 000 and, in 1965, it is likely to be at least twice the latter figure.* About 58 000 dwellings are required annually to house the increasing population and between now and 1965 more than 2 000 000 dwellings are likely to be required. Whether or not much by way of reform of conditions affecting more than 2 000 000 buildings already erected, can be achieved, much can and should be achieved in influencing the proper development of an equal number in the next forty years.

* Estimates based on past growth give 21 000 000 as the population in 1965.

The number of manufacturing plants in the New York Region grew from 19 416 in 1900 to 57 753 in 1920, or 197.5%; but the plants have become smaller on the average as the increase of employees is only about 100% in the same period. Railroad lines serving those industries have a mileage of 1 884. Terminal facilities are inadequate for the existing need, and transit lines are ten years or more behind what is required for efficient handling of passengers and freight.

No prospective development of the water-front is likely to absorb more than a small percentage of its mileage for commercial purposes. At present (1926), only 125 miles of 1 800 are so used, yet hundreds of miles are not being put to the best economic use because of false expectations regarding the potentialities of industrial growth.

The average density of population is 160 per acre in Manhattan, 30 per acre in the whole of New York City, including Manhattan, and 1 per acre in the remainder of the Region. In the city there is the comparatively ideal average of 7 houses to the acre, but in parts of Manhattan the density is as high as 150 families per acre. It is extraordinary how little variation there is in the average density of large cities and how congestion always seems to have its complement of vacant or sparsely developed land. To show that there need be no congestion with proper regulation of growth, 26 000 000 people can be provided for, at an average of between 20 and 30 to the acre, within a 30-mile radius of the center of the city. More even development must be secured if the decay that comes from the complementary processes of over and under crowding of city areas is to be prevented.

More than 2 800 000 people travel into and out of down-town Manhattan daily, but the crowding of this multitude into one small area will become less necessary as natural obstructions to horizontal growth are removed by improved transportation facilities. There is a growing tendency toward development of new neighborhood centers of manufacture and business. More belt-line communication is needed to give impetus to this movement. There is no true economic basis for the congestion of great cities like New York, and if it is continued the effect will be to strangle the pulse center of the community. A city has to avoid being stultified by its own wealth. Hilaire Belloc states that history proves that when cities reach their highest point of wealth they become congested, refuse to accept a remedy, and pass on to decay. He adds that:

"The main motive is a blunder in the science of economics. It is the idea that the destruction of a number of imaginary economic values is an expenditure of real wealth. So far is this not being the case that there is no example in all history of a congested street system being reformed without the wealth of the city increasing after the change."

If, in future years, cities can be made to realize that great public improvements, if properly conceived, are good investments, the future can be viewed with optimism. In the Park Avenue District in New York the gain caused by the improvements within and around the Grand Central Terminal was 255% in land value and 932% in values of improvements in 20 years. The total gain was from $60 750 000 to $311 500 000, or 410 per cent.

Increases in land values are greatest in the centers and outlying suburbs. Great areas lie between, where values are more or less stationary, and many areas are blighted. If people cannot live near their work they prefer to get as near the open country as possible. Tendencies toward decentralization are strong enough to overcome the difficulties inherent in making changes of location. The number of factories has decreased in Manhattan and increased in Brooklyn and Queens. Suburban increases of garages and theatres indicate the trend of outward movement. The rapid shifting of the population is doubling the number of children in suburban schools.

Heights of buildings even in New York have not reached the point of increasing average heights over older cities like Berlin, Paris, and central parts of London. The average height of buildings in Manhattan is only 4.8 stories, although there were 1 019 buildings between 10 and 19 stories in height in 1924 and 100 buildings of 20 stories and more, below 65th Street. Until more high buildings raise the average the effect of such buildings on traffic and business cannot be foretold.

High buildings have been the product of high land values and, in turn, high land values are causing high buildings. However, real estate owners and leading financial corporations now claim that the best business investments are low buildings, even in valuable locations. The following statements confirm the writer's views. Mr. W. Burke Harmon, of the National Real Estate Corporation, writes:

"All floors above the second floor can be largely eliminated as contributors toward the income of the building over a long period of years. The cost of upkeep of the upper stories and the interest on the investment represented thereby, plus taxes, would barely be met by the revenue derived from this space in normal times."

Mr. Richard M. Hurd, President of the Lawyers Mortgage Company, and an eminent authority on land values, writes:

"Low buildings in valuable locations pay a much higher percentage of income than high buildings. This is in line with my comments on office buildings, on which, as I told you, we never lend money, chiefly because such buildings are normally overbuilt.

"The term, 'taxpayer', is a misnomer and obviously a one-story building in a good store location approaches nearer in its earnings to pure ground rent than any other type of improvement."

These statements indicate how false are the economic standards on which much crowded development takes place. What justification can there be for crowding high buildings together, with all the evils of congestion incidental to this crowding, if they do not pay? As they become more crowded, they will become less profitable, owing to diminished light, air, and over-supply of space in central areas, and to the increased taxes necessary to meet expenses incidental to congestion.

Individual high buildings have their place and purpose and as long as they are made to conform to proper regulations regarding the amount of space surrounding them, they may be desirable elements in the growth of great cities. What is wrong with skyscrapers are the conditions which do

not give them a proper chance to perform their functions, owing to lack of space surrounding them. The greatest enemies of concentration are those who confuse it with congestion; and the greatest enemies of high buildings are those who deny that all buildings require adequate space surrounding them for movement and other social needs, and that the amount of space should be increased in proportion as bulk and height of building increase.

At present, in New York the assessments and taxes are higher than at any other time in the history of the city. The real estate assessment amounted to approximately $13 000 000 000 for 1926.

More than 95% of the tax permitted by law is levied. The budget for 1926 amounted to $437 000 000. The tax rate has increased in 20 years from an average 1.50 to an estimated 2.79 for 1926. The percentages of the total budget proposed to be spent include 30% for debt services and tax deficiencies, 19.9% for education, 14.7% for protection of life and property, and 1.5% for recreation, science, and art, which includes parks. The greatest increases in expenditures are for subways, policing, street cleaning, and fire prevention—all incidental to congested growth. As has been stated:* "More important than immediate economies will it be to make far-visioning plans for the future."

Financial plans will not be enough. The physical planning of the city must be made to follow lines that will lessen waste and reduce public contributions to private services. It is significant that the Planning Commission appointed by the Mayor of New York has as one of its duties that of discovering new sources of revenue.

Proposals to relieve this congested growth by construction of more subways, wider streets, bridges, tunnels, etc., put forward by responsible authorities would involve an estimated expenditure of about $2 000 000 000.

Congestion of streets is reaching the saturation point in some places. Forms of relief, such as traffic regulations, parking prohibition, narrowing of sidewalks, and street widening, are all more or less palliative. The point must soon be reached when nothing further can be done in these directions.

These and many other problems of the great city confront the regional and city planner. There are economic forces at work and scientific developments taking place that will aid in the task of influencing city development in the right directions. What then may be forecast as a reasonable prospect for the urban region of the future?

The Future Urban Region

On the whole the writer agrees with J. B. S. Haldane that science and human tendency are becoming less materialistic. It may also be assumed that the center of industrial gravity will shift to some extent as a result of the development of new sources of energy. Transportation has been the chief motive force in concentration in the past century, but it will be linked with electric energy in promoting new and more evenly distributed areas of con-

* *New York World*, September 11, 1926.

centration in the future. Great urban aggregations will continue to grow; and the hope lies not in restricting the quantity, but in improving the quality, of development.

The writer can visualize two forms of great city regions that will exist on this continent when the youths of to-day have entered the final laps of their race with life. Great centers like New York and Philadelphia will still be striving to maintain their supremacy, but a new kind of urban region will have sprung up to influence them and compete with them.

Just as the manufacturer has discovered the value of discarding old machinery in favor of new, the city will learn that old dilapidated buildings are a liability and that the making of great physical improvements is a sound investment. In the future old cities will be reshaping and rebuilding their blighted areas as a matter of self-preservation.

Developers of real estate will not be permitted to speculate in land, as a necessity of life. Those who sub-divide land for building will be required to make it fit for building by constructing roadways, sewers, and other local improvements in advance of the sale of the land. Playground space will have to be provided as an essential feature in any new sub-division just as street areas are at present. Building codes will require more durable forms of construction, and the cost of fire prevention will be greatly decreased. Great transportation and park corridors will radiate out from and surround the cities, giving rapid means of communication through open areas devoted to park and spacious residential areas. At strategic points along these corridors satellite cities will have grown up, connected by railroad and highway with the metropolitan center and amply provided with space for expansion of industry and healthy living conditions.

Several classes of highway will exist. There will be speedways from 120 to 150 ft. in width paralleling railroads and serving the lighter industry, business, and apartment-house areas. Interchange of freight and passengers between railroad and highway will be a common practice. The use of streets for loading and unloading of merchandise will be gradually disappearing. Owners of property will be required to carry on their business on their own premises, and streets will be more and more confined to public purposes. Buses and other highway vehicles will have properly equipped terminals as the best railroads have to-day. Parkways from 150 to 500 ft. in width, with driveways through them for rapid automobile traffic, will penetrate through areas largely used for residential purposes. In central areas elevated railroads will have largely disappeared. Air rights over many railroads will be used for elevated highways. The tendency in the centers will be to place railroads with their electric equipment underground, and to have raised sidewalks for pedestrians fronting on or arcaded into buildings. This will not add to congestion, but merely remove some of the effects of congestion created at the beginning of the Twentieth Century.

Zoning will have become more constructive and more stable. It will be based on adequate and sound standards of health and safety. Physical planning and zoning will be linked together so that, as the requirements of the law

in regard to height and area of occupancy are strengthened, less necessity will arise for restricting the character of use. Factories and apartment houses will have more spacious surroundings and will fit in agreeably with adjacent residences. The owner of the factory will have learned the lesson of the Fifth Avenue merchant that ugly ancillary features and disorderly surroundings are an injury to his business.

Interspersed between the closely developed areas along railroads and highways there will be areas zoned and permanently reserved for agricultural purposes. Regional co-operation will have ended the pollution of drinking waters and developed comprehensive systems of sewage disposal. The social needs of the community will be largely met without great loss of time in traveling, because it will be realized that there is enough land in the country to provide all facilities necessary for healthy living conditions within easy reach of every inhabitant.

The "hot dog" stand and the gasoline station will be things of the past. Just as the old English inn was a picturesque feature along the highway, so there will grow up a new kind of hostel, with pleasant surroundings where all the needs of the highway traveler can be provided.

Special ways will be set apart for pedestrians, so that walking will have become a restored art. Speedways will have bridges and subways provided for pedestrians, and separation of grades for important intersecting roads.

Motor cars will pay a proper share of the cost of highways and thereby keep up the balance between increase of vehicles and provision of highway facilities for motor travel. Rapid transit will not only pay for itself, but will yield a profit to the city for purchase of parks and playgrounds. More facilities for recreation, the results of education, and more stringent application of justice will have reduced crime.

High buildings will still be erected, but under proper regulations as to area of occupancy, so that they will have become less crowded and more in the nature of isolated monumental features of the city.

There will be a reaction against the crowding of high office buildings together and also against the apartment dwelling as a residence. A compromise will have been reached between the apartment building and the cottage which will give to a new type of home the advantages of each of the others.

Provision will have been made for numerous landing fields for airplanes —used for long-distance transportation and mail service. Commuting, not having increased on the whole, will be more than amply served by transit lines and improved highways. Trolleys will still operate on special rights of way, but bus services will have taken the place of many trolley lines now in use and will have become the most popular form of transit for short distances.

The more even and more open form of development, and the prevention of land speculation by irresponsible developers, will produce more stable land values. In the aggregate, land values will be no lower, but they will be more evenly distributed. Assessment of land and taxation will be more carefully adjusted to the best productive uses of land. For instance, taxes for urban

improvements based on potential building values will not be levied on land permanently zoned for cultivation, or for recreation areas, such as golf courses, thereby making possible the reservation of open areas on private land.

Forty years hence New York may have its 16 000 000 or even 20 000 000 of people with less overcrowding than its present 9 000 000. Manhattan will still be the center of distribution, of exchange, of banking, and of certain industries that can be economically carried on where land is relatively expensive in the hub of the region. There will be a few more bridges and tunnels between Manhattan, Long Island, and New Jersey, but they will be planned as part of a comprehensive system that will have spread industry and population over wide areas and lessened the areas of congestion, the areas of deterioration, and the areas of waste vacant land. Many high buildings, as they have deteriorated and become out of date, will have been replaced with lower buildings, as being more profitable. Belt-line railroads, boulevards, and speedways will link together the radial system of communications. Large open areas in private ownership will be used for cultivation and recreation in the suburbs. The blighted areas along the water-front of Manhattan, Brooklyn, and The Bronx will be replaced with modern buildings giving efficient service to the port and fronting on wide streets and squares, fittingly adorned to make a dignified entrance to the city and region. The East River water-front and the Harlem River Valley will have been developed on two levels, the lower for commercial uses and the upper for monumental business and residence structures. The Hackensack Meadows will have been reclaimed and divided in use between industry, residence, and recreation. Large areas in New York City, now held out of economic use for ambitious projects that can never be realized, will have been developed, with consequent relief to formerly congested areas.

Great new railroad terminals in The Bronx, Queens, and New Jersey will have been developed, and new business centers will have grown up in their neighborhood. Long Island, The Bronx, and New Jersey will be so linked together that great volumes of traffic now passing through Manhattan will be by-passed around it. A wide parkway will extend from New York to Philadelphia. It will be intersected by a speedway for passenger cars and be paralleled by a railroad, a rapid transit line, and a speedway for mixed motor vehicles. Numerous satellite communities will be spread along this park and transportation corridor.

Great central power plants will have been developed, and power will be distributed over wide areas, serving widely scattered industrial areas.

New Regional Communities

The writer has stated that the older cities will not be the only centers of the urban regions of the future. Great new centers will arise and be developed with the aid of knowledge of the past and in keeping with new opportunities. These new communities will be so developed as to cause the older communities to mend their ways.

The transmission system of the Shawinigan Water and Power Company of Quebec, Que., Canada, may be cited as an illustration. This Company, the fourth largest in the world, distributes 580 000 h.p. over an area of 15 000 sq. miles. It had a total output of 2 000 000 000 kw-hr. in 1925. The area served is intersected by an international waterway. Within it are three large and numerous small cities—connected by an elaborate system of railroads and highways.

The defect of this area is that the great waterway of the St. Lawrence is closed for navigation for several months of the year, but it illustrates the type of area that will provide scope and opportunity for great regional communities of the future. These areas will be so large and the places suitable for efficient concentration within them will be so numerous that there will be no necessity for congestion. Large sections of land suitable for cultivation will lie between the transportation and power corridors and focal points and maintain an efficient and economical balance of development. The older city regions will gain much of their impetus to improvement from competition with these new communities.

Thus, the growth of science, the pressure of economic forces, and perhaps the growth of average intelligence, will bring into being new communities and re-shape the old in accordance with sane, practical ideals of what a great regional community should be. All that city planners can do is to help in pointing the way toward the realization of these ideals and develop their science and art so that they will be ready to make their contribution to the demands of the future.

DISCUSSION

ROBERT KINGERY,* ESQ. (by letter).—In Mr. Adams' splendid forecast of the regional community of the future, the writer finds the expression that is the foundation of the entire activities of the Chicago Regional Planning Association, namely, "regional co-operation will have ended the pollution of drinking waters and developed comprehensive systems of sewage disposal". In the region surrounding Chicago, city planning has had its "ups and downs" just as in many other parts of the country. A large number of city and village plans have been prepared, splendid reports have been written, and nothing has been done about them. Many of the local and public officials scoff at city planning and call it the impractical dreams of the "uplifters".

The reason for this is not difficult to find. In most cases city and village plans have been prepared with a minimum of co-operation and aid from the local city engineer and official who, under the law, is charged with the responsibility for spending the money which would be used for carrying out the project proposed in the plan. The second reason is that the apparent objective of the plan commissions is a plan and a report, and not so much attention is given to perfecting organizations that will put the plan into the construction stage.

The City of Chicago is the notable exception. A great body of citizens has been appointed on a permanent plan commission and has insisted upon maintaining a staff of engineers for the purpose of carrying out the Chicago Plan.

Regional planning is far more difficult than city planning because of the greater number of local governing officials, each of whom has a specific duty under the laws of his State, and under the powers granted his particular office.

To proceed with regional planning in such a way that each of these public officials of highway commissions, drainage districts, sanitary districts, park districts, the private utility organizations, such as telephone, electric light, rapid rail transit, and others, has a share in the preparation of plans is to develop a plan or series of plans which, in advance, holds the confidence of the public or private officials who are going forward with their public works whether or not there is a regional plan.

In the Chicago Region, the Planning Association has thus far been moderately successful by combining, into a general highway scheme, the different programs of the many highway building agencies, simply by arranging that they meet over a common general map, study how their own programs fit, or do not fit, with those across the imaginary, invisible boundary lines. In practically every case these officials have agreed on such modifications of their programs as were necessary to produce a system of connecting highways.

The fact that six county boards, with a combined area of 3 150 sq. miles of unincorporated land, have adopted and are administering sub-division

* Secretary, Regional Planning Assoc., Chicago, Ill.

regulations which require the real estate men to meet certain high standards in the platting of land, indicates that the method used in drafting these regulations was sound. Members of the Sub-Dividers Division of the Real Estate Boards, plat officers of counties and cities, the surveyors' organizations, and the city planning engineers combined in developing and agreeing on these regulations. They are in ordinance form also, and are rapidly being adopted in the cities and villages of the Region. If a little group had retired to the privacy of their offices to develop such a regulation and then had sought to put it into effect, without having had the benefit of all the views that went into its determination, it is doubtful whether it would have been in effect in any of the cities and villages to-day.

If the Regional Planning Association of Chicago can make one suggestion to regional and city planners, it is that regional and city planning is not alone a gift of a few men who have had certain training and have done certain reading on the subject. Some of the most obscure city, county, sanitary district, and park officials and some of the public utility engineers can do, and are doing, by co-operation in the Region of Chicago, some very successful regional planning.

Howard Strong,* Esq.—The author has given a masterly presentation of some of the evils that have resulted from modern concentration of population; of certain economic and social fallacies that have controlled the development of the modern city; and has presented an enheartening picture of what may be hoped for the future of New York and, by implication, of other large cities.

However, as he states, who can calculate the forces that will mould the city of the future? Who can predict the scientific discoveries, the overturning in social and economic thought that may revolutionize human action? A pattern for the future growth of the city may be moulded and complete, when some simple invention may upset the entire calculation.

In 1890, or thereabouts, an ordinance was passed in Cleveland, Ohio, requiring that every self-propelled vehicle on the city streets be preceded 100 ft. in advance by a man carrying, by day, a red flag and, at night, a red lantern. It may be assumed that the development of the horseless carriage to its present stage of efficiency, has rendered somewhat impracticable this particular application of the accepted principle of the responsibility of the community for the safety of its citizens. The provision of Bear Mountain Park, thirty-five miles from New York City, would have been preposterous twenty-five years ago, but the present widespread use of automobiles has made such a regional park the greatest of boons. The proposal of a large neighborhood theatre in every community of consequence, in those days, would have led its proposer to a court of inquiry, but the moving picture has made such provision an accepted necessity of village life. The complex dynamic forces which operate and the infinite potentiality of scientific discovery and of changing thought, may lead along any one of a thousand different avenues.

What possibility, then, is there for foreseeing and preparing for the future? Does not the greatest hope lie in the direction of discovering the underlying

* Secy.-Director, Regional Planning Federation, Philadelphia, Pa.

principles which must control the life of large numbers of people living closely together, in bringing a general acceptance of those principles, and in relying on each generation, profiting by the experience of the past, to make its own application? For principles, if they are sound, are constant, however much their application may vary with the changing conditions. The Cleveland ordinance was one of the earlier recognitions of the responsibility of the community to protect its citizens against the dangers of community life. The application is now obsolete, but the principle is accepted and its application is being constantly expanded to new fields. If each succeeding generation can make some definite contribution in establishing these underlying principles, or in defining and charting the fields in which they apply, engineers will be assured, with the constant development of the science and art of planning, that the pattern of which Mr. Adams speaks will ultimately be found. It will be, however, largely a pattern of principle, the application constantly varying with changing conditions and demands.

What, then, are some of the principles the acceptance of which must be secured or the application of which must be extended?

The police power, the principle that a man may do with his own as he pleases only to the point where that use begins to endanger the health, safety, morals, or general welfare of other members of the community, is a principle written into common law, but its application is being constantly extended. The right to rob his neighbors of light and air, which was formerly claimed by the average citizen as a God-given right, is gradually disappearing under the expansion of this power; but recent adverse zoning decisions indicate that the application of this principle in its most complete sense is far from universal, and that its field of application is still more limited than some planners believe to be sound. Is it too much to hope, for instance, that the common right to beauty may some time be recognized under this power? Already the regional planner is touching upon this field, as is shown in the recognition, in a few States, that a flaming work of art setting forth the attractions of "Wobbly's gum", or the "cigarettes of which father has intimate knowledge", or, for that matter, the Sistine Madonna itself, however attractive they may be on the magazine cover or over the piano, may be a violation of human rights when set forth on a billboard that hides a lovely vista or some noble monument from the passer-by.

Another underlying principle, which must ultimately attain complete acceptance, is the recognition that community-created wealth belongs, not to the speculator, but to the whole community. The reformer who seriously proposes this is still nominated a Socialist, but a beginning of its recognition is found in the procedure of excess condemnation and the assessment of benefits. Many look forward to a modification of this economic system that will assure to the community the unearned increment which it creates, and enable the land speculator to apply his vision and imagination to some activity more socially and economically sound.

A whole set of principles with reference to land occupancy and rentals is yet to be developed. Mr. Adams quotes Belloc in his distinction between

imaginary and real economic values, and hopes for the time when cities will generally recognize the investment values of public improvements. The recognition of the vicious circle created by the high building, with its increasing land value and its consequent necessity for still greater height, seems to point to the coming recognition of a principle the application of which may change materially the facades of buildings in the financial districts and demonstrate anew the rental value of the low building. Certainly, the principles of taxation, as applied to assessments on land and improvements, and their effect on centralization and decentralization are vaguely understood. The regional planner is looking for the evolution of a new or a modified principle of local government that recognizes the validity of a definite relation between the area of governmental control and the social and economic unity of the group. The present administrative units of large metropolitan areas are in no degree identical with their common social and economic interests. The recognition of this principle will surely result in some form of regional government or federation which will aid greatly in solving metropolitan problems.

There are many nominally accepted principles that need a new statement and a new acceptance in terms of the new civilization. Life, liberty, and the pursuit of happiness, meaning life and work under wholesome and inspiring conditions, the liberty of open spaces and free movement, and that happiness which can be attained only through opportunity for education and culture and full rounded self-development, is one of them. Other principles are being discovered, whose validity is only beginning to be felt, but whose full recognition and application as practical standards of human life, will go far in assuring to future cities greater social and economic service to coming generations.

William J. Wilgus,* M. Am. Soc. C. E. (by letter).—No more important duty rests with the engineer, and none more fascinating, than pointing the way for the wise expansion of great centers of population. Critics very properly may say that the continued growth of cities is to be deplored, but the fact remains that this is a condition and not a theory. Modern opportunities for pleasure and profit in urban communities are causing human beings to be increasingly gregarious. To attempt to stem the tide will do no good. The engineer, in going with it, must do all in his power to alleviate its attendant evils and devote his gifts of vision and creativeness to forecasting the needs of the future and devising means for their attainment. This he must do while there is still time to prevent the unwise doing of things that later cannot be undone.

Mr. Adams has glowingly pictured the urban region of to-morrow as it should be; but to translate his convincing dream into the much hoped-for reality, two formidable obstacles must be overcome. They are (*a*) lack of centralized organization through which efforts may be co-ordinated and real results accomplished; and (*b*) a lack of capital with which to finance projects of enormous magnitude.

* Cons. Engr., New York, N. Y.

The first of these obstacles is serious because a multitude of varying interests, too often antagonistic or indifferent, have not found a common ground on which to approach the law-making bodies for needed legislation. The remedy would seem to lie in the voluntary co-operation of all interests in the regional community—political, corporate, and individual—by an organized method that would fairly recognize the weight that should be given to the voice of each member. Such a body, working through a small executive committee of high-minded, able, and public-spirited citizens, and guided by the advice of experts of note, should be successful in formulating plans and legislation acceptable to enlightened local sentiment and, therefore, compelling upon the legislatures and upon Congress. From a movement of this kind should come forth a compact organization having the will, the capacity, and the power to accomplish things for the general good.

The second of the obstacles would fade away if the idea could be dispelled that funds for public works necessarily must be provided through taxation. That is a bugbear that paralyzes the community and kills progress. The average citizen looks on taxes with aversion because he sees no tangible direct return for his expenditure. As a rule he does not object to paying for that which brings an obvious immediate reward that caters to his pleasure, convenience, or necessity, or by reason of which he may make or save money. A case in point is the Holland Vehicular Tunnel, beneath the North River, which has been financed by the States of New York and New Jersey on the promise of toll collections from those who will use the tunnel in preference to ferries. In this respect, the beneficiaries who pay the bill would have been even better served if real estate bordering the entrances and exits had been compelled to contribute toward the cost a fair share of the increase in value which it is reaping because of the changed conditions. Another instance is that of the Grand Central Terminal development, to which the writer ventures to refer with some diffidence because of his responsibility for its inception. There, departure from precedent and the utilization of dormant "air rights" have brought a golden reward from by-products much more than sufficient to carry the enterprise without placing an additional burden on the traveler or the public at large. In a word, lack of capital, as an obstacle to adequate planning and building for the future, will disappear if Man will have the ingenuity to utilize, to the last degree, all revenue-producing by-products that can be made to flow from the new conditions, and also the courage to allocate the remaining net costs among the beneficiaries, namely, the users and reapers of benefits.

Engineers, then, owe their fellow citizens, not only dream pictures of what should be done for their own and their children's welfare, but also forceful reminders of what they must do to realize them. These may be attained by organizing effectively for the adoption and fruition of sound plans, and by financing new projects in part through the utilization of by-products and in part through the allocation of the remaining costs among the beneficiaries rather than exclusively through taxation foisted on the public at large. Stated differently, as the writer sees it, effective organization and self-support to

the fullest possible extent, are the keynotes of success in the timely fulfillment of major plans for the future of regional communities.

FREDERIC H. FAY,* M. AM. SOC. C. E. (by letter).—This excellent paper brings strikingly to mind the rapidly widening field of city planning and the need of ever-broadening vision on the part of those who have to deal with the future development of urban communities. It is only a little more than thirty years since the World's Columbian Exposition at Chicago, Ill., awakened an interest in the question of the development of cities. In the popular mind, city planning in this country dates from the Middle Nineties, and at first dealt essentially with small units within the cities and with matters of appearance, such as the placing of public buildings, the development of civic centers and open areas, etc. City planning was then synonymous with the "City Beautiful". A few years later consideration came to be given to the orderly planning of the development of cities as a whole, and while attractiveness was still an important element, emphasis was laid more especially on the welfare of the people and the conditions under which they live and work. It is only a few years since, for the larger cities, that planning has been carried systematically beyond the boundaries of the municipality and that consideration has been given to the needs and the development of the larger territory, which will be a part of, or within the zone of influence of, the larger city of the future. With the increase in area within the scope of city planning comes also increase in the number and diversity of problems falling within the scope of the planner's consideration. Before many years, properly constituted agencies, systematically studying and planning for the development of States and of the Nation as a whole, will be common. When that time comes some broader term than city planning must be adopted to indicate the field of the planner's activity.

New York presents problems in regional planning that are doubtless as large, diverse, and complex as those of any great city of the world. Other cities of lesser size, however, present problems in regional planning on scales smaller than New York, but often with diversified features. In fact, each large urban region has planning problems purely its own, although many problems are fundamental and common to all.

The Boston Metropolitan District is an urban area in which regional planning along certain lines has been carried on for many years through force of necessity. In fact, the Boston Metropolitan District is probably the earliest example, in this country, of official action in regional planning. The District to-day comprises, in addition to the City of Boston itself, thirty-nine other municipalities.

Table 1 is a comparison of the areas and populations of the City of Boston, the Boston Metropolitan District, and the City of New York. It is interesting to note that in 1925 population density per square mile within the city limits of Boston was 16 306, as compared with the corresponding figure of 18 796 within the city limits of New York, Boston thus having a density about seven-eighths that of New York City.

* Cons. Engr. (Fay, Spofford & Thorndike), Boston, Mass.

What is the story of regional planning in the Boston Metropolitan District? Massachusetts was the first State in the Union to establish (in 1868) a State Board of Health. About that time the City of Boston and other near-by municipalities took steps to improve sanitary conditions along streams draining into Boston Harbor, by the construction, independently of each other, of certain sewerage and drainage works. The territory was so closely built upon, however, that it was soon realized that independent action by the several communities must prove ineffectual. The State Board of Health took a hand, and the result was the establishment, by legislative enactment in 1889, of the Boston Metropolitan Sewerage District and the creation of the Metropolitan Sewerage Commission to handle the sewage and drainage problems of the district as a whole, irrespective of municipal boundary lines. This is believed to be the first official step taken by any State in regional planning. In 1893, the State Legislature created the Metropolitan Parks District under the charge of the Metropolitan Park Commission, which in the succeeding years, has admirably supplemented the nucleus of the great park system previously established by the City of Boston, such that now the park areas of the Boston Metropolitan District are widely and favorably known throughout the country. In 1895 the necessity for co-operation between Boston and the surrounding cities and towns in the matter of water supply led to the creation of the Metropolitan Water Board and Water District, also by State legislation. More recently, the maintenance and operation of the Metropolitan Parks, Water Supply, and Sewerage Systems has been under a single commission, the Metropolitan District Commission. However, in 1926, the necessity having arisen for a large addition to the Metropolitan Water Supply System, a special commission was created by legislative enactment to develop a system of additional water supply.

TABLE 1.—Areas and Populations of City and Metropolitan District of Boston, Mass., Compared with New York, N. Y.

Districts.	Area, in square miles.	Population in 1925.	Density, in 1925, per square mile.
City of Boston	47.8	779 620	16 306
Boston Metropolitan District	409.8	1 806 845	4 419
City of New York	299.0	5 620 048	18 796

The regional planning of the Boston Metropolitan District thus sketchily outlined, has been that relating to certain specific problems in which the mutual interests of the cities and towns of the District forced co-operative action. In each case this regional planning and the constructions resulting therefrom have been carried out by an official State Commission.

More recently, in the Metropolitan Boston Region, a strong sentiment has developed regarding the need of regional planning on broad lines; planning that is not limited to a few immediate and specific problems, but looks ahead over a long period to the general development of the city of the future. Largely through the initiative of the Boston Chamber of Commerce, there was

created by legislative enactment in 1923 the Division of Metropolitan Planning within the Metropolitan District Commission. The Metropolitan Planning Board consists of seven members, four of whom are State or City officials representing separate departments, and three, including the Chairman, are appointed by the Governor from among the citizens of the District. The Metropolitan Planning Division was created primarily to study the question of transportation in its broadest sense in the whole metropolitan area, transportation by rail, water, highway, and air. The problem of transportation, however, is necessarily linked with and dependent on other problems of metropolitan development such that the field of activity of the Metropolitan Planning Division becomes a broad one. The Division is given a reasonable appropriation for its work, and it has a permanent engineering and technical staff. Therefore, while in New York the great problem of regional planning is being carried out by private agency, in Massachusetts many of the broad problems of regional planning for the Boston Metropolitan District have been and are being studied and solved through official action by the State.

The question may arise, "Why the need of regional planning?" In the case of Greater Boston, for example, where the cities and towns of the Metropolitan District having common interests are solely within the limits of a single State, why not annex these cities and towns to Boston itself and thus establish as a single municipal entity the real city of Boston as a single municipal unit? Then all problems of regional planning could be dealt with directly by the government of the larger city. This has been often suggested and as often rejected. It brings up an interesting point of city and regional planning, that is, the psychological feature. In the case of many of the smaller cities and towns surrounding Boston, local pride, historical tradition, and differences in racial and political complexion, all weigh against outright annexation. The communities are jealous of their existence as separate entities, although willing to join with others in matters of mutual concern. It seems unlikely that "Real Boston", as many people call it, will result from the annexation of approximately forty municipalities of the Metropolitan District, the interests of which are to large extent identical with those of Boston. On the other hand, these various communities are gradually being knit closer together through common bonds of interest, and the best development of the real Boston of the future can take place only through wise regional planning which takes account, not only of the physical, but also of the psychological problems involved.

What the Boston regional community of the future will be is largely a matter of speculation, although its development along certain lines may fairly be forecasted through economic necessity. As Mr. Adams well states, "There is no true economic basis for the congestion of great cities like New York, and if it is continued the effect will be to strangle the pulse center of the community." The work now under way in planning for the transportation needs of the future with the increased use of the automobile, will do much toward dispersing population and the development of suburban areas. The growth in population, therefore, of Greater Boston is likely to be almost entirely in the territory outside the present city limits. The Boston Metropolitan Dis-

trict offers a broad and inviting field for regional planning which, if well done, may be of inestimable benefit to those who are to live in Greater Boston in the next and succeeding generations.

William T. Lyle,* M. Am. Soc. C. E. (by letter).—The remarkable progress made during the last few years, and even during the last few months, in city and regional planning is attracting wide attention. This progress is not so much in the art itself as in the confidence of the public of its possibilities, a confidence promoted by an expanding conception in the minds of city and regional planners of the scope and dignity of their art. City and regional planning is assuming an aggressiveness not characteristic of recognized conservative engineering.

This paper is suggestive and stimulating. In city and regional planning the writer would call attention to the folly and even futility of incomprehensive work. The art must operate not only in its physical, but also in its human applications. The older planning was concerned with maps, layouts, and architectural developments; the new planning is considering human beings in their business, domestic, recreational, cultural, and even moral requirements.

City and regional planning needs both vision and courage. Its determinations are not always made on the basis of well buttressed predictions. It is doubtful if they can be, with the determining factors of transportation and power development in a state of uncertainty and change. City and regional planning constitutes a new field of engineering—broad, comprehensive, dignified—reaching out into the realms of economics and human relationships.

The new planning calls for promptness in execution. When a recognized need is experienced there should be a corresponding response in construction. In public works, however, a lag almost always occurs between the need and the fulfillment. Of course, exceptions may be cited to the rule. Some communities are more far-sighted, courageous, and energetic than others. In projecting and constructing its new water supply the City of New York furnishes a good example. The new work was carried through before the dreaded succession of dry years became an actuality. So, also, in its response to the challenge, "Shall we save New York?", it passed the zoning ordinance of 1916, which has wrought such a benefit in the stabilization of real estate values.

Regional planning to-day is applying the principles of harmonious relationships so important in business. Since their establishment, American cities have grown without regulation. They are notorious examples of discord, where selfish interests in private promotion schemes were permitted to operate without check and were even supported by law.

The unregulated liberation and production of power in modern civilization may constitute the gravest menace. Only when properly directed and utilized can it become a blessing. Prosperity will result in the even balance between a healthy need and an adequate and well-directed supply.

The author considers that "perhaps the most hopeful fact in the metropolitan regions of America is the extent to which land is being acquired for

* Prof., Civ. Eng., Washington and Lee Univ., Lexington, Va.

parks". Proofs of this are easily established, not only on hygienic, cultural, and moral grounds, but for economic reasons as well. The assessed valuation, in 1856, of the three wards adjoining Central Park, New York, was $20 500 000. By 1873, it had risen to $236 000 000. The natural increase as obtained by averaging the gain in the other wards was found to be $53 000 000, making the earning capacity of the park during seventeen years for the three adjoining wards, $162 500 000.

City planning heretofore has emphasized too much the visible to the neglect of the invisible. It has concerned itself with streets, parks, railroads, and civic centers, and has neglected drainage and water supply on the assumption that they are properly and exclusively in the province of the city engineer. This should not be so, for drainage and water supply powerfully influence the selection and improvement of parks and parkways, and, in turn, are equally influenced by them. The foul drainage channel by reason of its location and the architectural asset of trees and sloping banks is the ideal location for a parkway; and the great forest preserve or reservation the ideal location for a reservoir.

Much has been written on the subject of overcrowding and congestion. The companion idea of undercrowding deserves more thorough consideration. The fundamental law is the fullest and best use of each unit of area, depending on its location and other characteristics. Less need be said than formerly on the debated question of concentration *versus* decentralization. The future regional community will derive its character from the spreading of metropolitan populations.

In the new regional planning, governmental barriers that have restricted progress will be broken down. For example, a great river, the Delaware, the upper reaches of which have never been extensively utilized for public benefit, will be harnessed for power, and will be drawn from as an important metropolitan water supply. This discussion does not contemplate the consideration of political questions, although the writer is convinced that political doctrines that continually challenge human progress will eventually give way.

Mr. Adams speaks of great centers like New York and Philadelphia, striving to maintain supremacy in competition with the surrounding urban regions of the future. This may be the case, although it is to be hoped that wiser counsels will prevail in the development and perfecting of controlling doctrines of city and regional planning, namely, co-ordination and co-operation. The surrounding regions need the centers and the centers need them. Neither can fully prosper in adverse rivalry with the other. Subsequently, however, he speaks of the regional co-operation needed to end the pollution of drinking waters and promote the development of comprehensive systems of sewerage. It is this co-operation that is so necessary and that is so replete with rich reward. An example of the benefits of co-operation is to be found at Boston, Mass., where several municipalities, each guarding its local autonomy, have wisely united to obtain the benefits of a water supply, sewerage system, and parks which would be beyond the reach of each municipality operating independently. A great metropolitan region will come into its own as fast as it learns, practically, the important lessons of harmonious co-operation.

CHARLES WELLFORD LEAVITT,* M. AM. SOC. C. E. (by letter).—Throughout this paper one senses the fact that the author has built up his forecast largely upon the work done on the "Plan of New York and Its Environs". Therefore, in reading it, one should realize that there is little, if any, comparison between New York and any other city; that the forces acting in the creation of New York will, in all probability, act differently upon other metropolitan areas; and that the regional communities of the future will be unlike the regional community of New York.

"Regulation of city growth" is not always possible. The forces making for city growth are human, and while they are amenable to certain laws and regulations by the police for the general health and welfare of the community, they are not always willing to follow, for instance, the directions laid down by a regional plan. The success which the city builders are after may depend on their originality, backed by their energy; and those drawing up a regional plan should make it sufficiently flexible to take care of these city builders and not block them in their ventures, except when their acts might endanger the lives, health, and general welfare of the country.

For instance, if a plan of New York had been prepared some years ago it would undoubtedly have provided for large manufacturing plants, whereas, in the past twenty years, the author states that plants have been growing smaller although more numerous.

Guiding or regulating the location of people's homes into the so-called blighted districts where there is now perhaps only 1% density of population, in order to avoid the congestion of certain other popular sections, may be a very laudable, though difficult task. Forces other than general direction or regulation must be called upon, and here is one of the great problems of the city planner, to study the psychology of the builders and provide what may be necessary to attract them into the blighted districts.

The quotation from Hilaire Belloc is pertinent, and should be taken to heart. It should be possible, with all the enlightenment of past ages and present rapid growths, to develop plans that would stabilize city realty values and avoid what has recently become so prevalent, namely, the moving of commerce, manufacturing, business, shopping, and residential districts so rapidly from one section of the city to another that good buildings have not time to wear out, but must be sacrificed to the movement of one district into the fashions calling for another; and quite frequently the abandonment of the building suitable for one purpose, to the wretchedness of an area which has been blighted by this movement.

The cities of the old world are far more stable in character than American towns, built and occupied by a cosmopolitan race whose great objective is to speed up and arrive somewhere "where they aint", with a pot of gold in hand.

Such motives do not encourage stable real estate investments, which must come about from a population more satisfied and slower to move; although on the other hand, without movement, there results stagnation which may be even worse than constant movement. The ideal would be one of reasonable

* Civ. and Landscape Engr. (Charles Wellford Leavitt & Son), New York, N. Y. Mr. Leavitt died on April 22, 1928.

activity with a general tendency toward better conditions in both residences and business.

Water-front development is again peculiar to seaboard, lake, gulf, and coast towns and does not apply to some of the inland metropolitan regions, which also have a future.

Can any other section of the world compare with the Park Avenue District in New York? However, "we do find in such cities as Atlanta and Kansas City problems of growth just as puzzling"; but what has helped in studies of New York does not aid in these cities but rather tends to lead astray.

Again, in the quotation from Mr. Richard M. Hurd in regard to the returns on low *versus* high buildings, is found an argument most upsetting to smaller towns where a big price will be paid for the sky-scraper; and it is nearly impossible to convince any one that a sky-scraper is harmful to a town; for, while the writer feels with Mr. Adams and Mr. Hurd, that the building of tall structures is apt to hurt, yet in many instances towns have remained asleep until the tall building came to wake them into activity; but it did not become epidemic as in New York, Chicago, and Detroit. A hard and fast rule may not work for the smaller metropolitan regions.

Anything that may tend to re-establish a demand for land in these blighted areas is bound to be of great assistance, not only in that immediate neighborhood, but throughout the entire region. These blighted districts are usually equipped with sewers, water, electricity, and, frequently, paved streets, in which the city has a large investment without any chance to recapture it except by activity and building. Otherwise, this city money lies without return in adequate taxes, just as a sub-divider, who has equipped his land with all street improvements, is eaten up with interest if he does not sell his lots promptly.

Leaving vehicular traffic on the surface and putting wheeled transportation beneath and pedestrians above, may help a little for a time, but will not the section, so treated, soon again be overcrowded with no form for relief and thus in the end "confusion worse confounded" reign? Has all this not proved that the best way to produce reasonable living conditions, as well as areas in which to work, is by decentralization with careful thought given to building code and zoning?

Into the rural communities, along the main arteries of travel, is now pushed a ribbon-like development, making the roads between large cities such as New York, Boston, and Philadelphia, almost a continuous row of citified houses, and one wonders if the predictions of the author of "Road Town", published about twenty years ago, is not to be realized. In England, this ribbon development is giving the lovers of rural attractions considerable concern, because such rural drives as were enjoyed in the past, have ceased to exist in many cases and one drives from city to city through an apparent city.

Will the regional plan of the future correct these blighted districts, congested areas, and sky-scrapers, and relieve the owners of single-family houses from looking directly into the windows of their neighbors? Will some of the country outside the city remain rural? These are points over which the intelligent citizen must pause, and if such regional plans as have been drawn give

promise of relief, then the citizens of seaboard, lake, gulf, and coast towns as well as cities inland, will demand that they too be included in the comprehensive plan for the future.

MORRIS KNOWLES,* M. AM. SOC. C. E. (by letter).—The regional community is an interesting subject, and the author's forecast of future urban regions may well arouse enthusiasm and stimulate discussion. Comparison with present-day development serves only to magnify the problems; those of construction as well as those of administration. However, there is ample experience now, from the results of not anticipating and planning for the future in the building of American cities, to provide a background of helpful consideration. The measure of success in the future will depend upon how well this experience is to be utilized in planning and in effecting governmental and administrative control. The two are inseparable. If improvement is to be realized, first it must be conceived, then designed, that is, planned; and then comes the necessity of practical administration to convert the plans into actual accomplishments. A look into the future, as to the probable type of new governmental agencies, necessary to secure results is the burden of this discussion.

Aside from the inherent social instinct, concentrated community life has come about naturally because of the advantages that accrue from the pooling of human endeavors. Different forms of government have been evolved and machinery has been set up for the construction of public facilities and the administration of public affairs. Through these agencies, the needs of the community have been supplied; water and sewerage systems have been planned and built; streets have been laid out and paved; police and fire protection methods have been developed; and all the other conveniences and comforts of modern life.

In accomplishing these results, some extravagance and waste have been inevitable; more often than not the needs of the future have been under-estimated in the construction of public works; mistakes have been made which have proved costly or impossible to correct; streets have been laid out with insufficient width; there has been too much crowding of the land in building operations; water and sewerage systems, as constructed, have proved inadequate, and many other deficiencies have been found to exist.

Early Development of Comprehensive Planning.—Out of this has come the modern conception of comprehensive city planning, designed to correct some of the mistakes of present city activities and to create an ideal toward which to build in the future. The subject is quite new, its development as a definite, conscious ideal having been within the past ten or twelve years. However, it was soon realized that many of the problems of such planning would be of a regional character and necessarily must include the suburban, satellite, and semi-rural districts surrounding the city and, in many instances, neighboring communities.

Regional planning as a basis for community activities and the problems involved in such study were presented by Mr. Adams—then Housing and

* Pres. and Chf. Engr., Morris Knowles, Inc., Pittsburgh, Pa.

Town Planning Adviser of the Canadian Government—at the meeting of the National Conference on City Planning at Niagara Falls and Buffalo, N. Y., in 1919. Since then, much study has been given to the subject and to practical methods of adapting well-intentioned theories to actual practice. Various methods and agencies have been suggested, some of which have been tried and found to be partly successful; but there is still a realization that, while much educative effort has been developed, the correct solution has not yet been presented. The process of evolution in the consideration of the problem has been somewhat as follows:

(1) The need of a regional conception of utility development has been apparent.
(2) Realization that single unit utilities, however well planned and executed, sometimes fail to co-ordinate with each other, has brought about a recognition of the necessity of comprehensive planning.
(3) Failure to find ready means to carry well-intentioned plans into execution, has shown a need of an adequate agency to finance and execute these comprehensive plans.
(4) Thus has come about a recognition that a new governmental attitude is necessary.

It is the writer's purpose to amplify and explain some of this development of thought in this discussion and suggest a type of government for the regional community.

Utilities—A Basis for Regional Planning.—Probably the first recognition of regional planning originated through the need of co-operation in the development of public utilities, where the service was common among municipal units arbitrarily separated by political lines. The city, in addition to its legislative, taxation, educational, and police power functions, is an industrial plant and its government an organization for carrying on the affairs of municipal management. It is apparent, therefore, that public works and utilities are of first importance in considering co-operative action.

Where municipalities lie so closely together as to be practically continuous, many municipal functions can be most efficiently performed under a single management. Such services as water supply, drainage, sewerage, main thoroughfares, general park developments, and regional planning are obviously accomplished best under unified control. Only in this way can haphazard development and duplication be avoided. These problems cannot be correctly solved within man-made political boundaries, but must be treated as watershed and area problems for a district having similar conditions. Finally, it is generally true that economy, both in construction and operation, is obtained by collective action.

Entirely apart from these engineering and economic considerations, however, there are sound reasons of political morality for the co-operative solution of such problems. No one "liveth to himself" and urbans and ruralists are all "members one of another". The suburbanite, working and buying in the city, is as dependent on the city's service as the city dweller who trades

and visits in the environs, is on the facilities of the outdoor area. Mutual dependence involves mutual obligations and there is mutual advantage in sharing alike the common benefits in costs.

The earliest method devised to bring about concerted action among neighboring communities has been through organization of metropolitan districts for specific purposes. However, co-operative community development involves consideration of a much broader field of activity.

Problems of Regional Planning.—Because of the influence and effect of one group upon another in such matters as fire and police protection, water supply, sewage disposal, and prevention of the spread of disease, it is necessary to think in terms of the region, rather than of the separate units which enter into the combination. For example, one community may have an improved and sanitary water system, while a neighboring city may furnish an unwholesome supply. Similarly, the discharge of waste from one community may pollute the stream from which another draws its water; or, in the control of the milk supply, unified action is necessary if it is to be effective in accomplishing the desired results. These illustrations, while they refer only in a meager way to the many problems to be considered, include examples both of control and of planning.

Area Affected.—The region, with which such planning is concerned, might be defined as an area which, on account of the interdependence of the various communities therein, may be considered as a unit in physical and cultural development. Such an area might include several important cities, perhaps approximately of the same size, all having common interests and mutually dependent one upon another; or it might comprise a metropolis and its neighboring suburbs and satellite towns.

The latter type illustrates a most interesting fact about the modern growth of great cities; that is, the tendency to spill their populations out over a large area rather than to develop progressively outward from the center as was formerly the case. Thus, separate communities spring up all along the transit lines and at other favored spots, adjacent to the city, but outside its corporate limits. Mercantile establishments frequently find it profitable to move farther from the heart of the city; and high-class shopping districts, including theatres and hotels, are springing up in the outlying communities. Industries also find it to their advantage to choose sites farther from the center, where land values are lower and where there is room for new and modern housing developments which will be attractive to workmen.

Importance of Common Problems.—The planning and development of the region, therefore, including all the various towns and communities tributary to the parent city, offer far greater opportunities than in the case of the old-time progressive expansion of the city from the center outward; but, at the same time, new problems are introduced which were not present when one political boundary line enclosed the entire urban community, and growth beyond it was in concentric rings. Consequently, as the satellite communities grow, regional problems become grievous and separate municipalities find it difficult to arrive at any solution unless one helps the other, or joins with the other, and all agree on a common plan.

Advantages of Co-Operation.—Even superficial thought on the subject will convince one, therefore, that resulting benefits may be expected if a large number of political units—separated only by imaginary political boundary lines, but forming as a whole one unit as to economic, industrial, commercial, and social life—are united by some plan that makes concerted action possible in the conduct of public affairs. Some of the results of practical co-operation to be expected, are conservation of resources, economy in the development and construction of public facilities, and greater efficiency in governmental administration.

However, reference to some actual accomplishments of consolidation may be of interest and will afford convincing argument as to the advantages. The following is quoted from a paper* by Professor Chester B. Maxey, of the Western Reserve University, referring to the formation of Greater Philadelphia, during the Mid-Nineteenth Century:

"The immediate results of the Consolidation and Annexation were unquestionably beneficial. For many years Philadelphia and her environs had been disgraced by civil turbulence almost impossible to prevent or control. * * * These disturbances and disorders quickly disappeared when unified local government went into operation. * * * Other beneficial results of consolidation were the development of a comprehensive system of water supply and sewage disposal to replace the separate systems of the former independent municipalities; the establishment of a metropolitan park system; and a marked increase in the assessed valuation of property throughout the metropolitan area."

Similar illustrations could be given, but there is no need of repetition.

Regional Planning Commissions.—Naturally, in order to accomplish effective results in regional planning, there must be some form of centralized control over the major functions of the separate communities, in matters of common concern. Various methods of accomplishing such control have been considered and some have been tested, with more or less success. The Standard City Planning Enabling Act, as prepared by the Advisory Committee on City Planning and Zoning of the U. S. Department of Commerce, and published in preliminary form in February, 1927, makes provision for the establishment of regions and for the creation of regional planning commissions.

One method of creating the regions is that of having the Governor determine the boundaries and appoint the members of the regional planning commission. This would be done on request of the planning commission of any municipality, the county commissioners of any county, or upon petition of a certain number of citizens. An alternative method also is described, which contemplates the creation of the regional planning commissions on the initiative of one or more local planning commissions and the county commissioners of the counties involved. In the latter instance these agencies, by mutual agreement, would decide on the boundaries of the region and would determine the relative share of the cost of the work to be borne by the respective municipalities and counties and the size and method of selection of the regional planning commission.

* "Political Integration of Metropolitan Communities," *National Municipal Review*, August, 1922.

The organization of the commission and the powers and duties as proposed, would be similar to those of a city planning commission. Provision also has been made in the Act for certification of the regional plan to the various interested agencies within the region; for the adoption of the plan by municipalities; and for the legal status of the regional plan after its adoption.

This, so far as it goes, is a beginning, but an equally if not more important consideration is the creation of centralized administrative and executive control. In the city, after the planning commission has developed a general city plan, the existing departments of the municipal government are available for the handling of the detailed designs and for the construction of improvements; but in regional planning there is no form of centralized government available to bring about concerted action in matters of common interest, nor to initiate, execute, and administer the regional projects that have been conceived. Commissions or boards may be appointed of course to carry out some detail of the general plan, but the co-ordination of such specific features with other improvements proposed by the regional planning commission may be forgotten. Moreover, such efforts refer more particularly to construction problems and do not take into consideration the consolidation of the community in other important matters of public welfare. The real solution lies in the development of some form of definite governmental authority which will secure the benefit of combining the resources of the separate political units in matters of regional character; but which will guarantee to such separate units local control in affairs of purely local concern.

Methods of Organization.—While the details of organization and administration may differ, as proposed in any particular instance, the various plans tried, or proposed throughout the country, may be grouped under one of three headings, as far as general principles are concerned. Stated briefly, these are as follows:

1.—Annexation of Adjoining Territory.
2.—Metropolitan Districts for Specific Purposes.
3.—A Federated City Plan of Government.

Annexation.—This is the oldest method of consolidation and the one that has been resorted to in the growth of practically every city. It includes the actual incorporation of adjacent territory into the city, and complete centralization of authority with respect to public works, public safety, legislation, taxation, and all other municipal functions. The result may be brought about by mutual agreement between the city and the annexed suburbs; or, under some forms of legislation, by the sovereign power of the State, or by a majority of all the voters in the territory affected, regardless of the wishes of the voters of the suburbs to be annexed.

Voluntary annexation of neighboring suburban towns in the larger cities often may be difficult to accomplish. This is not difficult to understand, for the people of smaller communities are vastly more homogeneous in regard to their concerted actions than people of the wards of the city. They feel more at home and more friendly with each other, because the people in city communities are changing so rapidly that permanency of abode does not exist to

a sufficient degree to promote acquaintance and friendliness. Pride in one's own small community is natural and to be encouraged, and it is not to be expected that residents in such places will voluntarily delegate to a larger municipal authority, more or less removed, powers which have to do with purely local affairs and which now are thought to be capably managed by officials whom they know and who, perhaps, are neighbors.

However, if the need be sufficiently urgent, annexation may be carried out and has been, in several important instances, sometimes voluntarily and sometimes forcefully or involuntarily. The difficulty lies, not in any consitutional limitations in most States in applying the latter method, for the municipality, of course, is simply a creature of the State and subject to whatever laws the Legislature may formulate; nor is the only objection the fact that the principle of home rule would be discarded entirely.

The fact is that annexation, whether voluntary or otherwise, does not solve the problem. There is destroyed that very desirable quality of people wishing to do things for themselves; pride in small local affairs is lessened; the older, well-developed portions of the city are burdened with the cost of improvements in outlying sections; and the tendency is again toward centralization and congestion. Thus, the problems of municipal government become increasingly complex and difficult, leading too often to misgovernment and mismanagement.

Metropolitan Districts.—This method approaches the solving of regional problems through metropolitan commissions, each charged with some particular type of public works or activity, and functioning within a region known as a metropolitan district. This plan has had its greatest development in London, England, through the activities of the London County Council, and has been copied, to some extent, in this country. For example, around Boston, Mass., there have been various metropolitan commissions since about 1890, and some of the best examples in the United States: First, a Sewerage Commission, covering Boston and 15 towns within a radius of 15 miles or more of the State House; then, in 1895-96, the development of the Metropolitan Water Commission; and, about the same time, the Metropolitan Park Commission. Some time later, the Metropolitan Police was organized.

These various commissions have cared wonderfully well for certain types of public improvements, and for their proper design and efficient operation. It should be remembered, however, that the operation of these Boston commissions is entirely in the hands of the State through commissions appointed by the Governor. This paternalistic authority of the State over the communities is really more exacting and detailed than a municipality would be likely to have exercised. The local communities have nothing to say; they do not vote for appropriations or commissioners; they do not get together; the State does it all and then charges the cost to each.

Recently, having in mind that these things were not operating as well as if they were more unified, the authorities resolved to join the three commissions having to do with water supply, sewerage, and parks, into one Metropolitan Commission. This has helped, because it means that, when water-works are

planned, there will be some consideration given to drainage and sewerage and parks, and *vice versa*. It readily can be seen, however, that many other features of the metropolitan area also are affected. There is still a lack of co-ordination of the various governmental affairs within the region, which must be considered. Conflicting action rather than harmony is produced. Only recently a retrogression has occurred in the creation of a board for the development of a new, distant source of water supply.

There are many other metropolitan commissions functioning in American cities, most of them having to do with only one particular kind of public works. The Sanitary District of Chicago, for instance, comprises all of Cook County and some territory outside. Its Commissioners are elected by the people. Another example is the Miami Conservancy District. This is probably the largest area of its kind in the United States and is a somewhat special case. The District embraces all or parts of nine counties and includes the Cities of Dayton, Middletown, and Hamilton, Ohio. It was organized for the purpose of constructing and maintaining flood-prevention works, and its government rests with a Board of three, appointed by a Court, consisting of one Common Pleas Judge in each of the counties affected.

Another example is the Essex Border Utilities Commission, constituted by Special Act of the Ontario Parliament, in April, 1916. Its object has been the solution of problems affecting the whole of the border municipalities, as distinguished from those to be dealt with by any one of them in particular. These problems include sewerage, water supply system, health, parks, planning, etc. The Commission consists of nineteen members, eleven of whom are elected and eight are *ex officio*, all serving without remuneration.

While the metropolitan district plan is frequently adapted to the development of certain specific public improvements, there are certain faults and disadvantages to be considered. Sufficient co-ordination between the various types of improvements is lacking; control is remote from the people directly affected; and there is a possibility of much confusion and wasted effort from the overlapping jurisdictions of a great number of such commissions if many activities are undertaken.

Federated City Plan of Government.—This is the type of organization that has been adopted by the Pennsylvania Commission for the Study of Consolidation of Municipalities, after several years' study of the various methods, and this type is proposed for Greater Pittsburgh.

The plan proposed is somewhat analogous to that of New York City, but there are important differences. While New York comprises five Boroughs—each one a large city in itself, and some of which even have regional characteristics—the Pittsburgh Plan will include 124 municipalities, most of them already distinct and separate communities, which will be preserved within the consolidated city.

While the plan that has been proposed was formulated to meet particular local conditions within Allegheny County, in Western Pennsylvania, its general principles may be considered applicable to the majority of similar situations; and an explanation of its more important features may be of general interest.

The Greater Pittsburgh Plan.—The area included in the Pittsburgh Plan coincides with that of Allegheny County. Within this area, in addition to the City of Pittsburgh, there are three cities of the third class, sixty-six boroughs, and fifty-four townships. The population included will approximate 1 500 000. One of the basic principles adopted by the Commission in its preliminary consideration of the problem, as set forth in its report to the Governor, was:

"That such a plan, to be made satisfactory, should give to the constituent and smaller municipalities, proper and reasonable control of their local affairs * * *. No government must become too remote from the people. The greater things should be handled in a greater way; the smaller and more intimate things in a smaller way, a local way—home rule by home people. Local officials should and must be close to the citizens for whom they function, giving service as desired, never remote from or unmindful of the constituents, or out of constant touch with them."

An amendment to the Constitution of the State was found necessary in order to enable the adoption of such a plan. It was passed first at the special session of the Legislature in 1926 and again at the regular session in 1927. It will be placed before the people of the State in the form of a referendum in November, 1929.

While the constitutional amendment is largely of an enabling nature, the general features to be observed in the plan have been incorporated in it. This was done to insure certainty of rights to the smaller communities. They include provisions for the general functions and powers of the consolidated city; a statement that local powers are to be reserved to constituent municipalities; and an outline of the method of framing and adopting the new charter.

The charter, under which the consolidated city will operate, will be authorized by the General Assembly and will provide for,

"* * * the consolidation of the county, poor districts, cities, boroughs and townships of the County of Allegheny and the offices thereof, into a consolidated city and county, with the constitutional and legal capacity of a municipal corporation, to be known as the City of Pittsburgh and * * * provide for a charter for its government".

This provision will give to the consolidated city, authority to deal with problems affecting any two or more municipalities, or the whole district. Among such problems may be mentioned water supply, including the planning of a general system, where found advisable; sewerage systems, particularly the consideration of main trunk lines and of disposal; transit lines, including the beginning of a rapid transit system to serve adequately the greater city; main thoroughfares, through highways, tunnels, subways, and bridges; and other public works of a regional character which should be accomplished by, or under, the direction of the consolidated city government.

Another of the provisions relating to powers conferred on the new government refers to zoning, making such procedure constitutional beyond any possible doubt within the Greater City. Another grants authority to the Commissioners of the Central Government to create special improvement districts for the financing and construction of certain works, such as drainage, sewage disposal, or garbage collection and disposal.

Certain debts of the constituent units, incurred for the construction of public works which would be transferred to the Greater City, will be assumed by the Central Government. In addition, the charter may provide,

"For the assessment of property for taxation, the levying and collection of taxes and the payment of the costs of any public improvement, either in whole or in part, by special assessment upon abutting and non-abutting property materially benefitted thereby, and for this purpose real estate so charged shall be classified as urban, suburban, and rural, and adjustment made in accordance with such classification".

This obviously is the proper method of assessment for improvements rather than that which places the burden of the entire cost on abutting properties by general taxation through bond issues.

A guaranty against forcible annexation is given to the separate communities in case the charter is adopted, but there is nothing to prevent two or more of the separate municipalities joining together voluntarily whenever they desire.

The local powers to be kept by the several cities, boroughs, and townships are definitely stated in the proposed amendment, and include the following:

1.—The constitutional and legal capacity of municipal corporations, except as limited in the charter.
2.—The power to levy and collect taxes for any lawful power of the separate municipalities.
3.—The power to acquire, own, construct, maintain, and operate public property, works, improvements, utilities or services dealing with only local needs.
4.—The power to maintain a local police and fire department. In some cases this may be supplemental to the department of the consolidated city.
5.—All other powers not specifically granted by the charter to the consolidated city.

Provision is made for the voluntary surrender of any of these powers to the consolidated city, by vote of the electors in one of the separate municipal divisions, and by acceptance in each instance of such delegation of power and responsibility by the Board of Commissioners of the consolidated city.

Those who have given most thought to the situation, feel that the Pittsburgh Plan will provide a practical solution for regional problems of planning and for construction and operation of regional public works. Much will depend on the type and details of the charter yet to be drawn. However, even if all the results as to governmental operation may be as anticipated, the working out of the details and the thorough and practical planning of the region will be essential to effective accomplishment.

Wisdom of Regional Planning.—Community planning is based on the principle of co-ordination. Public facilities always have been planned to some extent but usually as independent and separate projects, so that there was a lack of harmony in fitting them into the general community plan. This has been the deficiency that brought about a realization of the need of something different and that has been responsible for the development of the present-day art of community planning. The important difference lies in the co-ordinating of all improvement plans and fitting them together into an har-

monious and unified scheme of general design whether it be for a village, a city, or a region.

Consequently, the planning of a regional utility, such as a water supply or a sewerage system, by a regional or metropolitan board may be contrasted with the separate planning of a similar utility for one of the constituent communities, by the city engineer or by a municipal commission. Efforts like the latter cannot be described as regional planning activities; real value can come only from a comprehensive consideration of all the problems that are of a regional character. Otherwise, the same difficulties that have become so manifest with the growth of urban communities will eventually be experienced as the larger regional area becomes more compactly developed.

The difficulties, at the present time, lie in the lack of governmental machinery for developing the regional plan, and after having developed it, in making the plan effective in its administration. Whatever the method may be, the three steps to be considered in the development of a regional community are: (*a*) The conception and creation of the form of consolidation; (*b*) the establishment of the boundaries of the region; and (*c*) the adequate planning of public facilities and services for this area.

The whole subject is so new that there are only a few precedents or experiments as illustrations of what to do or of what to avoid; but in all private and public endeavors, planning should precede execution. Therefore, whether the start be made through the creation of a regional planning commission, with the subsequent details of the regional municipal organization to be developed later; or whether the general plan of governmental consolidation be first conceived, and the planning done thereunder, perhaps is immaterial. In either event both are essential to complete success.

Finally, community planning, whether it be that which is concerned with a single municipality or whether it be sufficiently enlarged in scope to include many diverse political entities, should be conceived to accomplish more than the economical construction of public utilities, or the development of more efficient forms of public control. The psychological result should be to create a public consciousness and appreciation of community problems, and this, in turn, should be used to advantage in promoting enthusiasm for a large and intelligent program for the whole community. The modern development of American cities, and the advent of the automobile, which has made possible the scattering of populations over large areas at no sacrifice of time in transportation, have re-acted to a lack of participating interest in the larger civic affairs by those who make their homes in the suburbs or in the neighboring countryside. The larger community interests, because of their remoteness, have become secondary to those of the immediate local neighborhoods; but regional endeavors should be a means of bringing about a closer bond of sympathy and helpfulness in the solution of the many problems that confront the larger urban developments of the present day. The Pittsburgh Plan of Municipal Consolidation is offered as an advanced idea in the hope that it will merit public discussion and point the way to making regional plans effective through the development of a widespread civic consciousness in governmental affairs over large areas having common problems.

THOMAS ADAMS,* ESQ. (by letter).—From certain points of view, the writer agrees with Mr. Kingery that regional planning presents greater difficulties than city planning, but this should not be taken to mean that the technical preparation of a regional plan involves more labor and difficulty than the preparation of a city plan. The former covers a larger area than the latter, but it is not so hampered by the necessity of complying with legal requirements or of compromising with existing conditions. Subject to being based on sound principles and to being comprehensive in its treatment of problems, it may be said that the more elastic and the broader in outline the regional plan is, the better it will be.

Mr. Strong shows by his emphasis on principles that he has the right conception of what is most needed. The regional plan is confined so much to problems of the future that planners need not be greatly influenced by political expediency or by pressure of vested interests in existing bad conditions. Therefore, they have no excuse for developing a plan that is not sound in principle, from the point of view of what is best for the community. As Mr. Fay states, regional planning should be based on the policy of looking ahead over a long period of years, and in the development of its main features it should consider sociological as well as physical and economic problems.

It goes without saying that co-operation is the keynote of a regional plan. In fact, there can be no regional planning without much co-operation. The fact and extent of this co-operation between authorities of adjacent regions, which Mr. Kingery and Professor Lyle emphasize, are more important than the need of effecting governmental and administrative control as referred to by Mr. Knowles. The writer predicts the operation of governmental control through the city organization rather than through the unorganized region. Nevertheless, Mr. Knowles has raised a most interesting point which will have greater significance in the future, namely, the desirability of new types of government for great urban regions. On this subject Professor Munro, of Harvard University, has recently written in support of those who advocate a regional form of government.†

Mr. Kingery's claim that some of the most obscure local officials are doing some very successful regional planning does not carry conviction. The work and projects of these officials are no doubt being developed in co-operation with his association and thereby are given a regional emphasis. It is most dangerous, however, to assume that the piecing together of different local projects is regional planning, even if this is done with co-operation. A regional plan should develop from considerations of the region as a whole down to the local considerations rather than take the form of a collection and composite of local projects.

There does not appear to be much ground for concern about lack of centralized organization or lack of capital, in spite of the truth of Colonel Wilgus' statement that these represent two formidable obstacles to be over-

* Gen. Director of Plans and Surveys, Regional Plan of New York and Its Environs, New York, N. Y.

† *The Forum*, January, 1928, p. 108.

come. They do present such obstacles in relation to all major engineering projects which are proposed within or without a regional plan, but they are no greater than have to be overcome in connection with all forms of planning and government. Since they have to be fought in any event, it is better that planners should have to fight them for some purpose that is really worth while. The writer's fear, in getting the dream of a better city brought into reality, is not for the lack of organization or capital, but for the lack of well-informed public opinion regarding what is true and false in the building of the city.

The differences between New York and other regional communities of the future, referred to by Mr. Leavitt, only relate to certain physical aspects. The New York Region contains the same social and economic elements and reflects the same tendencies of growth as other great urban aggregations.

No regional plan will correct blighted districts, congested areas, and the evils of skyscrapers. All it can accomplish is to show what is likely to happen from certain conditions and tendencies and to stimulate the operation of social and economic forces in those directions that will bring greater convenience, health, safety, and public well-being than is possible to be obtained with the present haphazard and disorganized growth within meaningless political boundaries.

The distinguished authorities who have discussed this presentation of a difficult subject, involving an attempt to make shrewd guesses into the future, have given the writer a greater confidence in the general predictions that he ventured to put forward with great temerity. If some of the things hoped for cannot be attained, there still remains the satisfaction of having hoped.

Paper No. 1685

THE HISTORY AND DEVELOPMENT OF ROAD BUILDING IN THE UNITED STATES*

By Thomas H. MacDonald,† Esq.

Between this Sesqui-Centennial Year (1926) and the founding of the first Colonial settlement at Jamestown, Va., the great event of 1776 stands almost at the mid-point of time. The men who gathered in Philadelphia to affix their signatures to the Declaration of Independence looked back upon a period of American history a little longer than that which has since unfolded. At the end of their sesqui-centennium the journeys they made from their several homes were only slightly less arduous and time-consuming than they would have been at its beginning. To-day—150 years later—the same journeys are made in hours instead of days, and days instead of weeks.

The signers insisted that they acted for thirteen independent States. To-day, it is difficult to conceive of the States as separate Commonwealths possessing original authority and yielding only to a restricted power which they, themselves, have conferred on the Federal Government. In the popular mind they have become no more than the political subdivisions of the Republic.

To what extent was the form of government, as originally established, the product of inadequate facilities of communication between the Colonies; and what relation is there between the gradual transfer of authority to the Federal Government and the development of the railroads, the telegraph and telephone, the radio, the motor vehicle, and the modern improved highways? The writer is convinced that it would be wiser if, in the teaching of American history in the schools, more time were given to the study of such fundamental economic questions, and less to the lives and ambitions of political leaders and the wars in which America has been involved by their blundering.

It is an absorbing pursuit in reading history to speculate on the effect of transportation in shaping America's destiny as a nation. To what extent

* Presented at the meeting of the Highway Division, Philadelphia, Pa., October 6, 1926.
† Chf., U. S. Bureau of Public Roads, Washington, D. C.

was the general improvement of roads that followed immediately after the Revolution owing to the preservation and gradual strengthening of the bond which precariously united the Thirteen Colonies?

What seeds of disunion are to be found in the fact that the later movements of the people and the building of roads, canals, and railroads were mainly westward both from the South and the North; and that between the Hudson and the Mississippi not a single major waterway runs north and south?

What would now be the western boundary of the United States if exploration and travel over the Oregon Trail had been delayed by as much as a decade?

What conception of the true rôle of the railways was held by those who built the early roads? The writer is convinced that they thought of them as merely a new form of highway, to replace entirely the common roads. No other conception and no less profound ignorance of the economics of railway transportation can explain the hundreds of thousands of short lines built without connection or possibility of adequate revenue; and no other conception will account for the complete abandonment of the common roads.

What importance as an underlying cause of the Civil War attaches to the fact that, in 1850, there were less than 10 000 miles of such inadequately located railways in the entire country and, in 1860, but slightly more than 30 000 miles? And what, in view of the general agreement that the South was starved into submission, was the effect of the fact that, in 1864, there were less than 6 000 miles of railway under Confederate control, all in utter disrepair?

These are interesting historical speculations. In the forces with which they are concerned is found a truer cause of the course and progress of the Nation than many of those of a purely political nature to which such importance has been attached by historians.

Amusement as well as intellectual profit may be derived from this study of the history of transportation. Whenever opposition is expressed to the granting of franchises for the use of the public highways by common carrier motor trucks, the writer is reminded of the completeness with which the Governor of New Jersey disposed of a similar complaint by the Assembly in 1707. Of the result of this so-called monopoly he stated:

"At present everybody is sure, once a fortnight, to have an opportunity of sending any quantity of goods, great or small, at reasonable rates, without being in danger of imposition; and the sending of this wagon is so far from being a grievance or monopoly, that by this means and no other, a trade has been carried on between Philadelphia, Burlington, Amboy, and New York, which was never known before, and in all probability never would have been."

Let the legal retainers of the public service commissions strive as they may, there is no more adequate reply to the numerous complaints, which it is their duty to answer, than that.

When one hears the fear expressed, as frequently happens, that the improvement of roads and their use by motor vehicles will destroy the business of the railroads, the writer is again reminded of the instance cited by a

citizen of Pennsylvania in an essay he prepared in 1891 in the hope of winning a prize offered by the University of Pennsylvania. He was informed, so he states:

"By a gentleman in the business of furnishing road material, that a prominent official of a great railroad refused to deliver material for him at a point on their road where it would have been a great convenience to have had it, and gave as a reason that they did not wish to accommodate the turnpike company that wanted the material, as their road was too good already, and was competing with the railroad to the injury of their business."

If, in 1891, before ever the honk of a motor horn had disturbed the quiet somnolence of the peaceful Pennsylvania countryside, a "prominent official of a great railroad" could scent danger in highway improvement, it is not surprising in this day of greatest railroad prosperity, that other "prominent officials" betray similar fears, but it is problematical whether they still hope to halt the proper development of highway transportation.

These are merely random historical allusions by way of preface to the specific subject of this paper, which is confined to a review of the development of highway construction and maintenance.

Colonial Road Building

With the exception of the primitive streets of Jamestown no roads were built in the Colony of Virginia by the first settlers. The settlements were close to the river banks and fear of Indian attack kept the colonists from wandering far inland. The first road law of the Colony, which was also the first American law with respect to highways, was passed by the General Assembly in 1632. It provided for the laying out of the simple ways required by the small settlement in the following terms:

"Highways shall be layd out in such convenient places as are requisite accordings as the Governor and Counsell or the Commissioners for the monthlie corts shall appoynt, or accordings as the parishioners of every parish shall agree."

Brief and elementary as were its terms, this law was doubtless entirely adequate for a community in which, according to the inventory of goods and chattels made in 1625, there was but one horse, and that in the possession of the Governor.

The first New England law of record, and the second to be passed in all America, was enacted in Massachusetts in 1639. Although somewhat longer than the Virginia Act, its terms were similar in their general effect. It is notable from the point of view of the engineer, however, as the first law in which there is any specification as to the manner in which the roads were to be constructed. After providing for the laying out of the roads by two or three men chosen from every town, and after carefully protecting the rights of property owners from encroachment by the road builders, it lays upon the locators this single injunction, that, "in common grounds, or where the soil is wet or miry, they shall lay out the ways the wider, as six, or eight, or ten rods, or more in common grounds."

In this law is found the first provision, loose and flexible as it was, governing the width of the highways. As yet there was no definition of the manner in which the ways were to be made; and it was not until 1664 that, in the regulations established by the Government of New York, the first definite prescription of this nature was given. That part of the regulation was, as follows:

"The highways to be cleared as followeth, *viz.*, the way to be made clear of standing and lying trees, at least ten feet broad; all stumps and shrubs to be cut close by the ground. The trees marked yearly on both sides—sufficient bridges to be made and kept over all marshy, swampy, and difficult dirty places, and whatever else shall be thought more necessary about the highways aforesaid."

Although this was the first legal definition of a method to be followed, it is probable that the regulation merely embodied the common practice of the day and that methods and practices very similar were followed in all the Colonies.

That but little advance had been made by the opening of the Eighteenth Century is indicated by the Maryland Law of 1704, which contains much the same provisions with respect to clearing and grubbing, and merely increases the width to 20 ft. This law, however, is of interest mainly because of its Fifth Section which constitutes what is perhaps the first definite regulation for marking of roads in America, and, incidentally, indicates how easy it must have been to lose one's way on the rude tracks which served for roads. This curious provision was as follows:

"V. And that all the roads that lead to any Ferries, Court-house of any County, or to any church, or leading through any county to the port of Annapolis, should be marked on both sides the Road with Two Notches; if the Road lead to Annapolis, the Road that leads there, at the leaving the other Road, shall be marked on the face of the tree, in a smooth Place cut for that purpose, with the letters A A set on with a Pair of Marking-Irons and coloured; and so with Two Notches all along the Road; and where at any Place it leaves any other Road shall be again distinguished with the Mark aforesaid, on the Face of the Tree, with a Pair of Marking-Irons, and coloured as aforesaid. And any road on the Eastern Shore in Talbot County, that leads to the port of William-Stadt at the entering of the same, and in parting with or dividing from any other Road, shall be marked on the face of a tree, in a smooth place cut for that purpose, with the letter, W, and so with two notches all along the road. And the Roads that lead to any County Court-house, shall have two Notches on the Trees on both sides of the Road as aforesaid, and another Notch a Distance above the other. And any Road that leads to a Church, shall be marked at the entrance into the same, and at the leaving any other Road, with a Slip cut down the Face of the Tree, near the ground. And any road leading to a Ferry, and dividing from other public roads, shall be marked with Three Notches of equal distance at the Entrance into the same. And these Rules and Methods the Several Justices of the County Courts, shall, from Time to Time, give in charge to the overseers of the Highways, by them to be appointed for that purpose; who are likewise enjoined carefully and strictly to observe and perform the same, under the Penalty aforesaid."

Along at least one of these ancient roads in Southern Maryland, still known as the "Three Notch Road", notches, some of a remote date, may still be discerned in the bark of many of the oldest oaks.

The law in which this odd provision was made constituted, with minor amendments, the sole road legislation of the Province of Maryland for nearly three generations, and Maryland was not more backward than the other Colonies. Indeed it must be said that from the point of view of the road builder the progress made during the entire Colonial period was practically negligible, as may be seen from the following passages taken from the work of the Maryland historian, Thomas Scharf:

"* * * where water routes were not available, the means of locomotion, though various, were all primitive. Long journeys were made on horseback. People of consequence rode in their coaches, with four horses attached, the leaders mounted by liveried postilions. So Washington came from New York to Annapolis, to attend the ball given there in his honor after the peace. He left New York, December 4, and arrived at Annapolis, December 17, thirteen days to a ride which may now be made inside of eight hours. So Washington went to Philadelphia from Mount Vernon to attend the Constitutional Convention, having to lie over at Havre-de-Grace all night because it was too stormy to cross the Susquehanna. The stage-coach was just coming into use in this country at the time of which we write, and the importance of regular communication between one point and another was beginning to be seen. There were a few, but not many post-routes, and those chiefly maintained by private enterprise.

"The carrier's cart plied between Alexandria and Philadelphia, by way of Baltimore; the Conestoga wagon was the means of communication between Baltimore and Harrisburg, Frederick, Hagerstown, etc., while these outlying places in their turn were brought into intercourse with the backwoods and the wilderness by means of strings of pack-horses. * * * Roads were all bad and ill-kept, narrow, obstructed by gates and seldom permitting two vehicles to pass one another. * * *

"The good roads—comparatively good, we mean—and the best post-routes were due to private enterprise. The Kent Island post-route was owned by a Tilghman, and Henry Callister threatened an opposition unless it was better managed. * * * It took a day of almost twenty-four hours, to ride from Elkridge Landing to Annapolis (about 30 miles)—yet the thrifty Germans of Frederick County traded with Georgia by way of the Valley of Virginia, sending their manufactures of wool, flax and leather on the backs of pack-horses."

Pioneer Roads to the West

If such was the state of the roads in the settlements during the Revolution it may be assumed that the few roads which previously had been pushed westward across the mountains were even more primitive. The first of these was laid out in 1743 by the Ohio Company, a party of Virginia gentlemen who had been granted 200 000 acres on the Ohio River between the Monongahela and the Kanawha on condition that 100 families should be settled on it in two years.

According to Hulbert:

"The road was probably nothing more than a blazed trail with possibly some alteration of route at certain points; it may be that in low ground which could not be avoided the road was 'corduroyed', but this is quite doubtful."

It was over this road that Washington traveled, in 1753, at the behest of the Virginia Governor to inquire of the French their rights to build forts on the Allegheny River. Again, in 1754, when war with the French seemed inevitable, he made the same trip over the same road, this time taking with him 300 men and possibly 10 swivel guns, to move which it was necessary to widen and straighten the road. Finally, in the following year (1755), it was over this same road that Braddock advanced from Fort Cumberland with 2 200 men and 600 pioneers, leading the way, to widen and corduroy the trail for the Army. This time the road was evidently made with some care, for Washington complained that the movement of the army was being delayed because the road-makers were stopping to level "every mole-hill".

This, the first road across the mountains, was the only one until 1758, when Gen. John Forbes, sent against Fort Duquesne to redeem the failure of Braddock, built or rather opened a new one by way of Bedford and Ligonier, in Pennsylvania; and this road with its predecessor remained as the only routes of white-man travel across the mountains until 1775.

In that year the Transylvania Company was organized, and Daniel Boone was sent to mark out the Wilderness Road through the Cumberland Gap to Kentucky. Although made later than the roads of Braddock and Forbes, the Wilderness Road quickly became the most important of the three as a thoroughfare and for a time actually outrivaled the Ohio River as a pioneer route. Of this road a Kentucky historian says:

"The road marked out was at best but a trace. No vehicle of any sort passed over it before it was made a wagon road by action of the State legislature in 1795. The location of the road, however, is a monument to the skill of Boone as a practical engineer and surveyor. It required a mind of far more than ordinary caliber to locate through more than two hundred miles of mountain wilderness a way of travel which, for a hundred years, has remained practically unchanged, and upon which the State has stamped its approval by the expenditure of vast sums of money."

Although the State did undoubtedly approve and profit greatly from the work of the intrepid Boone, its approval apparently did not express itself in any substantial way, for in 1796, he wrote as follows to Governor Shelby:

"Sir, after my best Respts to your Excellency and famyly, I wish to inform you that I have sum intention of undertaking this New Rode that is to be cut through the Wilderness, and I think my Self intitled to the ofer of the Bisness as I first Marked out that Rode in March 1775 and Never rec'd anything for my trubel and Sepose I am no Statesman I am a Woodsman and think my Self as Capable of Marking and Cutting that Rode as any other man. Sir if you think with Me I would thank you to wright me a line by the post the first oportuneaty and he Will Lodge it at Mr. John Milers on hinkston fork as I wish to know Where and when it is to be Laat [let] so that I may atend at the time I am Deer Sir your very omble sarvent.

"DANIEL BOONE."

But, alas, the contract was given to others, to Boone's great disappointment. Such was the experience of the first American "engineer" who took it into his head to "go into contracting." How many have been the similar experiences of his successors the record does not state.

The mountains crossed, progress of exploration westward was rapid after the Revolution. The pioneers opened the trails and the Army followed close behind, establishing forts for the protection of travelers and settlers against Indian attack. The "road building" that was an incident of the advance of those brave and adventurous spirits, however, was invariably of the sort already described; that is, a mere breaking and blazing of trails in the difficult places, and, in the open country, only the choosing of a path which by continued use was worn into a well-marked route.

For the opening of certain of these routes, Congress, which under the Constitution was given the right to govern the territories, was urged to contribute money, and did actually contribute to a few, among them the famous Natchez Trace which ran from Nashville, Tenn., to Natchez, Miss., and Zane's Trace in Ohio. The character of the work done on the former is indicated by the fact that the appropriation was $6 000.

Of similar character were the great trails of the West, on which exploration began early in the Nineteenth Century. In all the annals of America there are no more thrilling passages than the records of the travels and the path-finding of the pioneers who, following the Santa Fé, the Overland, and the Oregon Trails, settled and held for the United States the great dominions of the West. The highways they marked out were so truly remarkable that they are still, in the main, the principal routes of travel in the territories they traverse. One of them—the Oregon Trail—has been described as:

"The most remarkable road known to history * * *. Considering the fact that it originated with the spontaneous use of travelers; that no transit ever located a foot of it; that no level established its grades; that no engineer sought out the fords or built any bridges or surveyed the mountain passes, that there was no grading to speak of, nor any attempt at metalling the road bed; and the general good quality of these two thousand miles of highway will seem most extraordinary."

Early Turnpike Ventures

It will not be possible, however, in this paper to follow the development of the routes of exploration westward. The principal object being the study of the development of road construction methods, the writer must return to the Eastern States, where, immediately after the close of the Revolution, the first great movement for the betterment of American roads was at its inception—the establishment of the turnpikes.

The first American turnpikes of which there is record were established in Virginia, Connecticut, and Maryland. From the interesting book by Frederic J. Wood entitled "The Turnpikes of New England", it is learned that Virginia led the way by the erection of gates on the roads leading into Alexandria from Snigger's and Vesta's Gaps. The travel on these roads had become so heavy that extensive repairs were imperative and, the resources of the territory traversed being inadequate, it was proposed to set up toll-gates as a means of collecting the necessary revenues, an idea suggested, no doubt, by the English experience with turnpike trusts which had been in operation for at least twenty years previously. The Act of the

Legislature providing for the erection of the turnpikes was passed in 1785, and, as an existing road was taken over and the only construction necessary was the erection of the gates, it is safe to say that they were in operation by 1786.

A heavy travel passed over this road for several years, and the tolls imposed by the Legislature were insufficient to maintain its surface. Accordingly, in 1795, representations were made to the Legislature that "an artificial bed of pounded or broken stone" was necessary, and that the expense of this, being too great to be financed by the usual methods, it should only be assumed by private enterprise. This is the first reference the writer has been able to find to any form of construction resembling what is now classed, very loosely, as a macadam surface. It is probable that stone and gravel surfaces had been laid in England for some years previously, and there may have been some more or less unsystematic use of stone in America also at an earlier date; but it is reasonably certain that this Virginia road was at least one of the earliest to be deliberately planned as a stone-surfaced highway. As a result of the representations made, the "Fairfax and Loudon turnpike-road company" was incorporated on December 26, 1795, and given the privilege of reconstructing the old turnpike from "Little River, where the present turnpike crosses it, to Alexandria." The first company finding the task too great, nothing was accomplished under its charter, and, in 1802, a new charter was granted to the "President, Directors, and Company of the Little River Turnpike Company." Under this charter, with the help of the State of Virginia, which appropriated the "muster fines" in 1805 to the purchase of 100 shares of stock, the old road was rebuilt and operated as a toll road for more than ninety years.

The second and third turnpikes were in Connecticut where, in 1792, the Mohegan Road, between New London and Norwich, and the Old Post Road, in Greenwich, were made subject to toll. A year later, in 1793, a gate was set up on the Reisterstown Road, in Maryland and, later, other gates were established on the York and Frederick Roads near Baltimore. These Maryland cases were followed, in 1801, by the establishment of a gate on the old road through Cumberland Gap, in Tennessee; and, in 1804, North Carolina provided for the construction of a 14-mile road through the Cherokee lands by granting to the builder the privilege of collecting tolls for fifteen years. All these were Government enterprises, and they are the only exceptions to the practice, which was shortly to become general, of allowing the turnpikes to be built by private capital. Later, these, too, were transferred to private companies, but the first road to be built in this manner was the famous Lancaster Turnpike, in Pennsylvania, which was built by the Philadelphia and Lancaster Turnpike Company, incorporated by the Governor on April 9, 1792. This road which was more than 62 miles in length, was built at a cost of $7 450 per mile and was finally completed in 1796.

Following this example similar corporations were created in rapid succession in all the States, and in his report to Congress, in 1808, Albert Gallatin,

the Secretary of the Treasury, was able to report definitely that 770 miles were completed in Connecticut, more than 3 000 miles were under construction or completed in New York, and hundreds of miles in other States.

The Character of Early Turnpikes

This same report of Gallatin's gives the first detailed description of the character of the "artificial roads" built by the early turnpike companies.

Referring to the road from Trenton to Brunswick, in New Jersey, he reports that:

"The distance is twenty-five miles; the greatest angle of ascent, three degrees; and the road is nearly in a straight line, the only considerable obstruction being the 'sand hills', through which it was necessary to dig at the depth of thirty feet, in order not to exceed the angle of ascent. The road is thirty-six feet wide, fifteen feet of which are covered with about six inches of gravel. A few wooden bridges, with stone abutments, and piers have been erected across the intervening streams. The whole expense is stated at $2 500 a mile."

On the road in Pennsylvania from Philadelphia to Perkiomen, which had two branches to Willow Grove and Chestnut Hill, he wrote:

"The distance * * * is twenty-five miles and a quarter; the two branches extend one ten miles, and the other seven miles and a half; making together near forty-three miles. The angle of ascent is four degrees; the breadth of the road fifty feet, of which twenty-eight feet, having a convexity of fifteen inches, are covered with a stratum either of gravel eighteen inches thick, or of pounded stones twelve inches thick. One-half of the stones forming the lower part of the stratum are broken into pieces not more than five inches in diameter; the other half or upper stratum consists of stones broken into pieces not more than two inches and a half in diameter, and this difference in the size of the stones is represented as a considerable defect. Side or summer roads extend on each side of the gravel or stone road. The five miles next to Philadelphia have cost at the rate of $14 517 a mile; the other twenty miles and a half at the rate of $10 490 a mile. Yet there were no natural impediments, and only small bridges or culverts were necessary. The capital expended on these twenty-five miles and a half is $285 000; the tolls amount to $19 000; the annual repairs and expenses to $10 000; the net income to about $9 000, or a little more than three per cent. on the capital expended."

Among Maryland roads he notes the Reisterstown Turnpike, 24 ft. wide and surfaced with 12 in. of pounded stone not more than 3 in. in diameter; the Frederick Road, 22 ft. wide and surfaced with 10 in. of pounded stone not more than 3 in. in diameter, over which were spread 2 in. of gravel or coarse sand, the entire surface having a crown or convexity of 9 in.

South of the Potomac Gallatin reports that few "artificial roads" had been undertaken. One, which he briefly describes—the road from Manchester to the coal mines of Falling Creek, in Virginia—was 36 ft. wide and graveled and the cost of 12 miles he gave as $50 000. This construction, he reports, was sufficiently substantial to admit wagons carrying 4 tons.

"The greater progress made in the improvement of roads in the northern parts of the Union," he ascribes, "to a more compact population, which renders those improvements more necessary, and at the same time supplies with greater facility the means of effecting them. The same difference is perceptible in the number of bridges erected in the several States."

In this famous report is direct evidence of the construction, prior to 1808, of roads surfaced with both gravel and broken stone. The Philadelphia-Perkiomen Road was constructed of a stone surface in two courses in a manner similar, except for the large size of the stone and the heavy crown and the absence of rolling and sprinkling, to the methods used in building modern macadam roads. Wherein lay the "defect" of using two courses, as mentioned in the report, is not made clear.

MacAdam's Principles

It is not to be assumed, however, that these roads embodied in their construction the principles of MacAdam; nor can it truthfully be stated that present roads do. They were probably patterned after the roads then being constructed in England, and the great road builder, whose name is now associated with any form of stone surface, had not yet demonstrated the particular methods which properly should be attributed to him. He was still engaged in the preparatory studies which led to the development of the methods he first applied when he became the Surveyor of Roads in Bristol in 1816.

According to MacAdam's view, the function of the stone surface was not to support the weight of vehicles, but to form a covering or roof over the natural soil on which, in its dry condition, he relied entirely to support the load.

He, therefore, regarded a heavy course of metal as unnecessary, and large stone as positively objectionable in that a road so formed would be likely to be more pervious than one made of small stone. His idea was that, "every piece of stone put into a road, which exceeds an inch in any of its dimensions, is mischievous"; and he based this conclusion not only on the thought that the use of larger stone would increase permeability, but, also, and perhaps mainly, on the greater tendency for the larger stones to be dislodged by the wheels of vehicles. He was also opposed to the use of heavy crowns on the ground that they were unnecessary for drainage purposes and that they tended to concentrate traffic at the center and, thereby, actually defeat the ends of drainage by causing the formation of ruts.

His methods, explained in his own words, were as follows:

"As no artificial road can ever be made so good, and so useful as the natural soil in a *dry state*. it is only necessary to procure and preserve this dry state of so much ground as is intended to be occupied by a road.

"The first operation in making a road should be the reverse of digging a trench. The road should not be sunk below, but rather raised above, the ordinary level of the adjacent ground; care should at any rate be taken that there be a sufficient fall to take off the water, so that it should always be some inches below the level of the ground upon which the road is intended to be placed: this must be done, either by making the drains to lower ground, or if that be not practicable, from the nature of the country, then the soil upon which the road is proposed to be laid, must be raised by addition, so as to be some inches above the level of the water.

"Having secured the soil from *under* water, the road-maker is next to secure it from rain water, by a solid road, made of clean, dry stone, or flint, so selected, prepared, and laid, as to be perfectly impervious to water; and

this cannot be effected, unless the greatest care be taken, that no earth, clay, chalk, or other matter, that will hold or conduct water, be mixed with the broken stone; which must be so prepared and laid, as to unite by its own angles into a firm, compact, impenetrable body.

"The thickness of such a road is immaterial, as to its strength for carrying weight; this object is already obtained by providing a dry surface, over which the road is to be placed as a covering, or roof, to preserve it in that state: experience having shewn, that if water passes through a road, and fills the native soil, the road, whatever may be its thickness, loses its support, and goes to pieces."

It must be borne in mind that MacAdam applied his art more often to the repair of existing surfaces than to the construction of new ones, and in making such repairs he particularly recommended and used the process which he called "lifting the road" which consisted in loosening the upper portion of the surface and breaking all old stones of more than about 6 oz. in weight before applying the new stone. As he did not have a roller he advocated applying the new stones in thin courses, allowing time between successive applications for the metal to be compacted by traffic. He suggested a three-time application as desirable and particularly insisted on the necessity of keeping the road well shaped during the intervals when it was being compacted.

He surprised the members of the Parliamentary Committee appointed to inquire into methods of improving the turnpikes and highways by informing them that he would prefer to construct his surface on a soft foundation rather than a hard one, because "when a road is placed upon a hard substance, such as a rock, the road wears much sooner than when placed on a soft substance".

This statement elicited from his amazed interlocutor the exclamation: "You don't mean you would prefer a bog?" to which the calm reply was; "If it was not such a bog as would not allow a man to walk over, I should prefer it."

With these views, so remarkably in accord with the most modern ideas, there is scarcely a fault to be found, yet the fact remains that they have been honored more in the breach than in the observance in American practice, at least.

As MacAdam did not begin to practice his art until 1816 and as his methods were essentially different from those common at the time in England, it is not possible that the stone surfaces constructed on the fast multiplying American turnpike roads prior to that date were macadam roads in the strict application of the term, although, from the descriptions available, it is probable that they were not unlike many of the roads to which the name is now applied.

When, in 1832, it became necessary to repair the surface which had been constructed on the Cumberland Road east of the Ohio River, the orders of General Gratiot, then Chief of Engineers, were that the macadam system was to be followed, and this system he defined exactly as MacAdam had described it in his "Remarks on the Present System of Road Making", published in 1820. It is not improbable that this was the first application of the true method in America, and it may have been the last.

The National Pike

The story of the National Pike has been told too many times to need more than a brief reference herein. The earliest Act of Congress relating to it was passed in 1802 and simply provided that 5% of the revenue received from the sale of Ohio lands should be set aside for public road improvement and that two-fifths of this amount should be devoted to constructing a road from the Potomac River westward to the Ohio River.

In 1805, the building of the road from Cumberland, Md., to the Ohio River was authorized, and the Act further provided that the proposed road was to have a right of way of 4 rods, a roadway of 20 ft., a maximum grade of 8¾%, and a surface of stone, earth, gravel, or sand, or a combination of these. Later, in Ohio, the width of right of way was increased to 80 ft.

The first contract for construction was let on April 11, 1811, and the road was completed from Cumberland to Wheeling, W. Va., about ten years later. The total length of this section is 131 miles and the total cost of construction was $1 706 845, or an average of $13 029 per mile. The entire section east of Wheeling was surfaced with broken stone put down in two courses. The specifications provided that the stone for the bottom course should pass a 7-in. ring, and that for the top course, a 3-in. ring. The top course was 6 in., and the bottom, 12 in., before compacting, and as the traffic was depended upon to effect the compacting, there is little doubt that travel over the road in springless wagons was not unduly comfortable, especially as it is said that the engineers in charge of the work had a way of erecting barriers which were frequently shifted in order to prevent honest travelers from using any part of the surface after it had become compact.

The first appropriation for continuing the "National Road" west of the Ohio River was made in 1825, and the final appropriation for completing it in Ohio and continuing it in Indiana and Illinois was made in 1838. The section in Indiana was constructed east and west from Indianapolis, and was practically completed before the Government discontinued its appropriations, but in Illinois no surfacing was laid. Congress provided that only grading should be done on this section, in order that the Government might later put down a steam railroad on the grade if it so desired.

Turnpike Companies the First Public Service Corporations

The turnpike-road companies, by which the majority of the early artificial roads were built, were the first public service corporations. They operated under charters granted by the State Legislatures, authorizing them either to build and maintain an entirely new road or to take over from the public the maintenance of an existing road.

What now seem to be very severe restrictions were imposed upon them. They were limited strictly to the building and maintaining of a road, and were not allowed to do anything else. Rates of toll were fixed in the charter, and the number of gates to be erected was also specified. The location of the road was not entrusted to the judgment of those who were investing their

money, but was delegated to a committee appointed either by the Legislature or by the Judge of the County Court.

In spite of these restrictions the stock of the companies at first was very attractive to investors; but it was not long before it was discovered that the roads could not be expected to pay a large return. Few of the companies were able to show, even at first, net earnings of more than 2 or 3%, and as time went on and the cost of maintenance increased, and as, finally, the railroad came to take away a large part of the traffic, even these small profits vanished, and the turnpikes became, generally, very unprofitable investments. Most of the hundreds of companies that were organized had failed and the roads had reverted to public control by 1850; but a few remained in operation, after a fashion, until very recent years, their roads anathema to all who were compelled to use them.

The word "turnpike" has come to be associated with a stone surface, mainly because the surviving "pikes" were all, or practically all, of that character. In the early days, however, many of the companies, perhaps the majority, built only a graded road. On many roads the surface was of gravel, in others, shell, and in some, in order to make the roads passable, the companies resorted to corduroy. Quite a large number, as will be noted later, were incorporated for the special purpose of building plank roads.

The railroads sounded the knell of the turnpike companies. One by one they came on financial difficulties so great as to cause them to give up their charters, until, by 1850, few were left in existence. With their passing the roads reverted to public control—which meant county control—and so out of the picture until the late Eighties, except for the rather curious vogue of the plank road.

The Plank Road Epidemic

The first plank road on the continent, and probably in the world, was laid at Toronto, Ont., Canada, in 1835-36. The originator is believed to have been Dr. Darcy Boulton. About ten years later, a road was built, in all respects like the Toronto example, at Syracuse, N. Y. This was probably the first road of its kind in the United States. Within four years more than 2 000 miles had been constructed in New York State alone, at an average cost of $1 833 per mile. Several were built, also, in New Jersey, and a number in Vermont and Connecticut. At least one was built in Massachusetts. These, so far as the record goes, were the only Eastern developments; but the idea spread to the interior States and there the planked surfaces may still be found occasionally.

Of the construction of the plank roads, Mr. Frederic Wood,* writes as follows:

"They were in nearly all cases of single track, laid on the right side of the road as one faced the large town to which it led. In the prairie regions the planking lay on the original surface of the ground, but in some places a small amount of grading was needed to avoid short, steep ascents. The sub-

* See also "The History, Structure, and Statistics of Plank Roads," published in 1850, by W. Kingsford.

grade once established, longitudinal trenches were dug in which sills consisting of 3-inch plank four and eight inches wide were placed, and on them were laid the planks, three inches thick and eight feet long, at right angles to the direction of the road. The sills were set slightly below the surface of the ground, and the planks were pounded down to rest upon them by means of a large mallet known as a 'commander'. No nails or pins were then needed to hold the planks down, and it is reported that it was hard work to take one of them up. After the planks were laid the earth was packed against their ends and soundly tamped into place. The portion of the highway not occupied by the plank road was usually maintained as a common dirt road and was locally known as the 'turn-off', because light loads had to leave the planks and follow it when passing a team proceeding the other way. In order that a wagon might regain the planked surface without its wheels sliding along the edges, the planks were staggered, that is, one-half of them had their ends in a straight line with each other, while the other half were alternately advanced to a line six inches farther out, producing a border effect like the battlements of a castle. Ordinarily, two stringers were used but occasionally three. Over the completed planking a layer of sand was spread and maintained, which preserved the road by reducing the cutting by the calks of the horseshoes. It was claimed for this coating that a saving of forty to fifty per cent was secured in the wear of the road. Very few double-track roads were ever laid, and in the few cases it was preferred to lay two single tracks, apart from each other and supposedly on opposite sides of the 'turnout'.

"Yellow pine was preferred for the planking in Central New York, on account of its durability and freedom from knots, but hemlock and white pine were extensively used while beech, maple, and elm were employed in some places. * * * Of course the planks would rapidly decay, and it was considered necessary to figure that a road would have to be rebuilt at the end of every seven years."

The Development of Modern Types of Pavement

Passing immediately to the later Eighties no development of any importance will be missed so far as the highways are concerned, except the inventions of the stone crusher by Blake in 1858 and of the steam road roller by Lemoine in 1859. The former, at least, was apparently not received with enthusiasm, because the author of a prize-winning essay wrote in 1890 that:

"Hand-broken stone is much superior to that crushed by a machine, which is generally of irregular shape and seldom cubical, so that it does not readily bind together, which is the essential qualification of macadam."

Some time during this period, probably after 1876, the third, or binder, course was added to the macadam process. In his book entitled "A Practical Treatise on Roads, Streets, and Pavements", published in 1876, the late Q. A. Gillmore, M. Am. Soc. C. E., makes no reference to it, except as a top dressing of gravel or earth spread on after the rolling of the last application of stone. This is the method practiced even in MacAdam's day of which he strongly disapproved. The consolidation of the road with stone chips flushed and rolled into the surface was apparently unknown to Gillmore when the first edition of his book was printed; but some time between 1876 and 1890 it became the common practice.

It was during the latter part of this same period (1850-90) that the first brick and sheet asphalt surfaces were laid; the brick in Charleston, W. Va.,

in 1872, and the first extensive sheet asphalt surface on Pennsylvania Avenue, in Washington, D. C., in 1879. Prior to 1879 the first rock asphalt surface had been laid opposite the City Hall in Newark, N. J. This was in 1870; and there are conflicting claims to priority in the construction of short experimental sections of sheet asphalt, one being that the first section was laid in New York in 1873 and the other that it was in Washington Square, Newark, in 1877. For many years, however, construction of both the brick and asphalt surfaces was confined to cities. Until 1890, at least, the only materials generally considered as practical for surfaces of rural highways were broken stone, gravel, and—where the materials were available—shell and slag. The latter were laid in the same manner as gravel and stone. The plank surface was already condemned. Surfaces of "burnt clay"* had been suggested, but were still untried.

The organization of the League of American Wheelmen in 1880 may probably be considered as the turning point marking the beginning of the modern period of highway improvement, and the League itself as the first of the influences which have led to so great a change in the public attitude. One of the principal objects of the organization was to secure better roads, and it worked energetically to attain its purpose; but it was not until eleven years later that the first tangible result of its efforts was accomplished in the passage of the first State Aid Law in New Jersey. Writing in 1889, Jeremiah W. Jenks† pictures the condition existing at that time when he states that:

"A very large proportion of our people, too, have never seen a really good road for hauling purposes, and have, in consequence, no clear idea of the gain that would come from good roads."

The Renewal of State and Federal Participation

The passage of the New Jersey State aid legislation in 1891 was the first practical step taken, anywhere in the United States, to remedy the situation. With one exception, it was also the first instance in which any State had undertaken to participate directly in the construction of roads. The exception is Kentucky, which had a State Highway Department and a well-defined State road policy from 1821 to 1837, and during that period completed upward of 340 miles of roads.

The next fruit of the League's efforts is found in the establishment of the United States Office of Road Inquiry in accordance with an Act of Congress approved March 3, 1893. The purpose of this Office, as defined in the statute, was to make inquiries in regard to systems of road management throughout the United States; to make investigations in regard to the best methods of road making; to prepare publications, and to assist agricultural colleges and experiment stations in disseminating information, on the subject. The appropriation made for this purpose was $10 000.

It will thus be seen that the renewed participation of the Federal Government after a lapse of fifty-five years was limited to activities of an educa-

* "Road Making and Maintenance," by Charles Punchard, published with other essays in "A Move for Better Roads," Univ. of Pennsylvania Press, 1891.

† "Road Legislation for the American State," by Jeremiah W. Jenks.

tional character, but these it must be said were carried on with excellent judgment and the utmost vigor possible with the meager appropriation provided.

The actual construction of the roads being still under the control of county and township authorities, the Federal Office carried its message directly to these local officials and by actual demonstration on short sections of object-lesson roads in every State, taught them the methods of road construction which, from its studies, it found to be best. The general public it reached through the medium of bulletins, lectures, and good roads trains, and there is no doubt that its urging was responsible for the creation of more than one of the early State highway departments.

Following the New Jersey precedent, laws providing for the establishment of such departments and the granting of State aid were passed in Massachusetts in 1892, in California and Connecticut in 1895, and in Maryland, New York, and Vermont in 1898. Thus, by the end of the Nineties there were seven States—all but one on the Atlantic seaboard—that had taken the initial step toward the solution of the road problem; and as the century opened they were followed by many others. The dates of passage of the first laws in the several States are shown in Table 1.

TABLE 1.—Dates of Passage of State-Aid Highway Laws.

State.	Year in which first State-aid law was passed.	State.	Year in which first State-aid law was passed.
Alabama	1911	Nevada	1911
Arizona	1909	New Hampshire	1903
Arkansas	1913	New Jersey	1891
California	1895	New Mexico	1909
Colorado	1909	New York	1898
Connecticut	1895	North Carolina	1901
Delaware	1903	North Dakota	1909
Florida	1915	Ohio	1904
Georgia	1908	Oklahoma	1911
Idaho	1905	Oregon	1913
Illinois	1905	Pennsylvania	1903
Indiana	1917	Rhode Island	1902
Iowa	1904	South Carolina	1917
Kansas	1911	South Dakota	1911
Kentucky	1912	Tennessee	1915
Louisiana	1910	Texas	1917
Maine	1901	Utah	1909
Maryland	1898	Vermont	1898
Massachusetts	1892	Virginia	1906
Michigan	1905	Washington	1905
Minnesota	1905	West Virginia	1909
Mississippi	1915	Wisconsin	1911
Missouri	1907	Wyoming	1911
Montana	1913	....	....
Nebraska	1911	....	....

The State-aid policy as adopted by the various States took a number of forms. In some States the aid offered consisted only of advice which might be accepted or rejected by the local authorities who retained absolute control over all the roads. In such States no financial aid was extended. In those States which provided for financial aid its acceptance generally implied an agreement on the part of the county to accept the supervision of the State

authorities until the work of construction was completed, after which the road reverted to full county control. In still other States the joint participation of the State and county in the construction of certain classes of roads, generally the most important ones, was made mandatory; and there were still other variations which differentiated the systems adopted by the various States.

Road Conditions in 1904

While the pioneer States were making this radical departure from long established methods of highway administration, certain seemingly unimportant and unrelated events were occurring in various parts of the country. Three men—whose names were Duryea, Haynes, and Ford—had made themselves horseless carriages; and in Bellefontaine, Ohio, a road had been built entirely of concrete. Concrete had been used as a base for block and sheet asphalt pavements for many years; but the short section built in 1893 in the Ohio city was the first to be built with concrete as the wearing surface. As with brick and asphalt surfaces, it was several years, however, before use of the new type was extended to the rural highways; and the same may be said of the automobiles. Although their numbers increased remarkably in the cities, it was several years before they became a problem to the rural highway builder.

In 1904, the U. S. Office of Public Roads, lineal descendant of the U. S. Office of Road Inquiry, took the first census of American roads. It found that there were then, in the United States, 2 151 570 miles of rural highways, of which 153 662 miles had been surfaced with various materials. Of these surfaced roads, 38 622 miles were improved with water-bound macadam; 114 899 miles with gravel, sand-clay, shell, plank, and other low-type surfaces (the great majority being gravel); and 141 miles with surfaces better than macadam. The last included 123 miles paved with brick, of which 104 miles were in the two States of Ohio and West Virginia, and 18 miles of bituminous roads, of which 2 miles were in Massachusetts and the other 16 in Ohio. Except for the oiled earth roads, of which more than 2 500 miles (included with the gravel and other low-type improvements in the previous classification) had been built in California by the so-called petrolithic process, these 18 miles were the only representatives, in 1904, of a type which was destined shortly to become exceedingly important. Sheet and rock asphalt surfaces had been laid in the cities since the Seventies, and both bituminous macadam and bituminous concrete surfaces had been built in England before 1890, but the only bituminous surfaces to be found anywhere in the United States in 1904 were 2 miles of tarred road in the Town of Tisbury, Mass., and 13 miles of bituminous macadam and 3 miles of asphalt in Ohio.

Modern Progress in Its First Decade

This year—1904—marks the end of a period. To that time there had been no important change in the methods of road construction that had been used for a century or more. Either of the major types of surfacing—gravel and macadam—was known to give entire satisfaction under the traffic normal to the country roads of the time. The other types that had been

developed and used in small mileage, such as the shell roads of the Tidewater States and the sand-clay roads of the South, were suggested by the availability of the materials rather than by any difference in the demands of the traffic that used them.

Viewed broadly the few types of surface constructed up to this time may all be considered as of one class. In the construction of all, the same principles governed; in all, a fragmental mass was bound together more or less firmly by a natural cement in the manner made familiar by a century of practice; and all alike depended for their efficiency on the conic principle of pressure transmission by which they spread the vehicular loads and thus reduced the intensity of pressure borne by the sub-grade.

That need was felt for no other kind of construction was due, of course, to the fact that the traffic on all roads was much the same. Even in the more populous States the greater part of the traffic using the roads consisted of relatively light, horse-drawn, steel-tired vehicles, to which were added near the cities a bicycle traffic which, although it might attain considerable volume, was never more than a negligible factor in determining the type of surface. This was the normal traffic condition which existed practically up to 1904. What makes that year a turning point in highway history is the fact that about that time there began the great outpouring of motor vehicles from the cities, which quickly set the inter-city roads apart from others as a class requiring different treatment.

The peculiar effect of the automobile on water-bound macadam roads is so well known as to require no description, and the manner in which the road builders met the challenge by substituting tars and asphalts for the weaker mineral binders has been an oft-told tale. First as dust layers, then as protective surface coatings, then as binders, introduced into roads of the macadam type by penetration, and, finally, as hot admixtures according to the bituminous concrete principle, these materials, borrowed from the stock in trade of the city street builder, solved the automobile problem in a manner that was apparently entirely satisfactory.

The effect of this development in the road-building art is shown by comparison of the statistics of 1904 and 1914, the dates which, to all intents and purposes, mark the beginning and crest of the wave of bituminous construction. In 1904, according to the records, there were in the entire country only 18 miles of bituminous rural roads, all in the two States of Massachusetts and Ohio. By 1914 there were 10 500 miles, a mileage which was nearly three-quarters of the aggregate length of all roads of higher type than macadam. This was the high-water mark of the lower forms of the bituminous types. That it by no means marked the end of their usefulness is indicated by the fact that 3 367 miles of the surface-treated and penetration types were built in 1924. The recession of the tide is indicated, however, by the fact that the mileage of the two types existing in 1924 was less than 50% of the mileage of all types better than water-bound macadam in comparison with the 75% level reached in 1914.

It is generally recognized that these two types, which came into use with the development of passenger automobile traffic, are especially adapted to that class of traffic. The relative decline in their use began when motor trucks in considerable numbers began to appear on the rural highways; and coincidentally an increasing swing toward the rigid pavements of concrete and brick and bituminous concrete on a concrete base is noted. The turning point was reached in 1914, or perhaps a year or two earlier.

Although the first concrete road had been built in 1893, there were no more than 5 miles of that type on rural highways in the entire country in 1909. In that year approximately 4 miles were built; in 1910, about 20 miles were added; the following year, 40 miles; and then the first big increase occurred in 1912, when more than 250 miles of rural highways were paved, to be followed in 1913 with 500 miles and in 1914 with more than 1 500 miles. At the close of 1914 there were 2 348 miles in the entire country; and 10 years later the mileage had increased to 31 146 and construction was proceeding at the rate of more than 6 000 miles per year, a rate approached by no other type better than gravel.

The more extensive use of brick, and of bituminous pavements of the mixed type on concrete base, began also at about the same time and was due to the same cause—the increased use of motor trucks. In 1914 there were approximately 1 600 miles of brick pavement; in 1924, there were 4 319 miles. In 1914 the mileage of rural highways paved with bituminous concrete or sheet asphalt was still negligible; in 1924, there were more than 9 700 miles of these types.

Trunk Lines versus Farm-to-Market Roads

The decade following 1904 was marked not only by the development of new types of road, but also by two other changes of even greater significance. The first of these was a general increase in the radius of travel by highway occasioned by the use of the automobile; and the second—the natural result of the first—was a change in the character of the public demand for highway improvement.

In 1904, the automobile had still to prove its ability for sustained performance. Its ownership was still limited to a small and wealthy class. The popular demand for improved roads was, therefore, still predicated on the use of the bicycle and the horse-drawn vehicle. The farmers, always conservative, were still, for the most part, either actively hostile to road improvement or lukewarm in support of it. In general, their demand was for the improvement of the roads connecting their farms with the railroad shipping points or near-by towns. More positive influence was exerted by city and town merchants who sought by road improvement to extend the trading radius and business of their towns, and by the limited but influential class of motorists who longed for smoother, mud-and-dust-free roads on which to operate their vehicles. All these influences combined at first to produce a demand for short stretches of improved roads radiating from the towns and rail shipping points. Later, as the automobile was perfected and its users

became more numerous, the latter created a demand for longer, unbroken stretches of improved roads, forming a network connecting the larger towns, a claim that was resisted by the farmers who continued to favor the so-called farm-to-market type of movement.

In the smaller Eastern States the conflict never became acute, largely because the distance between towns and market points was so short that the farm-to-market plan of improvement, when carried to its ultimate development, became practically identical with the inter-town or trunk-line plan. Thus, the issue was satisfactorily settled in Rhode Island as early as 1902 by the adoption of a definite system of State highways for construction by the State Board of Public Roads. A similar proposal by the Highway Commissioner of Connecticut, made originally in 1906, was enacted into law by the State Legislature in 1913; and, in the meantime, Maryland had settled the question definitely by the adoption of an inter-county seat, trunk-line system to be improved and maintained in its entirety with State funds under the State Roads Commission. Maryland's system was designated in 1908, and was the first to be placed completely under State control for both construction and maintenance.

That the controversy was not so quickly settled in many of the other States was due mainly to two reasons: First, the important lines of travel in a number of the States were not sharply defined. In some this resulted from sparsity of settlement, and in others from the contrary condition of close settlement with numerous centers of more or less uniform size and importance. States, such as Texas and Wyoming, were typical of the first group. In them, the long distances between centers and the condition of the roads delayed the development of highway traffic between the towns and promoted a use of the highways largely as feeders to the rail lines; and the same remoteness of the towns one from another prevented the early harmonizing of the two plans of development as in the smaller Eastern States by the evolution of one into the other. Of the second class there were such States as Iowa, Kansas, and Wisconsin, in which the very number and uniform size of the town centers caused a diffusion of traffic over many roads and delayed the recognition of routes of outstanding importance. In these States, also, the towns are essentially agricultural centers, and this fact contributed further strength to the demand for farm-to-market roads as opposed to trunk lines.

The Federal Aid Road Act

The instances mentioned furnish examples of one of the reasons for the prolongation of the controversy which raged over the question of farm-to-market *versus* trunk-line development. The second reason was simply that many of the States as yet had no State agency for the administration of a highway plan of State-wide scope, and the development of the trunk-line plan naturally presupposes the existence of such an agency.

The second of these reasons was promptly removed after the passage of the Federal Aid Road Act in 1916 by the provision of that Act requiring the

creation of adequate highway departments in all States as a condition precedent to participation in the benefits of the Federal aid.

The Act of 1916 appropriated $75 000 000 to be expended in five years under the direction of the Secretary of Agriculture in co-operation with the State highway departments, for the improvement of post roads. It provided for the apportionment of the appropriation among the several States in proportion to their area, population, and mileage of post roads; and it permitted the expenditure of Federal funds for improvement in any amount up to 50% of the cost, but not exceeding $10 000 per mile. This latter limit was later raised to $20 000 and then reduced to $15 000 as at present.

Since 1916, amendments have been made to the Federal Aid Road Act appropriating, or authorizing the appropriation of, additional funds to a total, including the fiscal year, 1927, of $690 000 000; and the mileage of road improved under the co-operative plan up to June 30, 1926, amounted to nearly 56 000.

A first step toward the ultimate settlement of the trunk-line question in all States was made when the U. S. Bureau of Public Roads, acting for the Secretary of Agriculture, as one of its first administrative acts requested of all States the submission of a 5-year program map showing the system of roads on which the State highway departments would request Federal aid during the period covered by the appropriations provided by the first Act of Congress. Although the systems designated in response to this request were understood to be merely tentative, the request of the Bureau had the effect of directing attention—in many States for the first time—to the desirability of establishing a definite program for the improvement of a system of highways as distinguished from the more or less casual improvement of unrelated sections of roads.

Load Limitation a Consequence of the World War

The Federal aid work had scarcely begun, however, when the World War intervened and practically put a stop to all operations; and the war did a number of other things to the existing improved roads which, however disastrous they may have appeared at the time, have turned out to be blessings in disguise. At the outset the construction and maintenance of highways were declared to constitute a non-essential industry. As a consequence new construction, except as required for the immediate service of the Army, was greatly curtailed. Maintenance also was greatly hampered by the difficulty of obtaining the necessary materials and the scarcity and high wages of labor. At the same time there was released upon roads generally inadequate to stand it an unprecedented traffic of heavy motor trucks. To this experience and the heavy damage which followed, the public owes the development of most of the sound principles and policies which now govern the improvement of highways.

The first result was a strong reaction against the use of heavy motor trucks. There were large numbers of people who, forgetting that a road is of service only in so far as it accommodates the need for economical transporta-

tion, demanded that the manufacture and operation of vehicles too heavy for the existing roads be prohibited. As few of the roads were designed to carry motor-truck traffic, to have taken this course would have amounted to the throttling of a new development in transportation before it had a chance to demonstrate its utility, and it was rightly opposed with great energy by the manufacturers of motor vehicles. The latter, on the other hand, took a position at the opposite extreme from which they demanded the right to manufacture and sell vehicles of large capacity and heavy weight, without regard to the strength of the roads, on the theory that the greater the capacity of the vehicle the smaller would be the cost of operation per unit of capacity. Their slogan was, "build the roads to carry loads", and this was met by the opposite party with the equally dogmatic demand that the loads should be limited to the capacity of the existing roads.

The issue thus joined, the principals to the controversy—highway officials on the one side and the manufacturers on the other—wisely agreed to submit their differences to the test of mutual discussion; and out of the series of conferences that ensued there came an agreement on certain fundamental facts and principles, which has served as the basis for a harmonious co-operation of the two groups, and which now constitutes the foundations of highway improvement policy in all States.

It was agreed at the outset that, for the first time in history, the weight of vehicles had become a critical factor in rural highway design. Hitherto, the minimum practical thickness of road metal had been sufficient to carry the maximum vehicular load. The development of the motor truck had altered this situation. It called for stronger surfaces that would spread its heavier load over a wider area of the sub-grade in order to reduce the intensity of the pressure to an amount that the soil could support.

It was clear also that whereas deterioration of the highways had previously resulted mainly from the attrition of the surface, a new form of deterioration approaching rapid destruction would result unless the roads on which the heavier motor trucks were being operated were strengthened so as to enable them to carry the increased weights; and whereas, the amount of the deterioration had formerly been a function of the volume of the traffic and of time, the new destruction by excessive weight might be caused by a few vehicles in a very short time.

It was agreed, therefore, that the highway officials must have definite knowledge of the maximum weight to be supported as a first condition of design; and this knowledge was supplied, in a measure, by the voluntary decision of the manufacturers to limit to 7½ tons capacity the future production of vehicles. Engineers were thus assured that if, in the reconstruction of the thoroughfares on which heavy trucking had developed, they would design to accommodate a vehicle of 7½ tons capacity they would not see their handiwork quickly destroyed by vehicles of much greater size and weight.

Differences Between Main Highways and Local Roads Accentuated

This alone, however, was not a sufficient basis for the design of all roads. The building of roads of sufficient strength to carry 7½-ton trucks required

a heavy investment of public funds, which could be justified only if the economies inherent in the transportation of goods in vehicles of large capacity were sufficient to outweigh the increased cost of the roads. It was recognized clearly for the first time that the cost of highway transportation is made up of the cost of the highways and the cost of operating the vehicles over the highways, and it was agreed that the common purpose of the public highway officials, vehicle manufacturers, and operators should be to reduce the total cost of transportation rather than one or the other of the elemental costs.

It could be proved that the number of trucks of large capacity already using some of the highways—principally those radiating from and connecting the larger cities—had already grown to the point where the combined savings in operating cost would more than balance the greater cost of providing highway service for them. As to these highways there could be little doubt of the wisdom and economy of building a type of surface adequate for the heavy truck traffic. Other roads, similarly located with respect to cities, had not yet developed a sufficient amount of the heavy traffic to repay the additional cost of the stronger construction, but it was not difficult to foresee that such a condition would develop in the future. On the majority of the roads, however, the development of traffic of sufficient weight to justify the higher types of construction was very remote; and it was apparent that the one-time prevailing condition of uniformity of traffic on all roads had been definitely broken down. Instead, a new and much different condition had arisen under which the main inter-city roads were found to be carrying traffic far in excess of the much greater mileage of local roads.

Under the new condition the economic justification for the improvement of the main roads lay to a far greater extent than formerly in the reduction of transportation costs and to a lesser degree in the effect on the value of property. The main roads had become through traffic arteries, as distinguished from the more numerous local roads, which continued to be of value primarily through the service they rendered in giving access to the land.

As to the main roads, which carried a wide-ranging traffic, it was now clearly apparent that the character of their improvement must be commensurate with the density of their traffic; that continuity of improvement was of the highest importance; and that the traffic was already so great that the loss in operation of vehicles in the absence of road improvement would exceed the cost of improvement. These roads also were distinguished in one other respect, namely, that their traffic tended to increase far more rapidly than that to be found on the local roads, the condition of which remained much as it had been. Where the main roads carried long-distance traffic, the local roads served the traffic of a neighborhood; where the main roads were collectors of traffic, the local roads were feeders and distributors; where the traffic of the main roads tended to grow in direct proportion to the growing use of motor vehicles and the growing resort of industry and the entire people to highway transportation, the local roads served the much lighter, and, from the standpoint of growth, the far more stable traffic produced by a single agricultural community.

It became apparent, therefore, that the economic justification of local road improvement would continue to rest largely in the value and importance of the land; that, in the main, the traffic would demand only a low type of improvement; and that continuity of the improvement was not so essential as in the case of the main, through roads.

The need of continuity in the improvement of the main roads was the first of the new conditions to be met with appropriate action. From 1915, all States in rapid succession designated systems of State roads, including generally the main inter-city roads, to be improved under the more or less direct supervision of the State highway departments; and the several State systems were substantially welded into a National network by the designation, in accordance with the Federal Highway Act of 1921, of the Federal aid highway system on which it is now required that all Federal appropriations shall be expended.

Economic Principles Enunciated

Continuity of improvement of the main roads thus being assured, it remained for a Joint Committee representing the American Association of State Highway Officials and the National Automobile Chamber of Commerce to enunciate a policy with respect to the rate and manner of the improvement, which could win general support and adoption.

Briefly, that policy may be stated as follows: It is accepted as a truism that the volume of traffic on the main roads is so great that the economies in transportation effected by road improvement clearly outweigh the cost of the improvement. This being true, the improvement should proceed as rapidly as available supplies of labor and material will permit and without other limit. All roads should be improved to the degree justified by the operating savings that may be expected to accrue to the traffic, and no road should be improved to any greater degree. Where the mileage of road to be improved is so great that the type of improvement indicated by the traffic can not be completed on the whole mileage within a short period the most important sections should be raised immediately to ultimate type, and the remainder of the mileage should be advanced through the initial stages of grading, draining, and low-type surfacing, in order to spread as much of the benefit of improvement as quickly as possible over the entire road system, further improvement to await the completion of the first stage over the whole system. This is known as stage construction, and it is the only feasible practice in the numerous States in which a large mileage of main roads remains to be improved in the face of a traffic already highly developed. It is also the logical plan of development for the main roads of the States in which traffic has not yet grown to the proportions justifying high type surfacing.

In any case the stage-construction plan takes account of the rapid growth of traffic, which is a characteristic especially of the main roads, by providing fully in the initial stage for the subsequent construction. Grades and alignments are designed to meet ultimate requirements; drainage structures are built of durable materials; rights of way of ample width for the future are

obtained; and the initial surfacing becomes the sub-base of the second-stage surfacing. Obviously the soundness of the plan is contingent on the complete and continuous maintenance of each stage of the construction, a kind of maintenance which—thanks to the war experience and the standard established by the Federal Highway Act—practically all States are now prepared to give.

The accepted policy contemplates the improvement of the main roads, to which these methods are applicable, as a responsibility of the States to be assumed through the agency of the State highway departments, and financed, in large measure, by the revenues derived from the taxation of vehicles and motor fuel. The local roads are viewed as the responsibility of the counties and lesser subdivisions. With a few important exceptions, as in the vicinity of large cities, the degree of improvement required does not rise above the lower types of surfacing, the expense of which may be met, as it should be, by taxation of the local land and property.

These, then, are the outstanding developments in highway improvement of the post-war period: The classification of highways according to traffic density; the designation of State highway systems in all States, the systems including the heavy traffic highways of State-wide importance; the interconnection of the State systems by means of the Federal Aid System; the improvement of roads in accordance with traffic demands to the limit set by probable operating savings; the stage-construction plan of progressive improvement of the entire system; and the development of adequate maintenance provisions. In the main, all are outgrowths of the war experience fostered by Federal aid.

Highway Research

One other great advance has characterized this period—the application of scientific research to the problem of developing types of construction and methods of administration and finance adequate to meet the demands of the fast-growing traffic. In this, also, the initial impulse came from the Federal Government, and, in co-operation with State highway departments and universities, it is continuing to support numerous studies in several fields, as a result of which there is being built up gradually the structure of a new science—the science of highway engineering.

The investigations include studies of the characteristics of materials—sand, stone, gravel, bituminous materials, cement, concrete, and brick; determination of the forces applied to road surfaces by standing and moving vehicles; of stresses developed in the structure of roads and bridges by live loads, by temperature, and by other natural causes; analyses of sub-grade soils and tests of methods designed for their improvement; and studies of the flow of water through drainage structures, of the run-off from drainage areas, of the effect of moisture on soils, and many others of fundamental importance and value.

Popular interest has centered on the large scale tests, such as those of the Bates Road, for which entire credit is due the Illinois Highway Department; the Pittsburg, Calif., experiments; the impact tests at Arlington, Va.; and

the intensive studies of highway traffic conducted by the U. S. Bureau of Public Roads in co-operation with the authorities of Connecticut, Maine, Pennsylvania, Ohio, California, Tennessee, and Cook County, Illinois.

Much that is of immediate practical benefit has already been derived from these investigations; but, for the most part, they are dedicated to the future. It is not to be expected that their fullest benefits shall be realized immediately. The building of a science is a laborious, a painstaking process, and at present (1926) the groundwork is not much further advanced than were the foundations of the modern science of medicine and surgery fifty years ago. If fifty years hence the science of highway engineering has been built up to the point now attained by the physicians and surgeons, this effort now being put forth will be abundantly repaid, and not too late. For the improvement of highways in the United States is a process that must be continued indefinitely.

Highway Conditions at the Close of the Second Decade

At the end of 1924, according to reports received by the U. S. Bureau of Public Roads, there was a total of 3 004 311 miles of highways in the United States, of which 707 138 miles had been improved in some degree, 235 471 miles by grading and draining, and 471 667 miles by surfacing. Of the roads surfaced, 64 086 miles were improved with sand clay, 246 357 miles with gravel, 60 467 miles with water-bound macadam, 45 172 miles with bituminous macadam, 9 691 miles with bituminous concrete, 31 188 miles with Portland cement concrete, 4 710 miles with brick and other block pavements, and 9 996 miles with various unclassified types of surface.

It is idle to talk of completion when less than one-fourth of the 3 000 000 miles of highways has been graded, only one-sixth has been surfaced, and one-sixtieth paved; when little more than one-half the mileage of the main State roads has been improved with any kind of surfacing, and there remain on these important arteries thousands of unsubstantial one-way bridges and dangerous railroad grade crossings; when the number of motor vehicles registered is doubling every fifth year and the traffic with them; when the size of cities, the magnitude of industries, and the amount of material wealth are increasing at an almost unprecedented rate. As long as these conditions continue it will be necessary to continue to build, maintain, and rebuild the roads.

At the present rate approximately 40 000 miles per year is being surfaced and the annual expenditure approximates $1 000 000 000. There is no indication of an early reduction in these rates of construction or expenditure, dwarfed as they are by the annual production of a 1 000-mile procession of motor vehicles and an annual expenditure for operation approaching $10 000 000 000. The nation has set its hand to the economic improvement of means of highway transportation. It is not a task to be accomplished in a day. It is, and must be, a continuous process. There is only one limit which may reasonably be set. It is this: No road should be improved by expenditures of public funds in excess of its earning capacity. The return to the public in the form of economic transportation is the sole measure and justification of the degree of highway improvement.

HISTORIC REVIEW OF THE DEVELOPMENT OF SANITARY ENGINEERING IN THE UNITED STATES DURING THE PAST ONE HUNDRED AND FIFTY YEARS

INTRODUCTION

By Harrison P. Eddy,* M. Am. Soc. C. E.

One hundred and fifty years ago the inhabited part of the United States consisted principally of the area east of the Allegheny Mountains and between the St. Lawrence River and the Spanish Province of Florida. The first census (1790) of the new Republic showed a population slightly less than 4 000 000.

Westward migration began during the Revolution and has continued with the extension of boundaries. Naturally, the course of migration was along the river valleys where ease of traveling was obtainable. Towns sprang up around border trading posts and forts, such as Pittsburgh, Cincinnati, Detroit, St. Louis, and Chicago.

The living conditions of the great mass of the people were extremely simple. Houses were of logs or of loose unpainted clapboards. Cooking was before open fires or in brick ovens. Lighting by night was by tallow candles, the sperm-oil lamp, or by the open wood fire. The friction match had not been invented, and flints and steel and tinder were the means for procuring fire. Clothing was chiefly homespun manufactured in the household with spinning wheels and hand looms. Few public water supplies and no public sewerage systems existed. Plumbing was practically unknown. Primitive methods for the removal and disposal of household waste and excretal matters prevailed.

At the time of the first census, only four municipalities had populations in excess of 10 000—New York, N. Y., 33 131; Philadelphia, Pa., 28 522; Boston, Mass., 18 320; and Baltimore, Md., 13 503. The remaining population was living under rural or semi-rural conditions.

The development of water supply and water purification, of sewerage systems and sewage treatment, and of refuse collection and disposal, has been coincident with the growth of cities. Land drainage has followed westward migration and the establishment of farms in the level areas of the western river valleys. Until the end of the Nineteenth Century the part played by the mosquito in the transmission of malaria and yellow fever was unknown, but, in the last two or three decades, an extraordinarily successful campaign has been waged against the mosquitoes conveying these diseases. In the early days the problem of ventilation was non-existent but, to-day, with large gatherings of individuals in halls, schools, and theatres, the problem has become acute.

During the 150-year period there has been an unprecedented utilization of science and engineering for the amelioration and control of man's environment. The papers which follow, outline the progress in those branches of engineering which have done so much to promote human health and comfort.

WATER-WORKS

By George W. Fuller,* M. Am. Soc. C. E.

Prior to 1870 the history of water-works in the United States presents a picture of isolated and spasmodic community efforts to obtain supplies, then, for about a generation, increased activity due largely to the enterprise of business men making water-works equipment, and then a continuous and fairly active growth caused by the rapid increase in urban population, culminating in the general recognition—since 1900—that the design and operation of modern water-works offer opportunities for research, engineering, and administrative skill of the highest grade.

The few water-works of the Colonies were crude affairs, frequently consisting of a bored log pipe line leading from a masonry walled hillside spring to a trough in the center of the town, as exemplified by the plant built at Schaefferstown, Pa., in 1730. As a rule, however, these early community works were large wells, from which the householders carried water, as is done in little European hamlets to-day. According to Mr. M. N. Baker, there were seventeen water-works in the United States at the close of 1800, all but one privately owned. It seems probable that public wells used by communities would increase this number, but the now unknown instances of such works can be discovered only as a by-product of more important historical research, through old newspapers and local records, in diaries, and in books of travel.

The early Seventies was the period of the great fires in Chicago, Ill., and Boston, Mass., and there has been a tendency to attribute the increased rate of water-works construction during this decade, from 243 plants in 1870 to 598 in 1880, to a better appreciation of the importance of public water-works as a fire-protection resource and an increased standard of living that demanded running water in homes. The facts, however, seem to be that the most important influences were furnished by promoters working for manufacturers of water-works equipment. The late J. James R. Croes, Past-President, Am. Soc. C. E., explained† the situation as follows:

"The rapid increase in the number of water works constructed within the last sixteen years is mainly due to the competition of enterprising business men. About the year 1870 Mr. Birdsill Holly, of Lockport, N. Y., a builder of pumping engines, began an active canvass of the towns which had no water supply, with the view of furnishing a type of engine and pump manufactured by him by which the pressure was pumped directly into the mains without the use of a reservoir, and at any desired pressure variable at will of the engineer, thus enabling the whole pipe system to be used as a fire engine if necessary. By organizing a private corporation to build works and asking from the public only a certain fixed annual subsidy based on the number of fire hydrants furnished and guaranteed to deliver on demand a fire stream under 100 pounds pressure, the Holly Company were able to induce many towns to allow water-works to be built.

* Cons. Engr. (Fuller & McClintock), New York, N. Y.

† In the preface to the Third (1887) Edition of his "Statistical Tables of American Water Works."

"The practicability of the scheme being proved, and the financial success of several such enterprises having been demonstrated, other pump builders followed the example of the pioneer, and with such success that competition has compelled all parties to build better pumping machinery than ever before and to increase their guaranties of efficiency, durability and economy of operation."

Table 1 shows the available data on growth and ownership of water-works used for public supply in the United States. These data are taken from the "Manual on American Water Works Practice," published in 1925, by the American Water Works Association. When it is realized that more than five years' work, with the help of more than 300 collaborators, resulted in a volume of more than 800 printed pages to tell what is good water-works practice, it will be appreciated how meager must be the historic outline which can be set forth in the limited space here available.

TABLE 1.—Growth of Water-Works in the United States, and Changes in Character of Their Ownership.

Year.	Total. plants.	Public plants.	Private plants.	Ownership unknown.	Percentage of Total.		
					Public.	Private.	Unknown.
1800	16*	1	15*	....	6.3*	93.7*	....
1810	26	5	21	....	19.2	80.8	....

* Since this table was compiled, another private water-works, built prior to 1800, has been discovered.

† Estimated.

Two supplementary comments are needed, to indicate:

First.—That although the proportion of privately-owned water companies is less than previously, the hit-or-miss type of franchise, or contract both as to quality of service and rates of charges, has largely disappeared. In its place have come State regulatory commissions which, under the provisions of the police powers of the State, now supervise rates of charges and in many States the quality of service, with or without the co-operation of State health commissions.

Second.—That the water-works industry is more extensive than is indicated by the number of plants used wholly or in part in supplying water to the public. The water-works for the exclusive use of many of the large industrial plants are both extensive and important. Water for condensing purposes is highly important, although the subject is clearly outside the scope of this paper.

Distributing Systems

There is little positive information about the distributing systems leading from the primitive collecting works in American communities. In Great Britain, where it was customary to supply water to each consumer for only a short time during each day, cisterns were constructed in the attics of buildings and connected by lead pipes to the street mains. A man (called a "turncock") went around every day, turned a cock on the service pipe and filled the cistern. If it did not hold enough water to meet the requirements for the next 24 hours, the occupants either did without water or procured some from outside the building.

The scheme of intermittent supply never gained a foothold in the United States, but house cisterns were used, on account of low street pressures They served a useful purpose, during periods of scanty supply, by making available, during the day hours of heavy draft and consequent low pressure, water which slowly filled them during the night.

The early pipes were practically all bored logs, sometimes with a ring of iron shrunk on each end to prevent splitting. Such pipes had long been used in Europe, and were not a makeshift adopted on account of the exigencies of construction in a new country, as is sometimes stated. As a matter of fact, bored wood pipe are still made and used to a considerable extent, chiefly for mine drainage in the East and for water-works on the Pacific Coast. The manufacture of such pipe, and of banded stave pipe was greatly improved about 1850 by Wyckoff, of Elmira, N. Y. The banded type was the forerunner of the large banded wood-stave aqueduct pipes used to-day in the West for irrigation, hydro-electric plants, and water-works.

About 1800 cast-iron pipe began to supplant wood pipe in England. Such pipe, with flanged joints, had been tried by the Chelsea Water Company, of London, about 1746, but without much success on account of difficulty with the joints. After studying the causes of the trouble, Thomas Simpson, the Company's engineer, about 1785, designed the first successful bell and spigot pipe with a lead joint. It was quickly adopted, but the facilities for manufacture restricted its introduction for some time. Such pipe, imported from Great Britain in 1807 and laid in Philadelphia, inaugurated the use of cast-iron water mains in the United States.

It was soon found, however, that, in some cities, the interior of uncoated pipe carrying water became tuberculated, and that the carrying capacity was much inferior to that of new pipe. The problem of preventing tuberculation was solved by Dr. Angus Smith, who in 1848 produced the coating that has since borne his name. Although this tar product, which rapidly came into general use, did not prevent tuberculation entirely, it was an excellent and inexpensive deterrent when made of the materials and prepared and applied as he recommended. After the success of this coating was proved, cast-iron pipe had no serious rival for water-works, except in localities where transportation charges made it preferable to use materials which were less expensive although they might not be so durable.

Quite recently a desire for a still better coating for cast-iron pipe, has developed, and the subject is again one of the live topics of discussion in water-works circles.

As the demand for cast-iron pipe began to increase, there was a corresponding increase in the range of thicknesses adopted for pipe walls, and in the shapes of the bells, spigots, and special castings. This complexity at last became intolerable, and in 1902 a standard set of specifications for pipe and specials was adopted by the New England Water Works Association. In 1908 the specifications of the American Water Works Association were adopted, and have since been the standard in America. Although they may need revision to-day (1926), as to coatings and quality of material, and perhaps in other respects, they have been invaluable alike to pipe purchasers and makers.

Wrought-iron pipe appeared in the Forties as a material for distribution mains and service pipes. The pipe was used as a shell, being lined with cement mortar and coated on the outside with some form of preservative. These cement-lined pipes had a decided vogue, particularly in New England, for about twenty-five years, but finally were adjudged less economical than cast-iron pipe in the long run. Owing to recent changes in commercial conditions, they are again back on the market.

In the Fifties, when hydraulic mining in California was becoming a notable industry, large quantities of water had to be dealt with. Although open flumes served as conduits in most places, there were occasional dips below the hydraulic grade where pipe of some sort had to be provided. Cast iron was out of the question on account of cost and transportation difficulties; wrought iron had to be used. When the late Hermann F. A. Schussler, M. Am. Soc. C. E., began the construction of the San Francisco Water-Works, in the Sixties, his knowledge of the satisfactory service of wrought-iron pipe in mining led him to use it for the larger mains of those works As a consequence of the early satisfactory experience in San Francisco, wrought-iron and steel water pipe gained a foothold on the Pacific Coast from which they have never been dislodged.

The first important riveted wrought-iron pipe in the East was laid in Rochester, N. Y., in 1873-75, but it was not until after steel had replaced wrought iron to a great extent that the construction of riveted pipe was considered seriously in this part of the country. Exterior protective coating and the lining of riveted and similar plate pipes have recently received much attention, and some of these methods are so encouraging that, even in the East, steel has become a strong competitor of cast iron in the larger sizes. Both materials, however, are relying, more than ever before, on coatings and linings to preserve their inherent advantages.

In this commercial struggle, active competition has arisen from reinforced concrete pipe, for places where the pressure is not too great. It has been used for aqueducts and other pressure lines for little more than a decade, but in this brief period has shown encouraging results as to low first cost, freedom from leakage, and maintenance of discharging capacity.

Not until about 1875 or 1885 was any general attention paid to what might be called distribution economics. The early distribution systems, after a time, did not deliver the theoretical quantity of water they should, at different parts of a city. This seems to have been one of the reasons for the attention paid to service reservoirs and stand-pipes long before any serious study was made of the hydraulics of distribution systems as a whole.

In some cities attempts were made to improve the distribution of water by partly closing the gates of mains that fed districts where the pressure was highest. When serious fires made an ample supply necessary in a section fed by one of these throttled mains, it was found that the practice was a hazardous makeshift. Engineers finally undertook a careful study of the subject, and an early result was a paper, presented in 1892 to the New England Water Works Association by John R. Freeman, Past-President, Am. Soc. C. E., which attracted wide-spread atttention.

Many years prior to this, one cause of low street pressures was known to be the leakage of water through defective plumbing fixtures, services, and street mains. The leakage inside buildings was attacked by metering the services, but progress was very slow for years, except in some of the thrifty New England cities. Where metering was impracticable, attempts were made to inspect the plumbing, but this also met with violent objection in many cities. To-day, it is difficult for anybody unfamiliar with the facts to realize the bitterness of the opposition to metering as late as the Eighties, and it is fitting in this general discussion to mention the long and forceful campaign for metering conducted a generation ago by Henry C. Meyer, F. Am. Soc. C. E., in his paper* and in other ways.

The opposition to metering service pipes on dwellings was so strong that the method of detecting waste, by dividing a city into districts and then searching for all instances of leakage in one district after another, was developed. In its most elaborate form, due to Mr. G. F. Deacon, of the Liverpool Water-Works, the water delivered to each district was measured by a continuously recording meter. By inspection of plumbing and by using early forms of what is now called the aquaphone, most of the serious leaks and cases of waste in a district were detected and remedied. After that, the district meter register indicated any material increase in waste. The system was tried in only one city of the United States—Boston. It was successful technically, but was so expensive that it was finally abandoned.

When Clemens Herschel, Past-President, Am. Soc. C. E., invented the Venturi meter, in the Eighties, he furnished the first reliable device for measuring large quantities of water supplied through pipes from reservoirs and pumping stations; for the actual discharge of pumps in those days was affected to such an extent by the unknown slip in the pump valves that the only sure thing about the discharge was that it was much less than the reading of the pump counters. Then, in the late Nineties, E. S. Cole, M. Am. Soc. C. E., developed the pitometer, by which the discharge of any pipe can

* *The Sanitary Engineer.*

be determined. With these devices, everything formerly accomplished by the Deacon district system can be done at much less cost.

Obtaining Water Supplies—Sources

With the early water-works there was rarely any difficulty in finding near at hand ample supplies which seemed to be of satisfactory quality. In Philadelphia, for example, after the early wells were deemed inadequate, an unlimited supply could be obtained by pumping from the Schuylkill River.

In New York, the case was unusual. Public water-works began with public wells, the first dug by the Dutch in 1658. Many others were dug later, and those in each ward were placed in charge of its alderman and councilmen. The wells in the heart of the town became so polluted and the water so offensive that it was little used. Just before the Revolution, a private company, under the direction of Christopher Colles, sunk a large well near the present site of the Tombs Prison, from which a less objectionable supply was pumped, by a Newcomen engine, to a small reservoir and then delivered by gravity through log pipes. The enterprise was soon abandoned on account of the war.

Next came Aaron Burr's water-works, built by the Manhattan Company in 1799, under an Act of the Legislature. The works consisted of a large well, two pumps, and the reservoir built by Colles. The Company made hardly more than a nominal attempt to furnish water, as its real object was to conduct a bank, permitted by an innocent looking clause, in its perpetual charter, regarding the investment of its surplus funds. In 1823, it had 23 miles of pipe, nearly all wood, two small steam pumps, and a masonry reservoir holding 550 000 gal. This plant and many wells furnishing water of very inferior quality supplied the city until 1830, when a well, 16 ft. in diameter and 112 ft. deep, was sunk at 13th Street and Broadway, most of it in rock. The water was too hard for domestic purposes, and was used chiefly for fire protection. A small steam pump raised the water to a large cast-iron tank, and the supply was delivered through about 9 miles of cast-iron pipe, from 6 to 12 in. in diameter. This was the first municipal plant in New York.

By 1832 the supply furnished in the city by the Manhattan Company and by the public and private wells was so offensive that all who could afford to do so purchased water brought in hogsheads from unpolluted wells in the northern part of the island. About 600 hogsheads were furnished daily in this way at $1.25 per hogshead. A very bad outbreak of cholera during that year was followed by an increase in the already strong demand for an adequate public supply. It was at first thought that water could be obtained from the Bronx River, but later it was shown that the nearest available supply was from the Croton water-shed. In 1835 the Croton project was approved by the citizens at a special election, bids for construction were opened in 1837, and Croton water, practically the first fit to drink after the days of Dutch control, was delivered in 1842, when the city had attained a population of more than 300 000.

Intakes.—The construction of intakes, by which water was drawn from rivers and ponds, developed so slowly and by such small advances that it is hardly possible at this time to give credit for significant improvements in design, except in one respect. The first public water supply in Chicago was established in 1831; it was merely a public well. The municipal water-works were begun in 1851. After the sewerage system of the city was built and the sewage was carried out into Lake Michigan by the Chicago River, apprehension was felt that the water about the intake in the lake would become dangerously polluted. The extension of the intake pipe farther out into the lake, beyond the area of pollution, was the remedy most favored. The City Engineer, the late E. S. Chesbrough, Past-President, Am. Soc. C. E., opposed this vigorously and insisted that only a supply drawn through a tunnel in the lake bed would be free from serious danger of interruption of service. Such a subaqueous tunnel was then an engineering feat of the first order, but it was at last built in 1867, establishing a practice followed in many cities, not only on the Great Lakes, but also on some of the larger rivers.

Dams and Reservoirs.—Turning to those works for which a supply is obtained by impounding surface waters, one naturally recalls first the dams which form the reservoirs. The development of the details of gravity dams has been slow but continuous. The outstanding novelties have been of a different nature, and of rather limited availability. First there is the hydraulic-fill dam, a form of construction first used by the late James D. Schuyler, M. Am. Soc. C. E., in making railway embankments in Western Canada; then the rock-fill dam, with an impervious covering on the back; and the arched dam, particularly suited for high, narrow gorges. Somewhat later the hollow dam was introduced, for the purpose of saving part of the cost of gravity dams. It has developed into two types, both having transverse parallel buttresses supporting the up-stream back. In one type the back, of reinforced concrete slabs, slopes gently upward to the crest, and the weight of the water on it contributes to its stability. In the other type, nearly vertical arches between the buttresses form the back. Although only bare mention can be made of these types, the general interest in them has resulted in a large volume of printed information regarding their relative merits.

Hydrology.—One of those features of the development of water-works practice that has had a profound influence is inextricably tied up with the gradual increase in the knowledge of hydraulics and hydrology. For a long time so much water was available that there was no shortage except what was due to lack of ordinary common sense in procuring a supply. Little by little, however, there were shortages that could not be explained by the engineering knowledge of those times, and so water-works engineers began to search for their causes. Later, the necessities of irrigation and hydraulic power development increased the interest in this group of subjects, culminating in the interesting utilization of the mathematics of probability, under the leadership of Allen Hazen, M. Am. Soc. C. E.

So far as the co-ordination and direct utilization of this kind of knowledge is concerned, it should be mentioned that in the Nineties the late F. P. Stearns,

Past-President, Am. Soc. C. E., in investigations for the Massachusetts State Board of Health, and C. C. Vermeule, M. Am. Soc. C. E., in studies of the water supplies of New Jersey, for the Geological Survey of that State, developed general methods of adjusting reservoir capacities to the run-off from a water-shed. Just before that time there had been in the West, a few cases of expensive irrigation reservoirs, which could not be filled. The economical maximum capacity of reservoirs to utilize the run-off of a water-shed was, therefore, manifestly more than an academic topic.

Underground Water.—Underground water supplies are more numerous than surface supplies, although their total yield is not so great. It is unfortunate, therefore, that nobody has yet undertaken to gather and digest all the existing definite information regarding the engineering aspects of underground supplies, as has been done with surface supplies.

Pumping Water

The Keystone State not only holds the record for the first public water supply, but also for the first public supply furnished by pumping. In 1754 Hans Cristopher Christiansen, a Danish millwright, began the construction of the first water-works of Bethlehem after the general method already in use in several places in Europe. His pump, constructed of lignum-vitæ and driven by an over-shot water-wheel, raised water from a spring to tanks on the hillside above the village.

The first steam pumps in America were used for draining New Jersey mines. They were built in England, of the Newcomen type as improved by Smeaton. The first Newcomen pump used for town supply was erected in New York just before the Revolutionary War by a short-lived private company.

The first steam pumping plant in Pennsylvania was put in operation in 1801, in Philadelphia, where a low-lift pump, on the Schuykill River at the foot of Chestnut Street, raised the water to an open basin, from which it flowed by gravity through a conduit in Chestnut Street to Centre Square, now the site of the City Hall. There, at another station, the water was elevated about 50 ft. to wooden tanks, of about 17 000 gal. capacity, on top of the building.

The boilers at both plants were wooden boxes, 9 ft. high, 9 ft. wide, and 15 ft. long, of 5-in. white pine plank thoroughly bolted and braced. The fire-box, constructed of wrought-iron plates with vertical cast-iron flues, was inside. The engines were the Watt vertical, double-acting type attached to a Cornish pump. The pump of each was of wood lined with copper. The steam cylinder was of cast iron.

It had been recognized, from the days of Savery and Newcomen, that the load on pumps is pre-eminently adapted for being carried by a steam engine. It is steady and always accompanied by enough water for condensing purposes. As a consequence, the early history of the development of the steam engine is largely that of the development of pumping engines. The condition is just the opposite, however, with boilers which furnish the steam to the pumps. The early pumping stations had boilers carrying very low pressure,

and, when more pumping capacity was added, the low pressure was retained in order that the old boilers could still be used. This condition kept station efficiency low, in spite of efficient pumping engines. As a matter of record of an important feature of pumping station development, the following statement, prepared by the late Charles A. Hague, M. Am. Soc. C. E., shows the maximum steam pressures in such stations:

Year	1800	1830	1850	1875	1900	1906
Steam pressure, in pounds.	5	20	50	75	125	175

There was a period of quiescence in the field of pumping machinery, down to the Sixties, due chiefly to patent conditions. Small pumps were usually direct-acting, and the larger pumps were improvements on the Bull-Cornish or Watt-Cornish types. In the Sixties the late Henry R. Worthington, M. Am. Soc. C. E., brought out the duplex, direct-acting pump, and other inventors followed soon with other devices for utilizing the duplex principle. At about the same time the Holly quadruplex crank-and-flywheel pump was introduced, and thus began a business competition between the two types of pumping engines that resulted in great improvements in each and a substantial reduction in their cost.

In England another type of pumping engine was developing, the Simpson compound engine, first used there in 1848, and in the United States in Philadelphia in 1872. Others were erected in a number of cities of the United States, the largest plant being that of the West Side Pumping Station in Chicago.

A few pumping engines used in the United States at that time were designed by consulting engineers, among whom the late E. D. Leavitt, M. Am. Soc. C. E., was prominent, but nearly all were designed by the builders. Competition was severe. It was necessary, not only to meet constantly rising guaranties, but also to reduce manufacturing costs, and naturally the improvements were in details rather than in general types. Finally, the experience with the Simpson type seemed so certain to establish it as the single standard for handling large volumes of water that the Worthington high-duty attachment, for the duplex engine, was brought out, and the Holly-Gaskill crank-and-flywheel engine was designed to improve the economy of the Holly quadruplex, crank-and-flywheel type.

In the Eighties, the Reynolds triple-expansion pump was designed, the first being built at Milwaukee in 1886; this soon became the standard high-duty, large-capacity, American pumping engine.

By 1900, earlier experience and commercial competition had rather definitely established certain types of pumping engines for the different kinds of service, and those interested in the subject will find them described by Irving H. Reynolds, M. Am. Soc. C. E.*

About 1900 the centrifugal pump became a really strong candidate for favor for water-works use. It was largely the development of reliable steam turbines and reduction gears that established such pumps in the favor they now hold in water-works practice. Originally, such pumps were used only

* *Transactions*, Am. Soc. C. E., Vol. LIV (1905), Part D, p. 513.

for low-lift service, but the field has gradually widened as the methods of design have been improved, and electrically driven centrifugal pumps are now operated against very high heads. This development has brought about one interesting change in pumping-station practice.

In the early plants these turbo-centrifugal units were generally placed in an old pumping station, where it was desired to handle the largest possible quantity of water with pumps occupying a definite space. The steam pressure was low, and other conditions were unfavorable for economy, but when turbo-centrifugal pumps were put in service under better conditions, using superheated steam at pressures most suitable for turbines, their economy rose very favorably, just as it did in the early days of turbines in industrial power plants and central stations. It became very evident then that station economy, rather than prime-mover economy, was the real measure of the success of the design.

Electrically operated centrifugal pumps, when the motors and pumps are suitably designed for the loads carried, are now standardized equipment. The chief drawback to their use is the possible unreliability of the current supply from outside sources. This is a serious matter where only a small quantity of water is stored in tanks or reservoirs.

The danger of interruption of current supply for motor-operated pumps, both centrifugal and reciprocating, has been met in many small pumping stations by adding a high-speed gasoline engine to help out in emergencies. Although the gasoline engine is cheap, its fuel is much more expensive than the oil used in Diesel engines. These were introduced about 1895, and have been improved steadily ever since, until to-day they are capable of satisfactory operation for a considerable range of speed, although, like all internal combustion engines, they must not be given overloads. Two considerations seem to be chiefly influential in determining their use. The first is the present and probable future price of fuel oil and its availability at any place; the second is the length of satisfactory service of these engines. Concerning the second point, there is difference of opinion which probably cannot be reconciled until after longer experience with them.

The reciprocating well pump has been slowly improved, but, usually, it is not economical. The shocks and vibrations attending its operation and its relatively complicated construction make its maintenance high in comparison with the quantity of water it delivers. Attempts to avoid these drawbacks have taken two forms, both successful and widely used: The air-lift and the centrifugal well pump, which deserve more than this brief mention.

Quality of Supplies

Presumably, this branch of the topic is the most important to develop in historic outline at present. Its consideration relates to the development of the modern germ theory of disease, particularly regarding the transmission of water-borne disease. In a strict technical sense, modern views as to the relation between the quality of a water and the health of the communities using such water date from the early or middle Eighties. Such matters,

however, were then under discussion for the most part by highly trained scientists in a few of the larger cities, and the general mass of water consumers, even including those well informed on educational topics in general, did not give much recognition to the significance of water-borne diseases until after the terrific outbreak of Asiatic cholera in Hamburg, Germany, in 1892-93.

The best index of the successful fight waged against water-borne disease in America is the decrease in the typhoid fever death rate, shown by Table 2. Although the pasteurization of milk, fly suppression, and the education of the public in the rules of sanitation and hygiene have contributed to this decrease, the improvement in the quality of water supplies has been the chief cause.

Prior to the development of modern views as to transmission of disease, there was a well-recognized belief that a public water supply should not be obtained from a filthy source. This theory, originating in England, had much to do in explaining the progressive changes made by numerous cities and towns in efforts to get water from clean sources. Most of the rivers of Western and Central Europe are only of moderate turbidity, and can be clarified suitably on sand beds such as were first constructed at London in 1829. The idea of these sand beds spread quite rapidly to various places in England and on the Continent.

Kirkwood's Report.—In 1866-68, the late James G. Kirkwood, Past-President, Am. Soc. C. E., then Chief Engineer of the St. Louis, Mo., Water-Works, made a thorough-going study of the methods used in filtering European supplies. It was a most admirable report, and its merit was well recognized by its translation into German and its becoming a standard work of reference in several European countries. On account of the unusually heavy turbidity or muddiness of the local rivers at St. Louis, Mr. Kirkwood did not recommend sand beds for the local supply, and this report was followed by no activities in the adoption of European filtration practice other than the two small sand filter beds which he built for Poughkeepsie and Hudson, N. Y., in the early Seventies.

Conditions in the Early Nineties.—It is difficult for the younger engineers to realize the extent to which the United States suffered from the scourge of sewage-polluted waters, which caused severe epidemics and in many places continuous or endemic conditions as to typhoid fever. The explanation is simple enough when one considers the close proximity of sewer outlets and water-works intakes. No wonder typhoid fever records were frequently from ten to twenty times higher than ordinarily found at present. The scourge was particularly severe in the manufacturing cities of Massachusetts and in the steel districts of Western Pennsylvania, where many of the population paid little or no attention to warning notices against drinking public water supplies. One of the sad features of the Columbian Exposition at Chicago in 1893 was the number of visiting engineers who contracted typhoid fever while there.

‖‖ Coagulant applied during periods of high turbidity.

Lawrence Filter.—When the Massachusetts State Board of Health was re-organized in 1886, one of its most important steps was the establishment of the Experiment Station at Lawrence where, since that date, a vast fund of information has been developed on the subject of purifying water and sewage. One of the outstanding characteristics of these investigations, under the direction of the late Hiram F. Mills, Hon. M. Am. Soc. C. E., was that it embodied data of an engineering, chemical, and biological nature. Such thorough-going and unusually well co-ordinated data have had much to do with the development of sanitary engineering during the past forty years. In 1891-92, one of the most important pieces of work at Lawrence was an investigation of the ability of ordinary sand filters to remove typhoid fever germs, a matter of more than usual importance in the Merrimac Valley, where the Lawrence water-supply intake is only eight miles below the Lowell sewers.

In the late summer of 1892 Asiatic cholera appeared on vessels quarantined in New York Harbor, and, under these circumstances, it was not difficult for Mr. Mills to obtain from the City Council of Lawrence, authorization for the construction of the Lawrence filter. This filter was completed in September, 1893, and embodied in its design the application of many of the data derived under Mr. Mills' direction at the State Experiment Station. The success of this filter, in reducing typhoid fever in that city, was so notable that it became a landmark in the train of developments which characterized the improvements in the quality of water supplies in America.

Louisville Investigations.—What the Lawrence experiments were to the development of slow sand filters, the results of the investigations at Louisville, Ky., were in respect to rapid or mechanical filters. The late Charles Hermany, Past-President, Am. Soc. C. E., found, as did Mr. Kirkwood at St. Louis, that the muddy Ohio River water was not susceptible to filtration in a practical way through sand beds, as used in Europe and later adopted with some modifications at Lawrence. In 1895 he began investigations, continuing for nearly two years, on various ways of coagulating and filtering muddy Ohio River water, the writer being in immediate charge of the work. Prior to that period mechanical filters had been in use at a few mills, for removing coarse material, but had obtained practically no standing for municipal supplies. They had been studied shortly before by the late E. B. Weston, M. Am. Soc. C. E., at Providence, R. I., and extensive investigations immediately followed those at Louisville, one set being conducted at Cincinnati, Ohio, by the writer and the other at Pittsburgh, Pa., by Mr. Hazen. In those days mechanical filters were contained within wooden tubs or metal cylinders, and it happened that their status became largely enhanced through the development of reinforced concrete for the filter units such as first adopted at Little Falls, N. J., in 1901. Since that date there have been marked developments in mechanical equipment for the efficient control of various filter arrangements.

Filtration Practice.—At present (1926) there are approximately 635 filter plants, having capacities in excess of 1 000 000 gal., serving about 23 750 000

people, and having a total daily rated capacity of 5 000 000 000 gal. There are 47 slow sand filters and 588 mechanical filters, having a rated daily aggregate capacity of 915 000 000 and 4 085 000 000 gal., respectively.

Algæcides.—One aspect of the quality of water has been the tastes and odors associated with the growth and decay of various forms of microscopic life. The late George W. Rafter, M. Am. Soc. C. E., began a painstaking study of this matter, at Rochester, N. Y., and, later, at Boston, Mass., with the aid of the late George C. Whipple, M. Am. Soc. C. E., who for about fifteen years conducted thorough-going investigations into the various factors related to tastes and odors in surface water supplies at Boston and New York. To the engineer, perhaps, it may be of most interest to indicate that by the use of copper sulfate or other algæcides much can be done toward controlling these tastes and odors by killing the organisms producing them.

Aeration.—Stored waters frequently stagnate, with the result that water in the lower parts of deep reservoirs becomes offensive to sight and smell. Aeration will restore the depletion of atmospheric oxygen, lessen the free carbonic acid, and offset the products of decomposition found in the deep parts of large reservoirs. Advantageous use of aeration is to be found in the works of the Catskill project for New York City.

Chlorination.—One of the results of the cholera epidemic at Hamburg was the development of the fact that bleaching powder was an efficient sterilizing agent, although in Europe the idea was to apply it in cases of emergency only. Beginning in 1908, with the Boonton Reservoir supply of Jersey City, N. J., the regular use of chlorine was adopted for the purpose of destroying objectionable bacteria. This practice has become general in America, and it is estimated that there are in service now more than 3 200 chlorinating plants, capable of supplying about 4 000 000 000 gal. of water daily.

Iodizing.—Beginning in 1922 at Rochester, N. Y., there recently has been added to public water supplies intermittent small doses of sodium iodide, for the purpose of supplying the deficiency of iodine. This deficiency in some water supplies is believed to be an important factor in the causation of common goiter.

Methods of Analysis.—The quality and composition of waters in various parts of the United States vary greatly, and the methods of analysis suitable in Western Europe and in New England are quite inadequate for many of the waters of the Southern and Western States. It is of importance to record an unusual amount of good team work in America in improving and unifying methods of analysis. The first edition of "Standard Methods of Water Analysis" appeared in 1905, under the auspices of the American Public Health Association, and, in 1925, its sixth edition appeared under the joint auspices of that Association and the American Water Works Association. It is of interest to note that the standard methods in use in America are to be translated into French and German, under the sponsorship of the Health Section of the League of Nations. It is to be hoped that the co-operative work, carried on in America for thirty years, may assume a wider scope under the guidance of an international committee.

Iron Removal Plants.—Many ground-water supplies contain objectionable quantities of iron and manganese, so that, on exposure to the air, objectionable deposits and discolorations are formed. It is thoroughly practicable to remove these objectionable constituents by aeration and filtration. Chemicals are sometimes used—and in a few instances iron settling basins—for the removal of the deposit, rather than filters.

Removal of Carbonic Acid.—Some water supplies, particularly those derived from deep underground sources, contain large quantities of free carbonic acid, and this is of much significance in connection with the correction of corrosion of metals. It is thoroughly feasible, by aeration and filtration, and, if need be, with the aid of quicklime, to reduce the carbonic acid content to practical limits for safe use. A plant for removing such corrosive properties has been established for the new deep well supply at Memphis, Tenn.

Water Softening.—There are a few well-known water-softening plants in America. The most comprehensive data have come from Columbus, Ohio, in a paper by John H. Gregory, M. Am. Soc. C. E.* Some supplies of hard water undoubtedly should be softened, but views have not been well crystallized as to where to draw the line separating a hard water justifying softening from one where it is not worth while to pay the cost of such softening. This view, however, for public supplies, does not relate to the opinions held by those in charge of the water supplies of many industrial and power plants. What is said of softening also applies to the removal of carbonic acid and other corrosive properties.

Filter Loading.—Engineers are faced to-day with one problem that very soon must receive more attention than has been accorded to it hitherto. Sources of water supply are being contaminated by industrial wastes to a serious degree in some sections, and the pollution due to the discharge of sewage into such waters after little or no treatment is causing apprehension in well-informed circles. The time is fast approaching when the loads thrown on some water purification plants will be unreasonably heavy, and engineers should consider carefully the advisability of abandoning the old attitude that, except in unusual instances, it is a matter of indifference as to purification of sewage so long as public water supplies derived from a polluted source are purified. In twenty-five years cities have grown rapidly, and the industries discharging objectionable wastes have grown even more rapidly. Rivers and lakes have about the same volume of water now as they had a century ago. What was good practice in 1900 is no longer such in many cities, because of the changes that have taken place. This view is adopted in the treaty between the United States and Great Britain, ratified in 1909, in which it is stated that boundary waters between the United States and Canada should not be polluted on one side of the river so as to be injurious to those living on the other side. These matters were interpreted to deal with filter loading, after the International Joint Commission, to which these matters were referred, had conducted extensive investigations and inquiries.

SEWERAGE AND DRAINAGE OF TOWNS

By Harrison P. Eddy,* M. Am. Soc. C. E.

Historical

Early American Conditions.—At the founding of the United States, the living conditions of the great mass of the people were extremely simple. Plumbing was practically unknown. Few public water supplies and no public sewerage systems existed, and primitive methods for the removal and disposal of household wastes and excretal matters prevailed.

Sewerage and Growth of Cities Coincident.—The development of sewerage systems and methods of sewage disposal has been coincident with the growth of cities. At the time of the first census, in 1790, only four municipalities had populations in excess of 10 000—New York, N. Y., 33 131; Philadelphia, Pa., 28 522; Boston, Mass., 18 320; and Baltimore, Md., 13 503. The remaining population was living under rural or semi-rural conditions. Individual water supplies, in the form of wells, and wastes disposal systems, in the form of privies and cesspools, existed on the same premises, too often in close proximity.

Effect of Introduction of Public Water Supplies.—With the introduction of public water supplies into growing towns, and the gradual increase of houses provided with plumbing, the need for prompt and inoffensive removal of liquid wastes became acute. The pail system, for the collection and removal of excretal wastes, as adopted to a considerable extent in Europe, never became popular in America. Leaching cesspools took care of liquid wastes where soil conditions were suitable, but in many instances offensive wastes were discharged on the ground or into surface gutters. Drains built by individuals or by groups of persons, for the removal of surface waters, were often utilized to carry the liquid wastes to the nearest watercourse.

In Boston it was not until 1823 that the city took over the maintenance of existing drains and the building of new ones. Fecal matters were excluded by law until 1833. Even then, only liquid wastes were allowed, the admission of solid matters being prohibited.

These early drains and sewers were built without regard to the needs of the community as a whole, and did not follow any technical basis of design. The materials of which they were constructed were stone, brick, and wood. Sections were circular, semi-circular, rectangular, and of various odd shapes. In many cases slopes were inadequate, and sometimes actually pitched the wrong way.

Introduction of Water-Carriage System.—Due to the poor design and construction of the early drains there was a marked prejudice against the discharge of excretal matters into them, it being claimed that this would cause offensive odors and be detrimental to health, and it was not until about 1850 that the water-carriage system for liquid wastes, including excretal

* Cons. Engr. (Metcalf & Eddy), Boston, Mass.

matters, began to come into general use. In Baltimore, the prohibition relating to the direct discharge of such matters into sewers continued until 1911, at which time the new and comprehensive system of sewers and the sewage treatment plant were put into operation.

Yellow Fever and Cholera.—In the early days of the Republic many epidemics of yellow fever and cholera occurred. In New York there were epidemics of the former in 1791, 1795, 1798, 1799, 1805, 1819, and 1822. That of 1798, when the population was only about 80 000, resulted in more than 2 000 deaths.

In Southern cities yellow fever persisted almost until the Twentieth Century. Even before the discovery of the part played by the mosquito in the transmission of the disease, the introduction of sewerage and the drainage of cities resulted in a marked diminution of this malady, due to the reduction of breeding places for mosquitoes.

Cholera, another disease now unknown in America, was prevalent from time to time in the past. Serious epidemics occurred in 1832, 1834, 1849, 1854, 1866, and 1873, thousands of deaths resulting from it in New York alone. A relation between this disease and improper drainage and filthy methods of disposal of household wastes appears to have been recognized to some degree at an early date. This recognition undoubtedly was a stimulus to the establishment of drainage and sewerage systems in the larger towns.

Sewerage Systems

Early Systems.—The first complete systematic sewerage system in the world appears to have been that of Hamburg, Germany, begun in 1843 after the plans of the elder Lindley, a distinguished English engineer. In the United States the first application of engineering skill to the design of sewers was in 1857 when the late Julius W. Adams, Past-President, Am. Soc. C. E., was appointed to prepare plans for the sewerage of Brooklyn, N. Y. For many years thereafter these sewers served as models. In the following year the late E. S. Chesbrough, Past-President, Am. Soc. C. E., submitted his first report on a comprehensive sewerage system for Chicago, Ill. In 1874 the late J. Herbert Shedd, M. Am. Soc. C. E., established the basic principles for the design of a sewerage system at Providence, R. I. Two years later, a committee, consisting of Messrs. E. S. Chesbrough, the late Moses Lane, M. Am. Soc. C. E., and Dr. C. F. Folsom, reported on the sewerage of Boston, Mass., advocating the general plan of main drainage now in effect. In 1880, the late Col. Waring at Memphis, Tenn., and Benezette Williams at Pullman, Ill., constructed the first systems of separate sewers in America. The separate sewerage and drainage systems of New Orleans, La., followed in the early part of the present century, and, in 1911, one of the largest separate systems of sewers in the country went into service at Baltimore. At present (1926) no large municipality is without its sewerage system.

Storm-Water Drains, Separate Sewers, and Combined Sewers.—Following the advocacy of separate sewers by Col. Waring, and with the increasing need for sewage treatment, American practice tended toward the separation

of storm drainage and domestic sewage. Of recent years, however, experience with American municipal administration has shown that it is practically hopeless to secure complete elimination of storm-water from separate sewers and of sewage from storm drains, particularly in the larger cities, and the tendency has been to build combined systems, using intercepting sewers with storm-water overflows when necessary to carry the dry-weather flow a long distance for treatment or disposal.

Pumping.—Although steam-driven pumping machinery had been developed for water-works and for mine drainage prior to the beginning of the Nineteenth Century, there was at that time no comprehensive sewerage system in America, and, consequently, no demand for sewage pumping. Such sewers as were built at an early date discharged by gravity. One of the earliest sewage pumping stations is that of the Boston main drainage works, put into service in 1884. This was followed in the succeeding year by the station in Milwaukee, Wis. In recent years notable pumping plants have been established at Washington, D. C., Baltimore, Chicago, and New Orleans.

The earlier stations were equipped with steam-driven plunger pumps; later, steam-driven centrifugal pumps were used with success, and, more recently, electric motor-driven pumps have predominated. For lifts of only a few feet, screw pumps have been used for many years in connection with flushing tunnels at Milwaukee and Chicago where lake water is pumped to provide additional dilution in sewage-laden streams. At New Orleans very large screw pumps are used for handling drainage or storm run-off. Now that pumping equipment has become more dependable and efficient, and electric current is almost everywhere available at reasonable cost, engineers do not hesitate, as they once did, to resort to pumping. On both small and relatively large projects, automatically operated equipment is commonly used, thus avoiding the necessity of constant attendance by an operating staff.

Design.—There is little evidence to indicate that prior to about 1850 engineering skill entered into the design of sewers. Following this date empirical formulas for determining their requisite size came into use. Among the best known of these were those of Hawksley (London, 1857); Bürkli-Ziegler (Zürich, 1880); Adams (Brooklyn, 1880); McMath (St. Louis, 1887); and Hering (New York diagrams, 1889). These formulas have given place quite generally to adaptations of the "rational method" for estimating quantities of storm-water run-off. This method, which takes into consideration the fact that the rate of run-off at any point is dependent on the rate of rainfall and the time required for the water to reach the drain, was advocated by the late Emil Kuichling, M. Am. Soc. C. E., in 1889. However, it should be noted that in the modern city the covering of streets and sidewalks with smooth, water-proof pavements and the utilization of a large part of the remaining areas for building purposes, is bringing about a larger proportion of impervious area. These changes cause rates of run-off more nearly equal to rates of precipitation than formerly, resulting in the need for more liberal sewer and drain capacities.

Materials.—The early sewers, built after 1850, were generally vitrified clay or cement mortar pipes for small sizes, and brick for the large sections. In the older part of New York a great deal of wood-stave sewer was used. In 1885, at Washington, David E. McComb, M. Am. Soc. C. E., was the first American engineer to build large sewers of concrete. Since then, concrete for large and medium-sized sewers has come into wide use, those at St. Louis, Kansas City, Mo., Detroit, Mich., and Philadelphia being particularly large. In some cases, also, segmental vitrified clay tile has found favor.

Construction Methods.—With increasing activity in the establishment of sewerage systems and in general building construction, and also as a result of advancing wages, there followed improved methods of construction. Excavations for the early sewers were made by hand, stagings being used in deep trenches. This method was then modified by the use of bucket machines, such as those devised by Howard A. Carson, Hon. M. Am. Soc. C. E., during the construction of the Boston main drainage works. Later, on large work, the steam shovel was used; still later, the drag-line excavator; and, on smaller work, the trench excavating machine has come into quite general favor.

For rock excavation, except on small jobs, hand drilling has been replaced by power drills, first of the tripod type and later of the hammer type; and improved explosives have displaced black powder.

Advance has also been made in the methods of handling water encountered in trenching. The old hand-operated diaphragm pump is now driven by a direct-connected gasoline engine, and has been replaced on large work by power-driven pumps of several other types.

Marked progress has been made in the construction of concrete sewers, the hand-turning of concrete having been superseded largely by machine mixing, and collapsible steel forms in many instances having replaced the old wooden ones.

Maintenance.—The early sewers and drains apparently did not receive any attention until stoppages or other troubles occurred, and this is practically true at present in many cities. With the organization of sewer departments in the better managed cities, however, regular maintenance has become more general, and has been facilitated by the development in the past fifty years of improved equipment, such as devices for flushing and for removing obstructions.

Plumbing.—Coincident with the development of public water supplies and the introduction of the water-carriage system for sewage there occurred an evolution in the art of household plumbing. The flush water-closet was invented about 1809, but practically all really sanitary types have been developed within the past forty years.

About 1855 attention began to be given to possible dangers to health from the escape of sewer air or sewer gas. Subsequently, strenuous efforts were made to prevent even the most minute escape of sewer air into houses, and there ensued an era of complicated plumbing layouts fostered by elaborate plumbing codes.

The first important plumbing legislation in Massachusetts was in 1882 when the City of Boston was authorized by the Legislature, to regulate plumbing by ordinance. In 1924, the late George C. Whipple, M. Am. Soc. C. E., as chairman of a sub-committee, reported to the Department of Commerce on minimum requirements for plumbing. This report described the situation relative to plumbing codes as chaotic, and disclosed an utter lack of uniformity in legal procedure governing such matters. The findings of this committee marked an important step toward increased standardization and simplification of plumbing practice.

Sewage Disposal

Stream Pollution.—In the early days filthy privy vaults and overflowing cesspools in populous districts led to the construction of common sewers, which discharged generally into the nearest stream or other body of water. By this practice the nuisance at the individual premises was transferred to the point of discharge of the sewer, resulting in an extension of the offensive conditions to the stream or along the water-front. The construction of intercepting sewers with a single outlet, in turn, served to concentrate the polluting material, and with increasing volumes of sewage the intensity of pollution in many instances became intolerable.

In 1872 the State Board of Health of Massachusetts was authorized to investigate the problem of stream pollution, and in the following year William R. Nichols, Professor of Chemistry of the Massachusetts Institute of Technology, submitted to the Board a comprehensive report on sewerage, sewage disposal, and stream pollution. In the same year the late Phinehas Ball was engaged in a study of the Worcester sewage problem, and in 1875 the late J. P. Kirkwood, Past-President, Am. Soc. C. E., made an investigation and report on stream-pollution conditions in Massachusetts. Since that time numerous investigations and reports have been made by other investigators and also by State and Federal departments.

Legislation and Administrative Control.—Nearly all the States have passed legislative measures intended to restrict and control stream pollution. Some of these laws and regulations have been so drastic as to be impossible of strict enforcement. Recently, however, a tendency toward a more rational regulation of the use of streams has developed, as illustrated by the formation of the Sanitary Water Board of Pennsylvania and its classification of streams in three groups, with restrictions for the disposal of sewage and industrial wastes applicable to the needs of each group.

In general, the control of stream pollution has been vested in the respective State departments or boards of health. In the case of interstate streams, only the Supreme Court of the United States has jurisdiction. There have been, however, a few agreements between the departments of health of several States. The first of such agreements was that in 1922 between the Health Departments of Pennsylvania and New Jersey, with respect to the Delaware River. Since then the Health Departments of Pennsylvania, Ohio, West Virginia, Kentucky, and New York have executed general agreements relating

to the streams passing through these States. In this manner it may be possible, by exercising their respective local authority, for the several States jointly to accomplish control of pollution of interstate waters without recourse to Federal authorities.

Scientific Research.—In 1880 the discovery of the bacillus of typhoid fever, by Eberth in Germany, marked the beginning of a new era in sanitation. Previously, the relation of pollution to disease had been but faintly understood, such sanitary works as were built being due to a desire for cleanliness and a sentiment of common decency. Although such motives remain in force to-day, and in fact in many instances govern, the most vital consideration now is "prevention of disease."

Fifty years ago the science of bacteriology was in its infancy, and its application to matters of stream pollution and sewage disposal had not been grasped. In 1877 Shloesing and Muntz, in France, and, in 1882, Robert Warington, in England, proved conclusively that the oxidation of ammonia and organic matter was effected by the agency of living organisms, and Warington proceeded to devise practical methods whereby living organisms could be utilized for the nitrification of the organic matters in sewage.

In 1887 the Lawrence Experiment Station of the Massachusetts State Board of Health was established, under the direction of the late Hiram F. Mills, Hon. M. Am. Soc. C. E. Through its studies the fundamental biological conditions underlying the oxidation processes of sewage treatment became established. These researches have been continued to the present day (1926), constituting an unparalleled contribution, from a single source, to the art of sewage treatment.

Dilution.—Although sewage disposal by dilution was the earliest method adopted by municipalities, it was not until about 1887 that investigation of the factors entering into it was made by the late Rudolph Hering, M. Am. Soc. C. E., in connection with the problem of sewage disposal at Chicago. His studies resulted in the construction of the Main Drainage Canal of the Sanitary District of Chicago, completed in 1900. In Massachusetts studies undertaken at about the same time established the limiting dilution ratios which served as a basis of general practice for many years. More recently much information bearing on the disposal of sewage by dilution has been accumulated. Particularly noteworthy have been the studies made by the United States Public Health Service in connection with the Ohio and Illinois Rivers.

Although seacoast municipalities have seldom adopted methods other than that of dilution, it has often proved necessary, even with them, to take precautions with respect to the location of outlets, so that pollution of shores and bathing beaches should be prevented. In the case of the Boston main drainage works, for instance, special attention was paid to the location of outlets, the sewage being temporarily stored, and released only at ebb tide. In the case of certain seacoast towns where it is desirable to protect shellfish areas from contamination, treatment of the sewage has been adopted, with the addition of disinfection.

Broad Irrigation.—The treatment of sewage to render it inoffensive was undertaken even before the principles involved began to be understood. The

earliest method was that of broad irrigation, or the application of the sewage to relatively level areas of land, where it could become absorbed and purified by the soil. To operate satisfactorily, large areas of porous and easily drained soil were required, and, to avoid annoyance from flies and odors, it was necessary that the "sewage farms", as such tracts were called, be well isolated. Usually an effort was made to utilize the manurial value of the sewage by growing crops on the irrigated fields. Among the first attempts of this sort in the United States may be mentioned the farm established at Lenox, Mass., in 1876, where both subsurface irrigation and broad irrigation were used; the broad irrigation areas at the State Insane Asylum in Worcester, in 1876; at Amherst, Mass., and at Pullman, Wash., in 1881; and at South Framingham, Mass., in 1889. Due to the large tracts of land required, however, and also for esthetic reasons, this method of treatment never was adopted widely in the United States, and, with a few minor exceptions, is no longer in use.

Intermittent Filtration.—As a result of the Lawrence Experiment Station studies there was developed in New England a modified form of broad irrigation, known as "intermittent filtration," by which crude, or settled, sewage is applied evenly to the surface of prepared areas of sand or other fine material a few feet in depth, underdrained by lines of tile with open joints. During its passage through the bed the sewage is purified as a result of the removal, and changing, of the organic matter into more stable substances, by physical and biological agencies in conjunction with atmospheric oxygen present in the interstices of the sand. The process derives its name in part from the necessity of intermittent application of the sewage in order that the air required for the oxidation of the organic matters may enter the voids of the sand. In New England, where soil conditions are favorable, this method was promptly adopted by many towns. The area required is much less than for broad irrigation, but greater than for later types of filters. Owing to the large area required, and the cost of operation, this method is adopted now only for small towns where conditions are favorable.

Chemical Precipitation.—Another early method of sewage treatment is that of "chemical precipitation", involving the addition of lime, lime and sulfate of iron, or other coagulants, to form an inorganic floc, which absorbs and on settling carries down with it particles of suspended solids, leaving a relatively clear liquid. The sludge produced is large in volume and somewhat offensive in character.

The earliest plants of this type were those at Coney Island, New York, put in operation about 1887; at East Orange, N. J., in 1888 or 1889, and at Worcester, in 1890. Later, other plants of this type were built at various places, the most recent large one being that at Providence, built in 1902. Due to the incomplete purification secured, the high cost of operation, and the large volume of sludge produced, chemical precipitation as a means for treating sewage, has gone out of favor, although it is still recognized as of value in the treatment of some industrial wastes. Recently, the City of Worcester abandoned this method of treatment and, in 1925, put into operation a large Imhoff tank—trickling filter plant.

Septic Tanks.—The sedimentation of sewage in tanks, without the use of chemicals, has been practiced for many years. The combination of the sedimentation of solids and their digestion by bacterial action has been utilized in the septic tank, the Travis tank, and the Imhoff tank.

The septic tank is a sedimentation tank, designed and operated so as to foster the decomposition of the settled solids in the absence of oxygen. It was originally believed that nearly complete liquefaction of the suspended solids could be obtained in this manner. Experience has shown, however, that the proportion thus liquefied is much less than was formerly thought. Such tanks, unless covered, frequently are offensive smelling, the treated sewage is black and foul, and difficulties in operation result from the accumulation of the solids in the form of a floating mass of scum on the surface of the sewage.

Similar tanks were first used in America at the State Insane Asylum at Worcester in 1876, and later were adopted at other places. An installation at Saratoga Springs, N. Y., in 1903, led to a lawsuit brought by the owners of certain septic tank patents, which resulted in judgment for the plaintiffs. From the beginning of septic tank patent litigation the consensus of opinion among American sanitary engineers has been that the patents covered principles and practices which had long been known and publicly used. Consequently, under these patents, which long since have expired, the payments were few and small.

Imhoff Tanks.—The favor in which septic tanks were once held later turned largely to the two-story tank in which the processes taking place in the septic tank are separated, sedimentation occurring in an upper compartment, and digestion of the solids going on in a chamber below, separated from the one above by a sloping partition containing narrow slots through which the solids pass into the lower compartment.

This tank was developed for the Emscher District, in Germany, and was introduced into this country largely through the efforts of Mr. Hering.

The earliest plant in America was that at Madison-Chatham, N. J., in 1911, and the first large tanks were constructed at Atlanta, Ga., in 1912. Since then there have been many important installations, among them those at Rochester, N. Y., Fitchburg, Mass., Cleveland, Ohio, and Philadelphia. This tank is a material improvement on the older septic process in that the treated sewage is less offensive and the solids may be digested to such a degree that the resulting sludge is practically free from odor and can readily be dewatered on porous beds. In some places, however, difficulties have been experienced due to unfavorable sludge digestion, which has resulted in foaming or in excessive scum formation. Recent work, at the New Jersey Sewage Experiment Station, and at other places, indicates that by controlling the reaction (pH) of the sludge and scum, proper digestion can be secured.

Separate Sludge Digestion.—It has been held by some engineers that the processes carried out in the two-story tanks can be accomplished better in two separate tanks, the solids being settled out in one and drawn or pumped from it into the digestion tank. In some cases the sedimentation tanks have been

equipped with mechanical devices for the continuous removal of the settled solids.

The earliest attempt at separate sludge digestion on a large scale in America was at Baltimore in 1912, where open tanks were introduced for the storage during digestion of solids removed from preliminary settling tanks. On the whole, the Baltimore experience, although not yet fully satisfactory, has demonstrated that sludge may be digested in separate tanks and that this process may prove of advantage in some cases, if conditions favorable to the requisite biological action can be provided and maintained.

Separate sludge digestion generally has resulted in acid fermentation accompanied by offensive odors and the production of a foul-smelling sludge. Research at the New Jersey Sewage Experiment Station and at Harvard University has shown the importance of controlling the reaction of the sludge and the advantage which can be secured by maintaining a favorable temperature. At Plainfield, N. J., experiments relating to this subject have been carried out on a large scale, and at Boonton, N. J., a plant has been constructed in which provision has been made for collecting and burning the gases from sludge digestion and for utilizing the heat therefrom for heating the glass-housed sludge beds and the contents of the separate sludge digestion tanks.

Contact Beds.—Because of the large areas required, and the unavailability of suitable soil for broad irrigation or for intermittent filtration, coarse-grained sewage filters, in the form of contact beds, originated in England in the early Nineties and were adopted somewhat later in America. Contact beds consist essentially of tanks, filled with broken stone, coke, or other coarse medium, which are alternately filled with settled sewage and emptied, periods of several hours being allowed for standing full and remaining empty.

Oxidation and nitrification are brought about by the film of micro-organisms growing on the surface of the medium, the supply of oxygen being obtained from the air entering the voids of the material during the draining period. Comparatively few contact beds have been built in America, and several of those have now been replaced by other forms of treatment. This was due to the almost coincident development of trickling filters, which are superior to contact beds in some respects, chief among them being the much larger volume of sewage which can be treated on a unit area of trickling filter.

Trickling Filters.—Trickling filters, also adopted in England on a large scale prior to their use in America, differ from contact beds in that the sewage is distributed more or less uniformly and continuously over the surface of beds of coarse material. A trickling filter is primarily a bed of broken stone several feet deep, laid on a concrete floor covered with a system of underdrains. Settled sewage is applied intermittently, at short intervals, to the surface of the filter in the form of fine drops, by using symmetrically spaced spray nozzles or other devices, comparatively few mechanical distributors, such as are commonly used in England, having been built in America. As the sewage is sprayed through the air and passes through the porous bed, atmospheric oxygen is absorbed and is utilized in the biological oxidation and

mineralization of the organic matter. The effluent is usually settled in order to remove humus-like solids which, from time to time, escape from the filter and thus prevent it from becoming clogged.

The first municipal filter of this type to be put in service was that at Reading, Pa., in 1908. At present, trickling filters preceded by Imhoff tanks, probably constitute the type of treatment most generally in use in America. The largest installation of such filters is that at Baltimore, where about 30 acres are in use.

One unsatisfactory feature of the trickling filter is the occurrence at times of large numbers of the small gray fly, *psychoda*. Control of these flies has been accomplished by flooding the filters for brief periods at regular intervals, during the breeding season, although this has interfered somewhat with the efficiency of the filters. At Schenectady, N. Y., during the last two years, considerable success has attended an effort to control this fly by treating the settled sewage, just prior to its application to the filters, with either bleaching powder or liquid chlorine. The control of odors around the Imhoff tanks and the trickling filters, by the treatment of the sewage with liquid chlorine, is also being investigated, and gives promise of beneficial results under some conditions.

Activated Sludge.—During the past ten years the activated sludge process has been adopted in a number of places in the United States, Canada, and abroad. The process is the outcome of experiments on the aeration of sewage, by numerous American workers, particularly the investigations at the Lawrence Experiment Station in 1912, which led to the work, in England, of Fowler and Mumford in 1913 and of Arden and Lockett in 1914. This treatment consists essentially of aerating sewage with a mixture of aerated or activated sludge and subsequently allowing the mixture to settle. The development of the process as a practical means of treating sewage has resulted largely from investigations made at Milwaukee, Chicago, Indianapolis, Ind., and several other places.

Beginning in 1914, the City of Milwaukee conducted what is undoubtedly the most extensive large-scale experimental investigation ever carried out in the field of sewage treatment. Based on the results of these experiments, a plant, the largest in the world at present (1926), has been constructed at Milwaukee, which was put into operation in 1925. At present, there are comparatively few activated sludge plants in America, that at San Marcos, Tex., built in 1916, having been the first. Large plants have since been constructed at Houston, Tex., Indianapolis, and Chicago. In the latter city a plant for the treatment of the sewage from a population of 800 000 is now under construction.

Racks, Grit Chambers, and Screens.—In order to protect pumps and other mechanical equipment from clogging and injury, and to simplify and improve the efficiency of various processes of treatment, it has become general practice to provide preliminary treatment for the removal of trash, mineral matter, and the coarser suspended organic substances. In a few cases provision has also been made for the removal of floating oil and grease.

Cage racks for the interception of trash were constructed at the main drainage pumping station in Boston and first operated in 1884. Grit chambers for the removal of the heavier mineral solids were built at Worcester in 1904. Stationary bar screens, manually and mechanically raked, have been in use for a long time, but only during the past 15 or 20 years has there been a marked development in fine, moving screens cleaned by brushing or flushing. The first of these in America was the Weand screen built at Reading, in 1908. This was followed by the Riensch-Wurl screen at Rochester in 1916 and later by others, such as the Dorrco and Link Belt screens, at various places. During the last few years such screens have been used for treating sewage preparatory to more complete treatment by other processes, and for removing the larger and more easily visible floating and suspended matter where more complete treatment is not necessary.

Sludge Disposal.—One of the troublesome features of sewage treatment has been the disposal of the solid particles removed by screening or by sedimentation. In general, screenings have been used for filling, or have been plowed under in an effort to utilize their fertilizing properties. To a limited extent, also, screenings have been incinerated. Sludge from septic and single-story settling tanks is generally offensive and difficult to dry satisfactorily on beds of sand or similar material. Properly functioning two-story tanks produce sludge which is easily dried and inoffensive. As rains and freezing weather interfere with drying in the open air, beds have been built with covers, like greenhouse structures, notably at Marion and Alliance, Ohio. At Houston and Indianapolis activated sludge has been lagooned.

During the early years of the treatment of sewage, attempts were made to utilize its manurial value by growing crops on the areas used for broad irrigation. Later, there was considerable effort to utilize the fertilizing ingredients in the sludge resulting from chemical precipitation. In some cases such sludge was dewatered by the common filter press, notable plants being at Worcester and Providence.

Recently, air-dried digested sludge has been sold to farmers at Baltimore, Rochester, and Schenectady. The value of such material is small, because of its high water content and the low proportion of fertilizing ingredients contained in it. In some localities it appears to have been profitable for farmers to haul and utilize such sludge, even if a nominal price had to be paid for it.

In the case of activated sludge, the proportion of fertilizing ingredients, particularly nitrogenous compounds, is materially greater than in sludges from other processes, and, therefore, the opportunity for its profitable utilization as a fertilizer has proved somewhat attractive.

By far the greatest progress in this direction has been made at Milwaukee, where a large plant has been built for dewatering and drying activated sludge, thus converting it into a marketable fertilizer which is being sold under the name of "Milorganite." At Chicago, also, for several years, activated sludge has been dewatered, dried, and converted into fertilizer.

Disinfection.—Where treated sewage is tributary to public water supplies or where effluents are discharged into tidal waters used for oyster culture, it

has become customary to provide for disinfection with chlorine. The first plant for this purpose was at Brewster, N. Y., on the Croton water-shed, where an electrolytic plant for the production of chlorine from salt solution was built in 1892. In 1909 the efficiency of hypochlorite of lime for the disinfection of sewage, was demonstrated, and, at present, Providence is using this agent to disinfect the effluent from its chemical precipitation plant. Liquid chlorine, however, is used more generally. Chlorination plants have been installed at Cleveland and at a number of other places where raw or treated sewage is discharged into waters used for bathing.

Industrial Wastes.—England, due to her smaller streams, was compelled to devote attention to the treatment of industrial wastes, as well as of sewage, long before it became urgent to do so in America. Rafter and Baker, in their book, "Sewage Disposal in the United States," published in 1894, state as follows:

"Thus far in this country manufacturers have not, except in a few instances, been compelled to purify their own polluted wastes, and inasmuch as few have undertaken the purification, of their own volition, very little experience under American conditions has thus far been gained."

Even to-day the foregoing statement holds true in considerable degree, although that part dealing with the lack of experience under American conditions should be modified. In New England and elsewhere numerous plants have been built for the treatment of industrial wastes. Furthermore, manufacturers are less wasteful than in previous days, and the quantities of polluting matters discharged in the waste waters are in some cases somewhat less. In general, the processes used in treating industrial wastes include sedimentation, chemical precipitation, intermittent filtration, oxidation in trickling filters, or, in short, processes or combinations of processes which have been found applicable to the treatment of sewage.

Increase in Sewage Treatment.—In 1875 not one of the sixty-seven cities having a population of 100 000 or more by the 1920 Census, used any method for the treatment of its sewage. By 1900 only two of these cities—Worcester and Reading—had built treatment plants, their aggregate population then being approximately 197 000. At present (1926) about twenty of these cities, with a total population of approximately 6 500 000 by the 1920 Census, have treatment plants. Of these plants those receiving the sewage from a population of about 3 700 000 consist of tanks only, or of tanks preceded by screens; the remaining plants, receiving sewage from about 2 800 000, provide for tank treatment combined with some oxidation process, such as activated sludge or trickling filters.

The change in the art of sewage treatment chiefly by biological processes is illustrated by a comparison of the space required by different types of plant for the treatment of a unit volume of sewage—for example, that from a city of 100 000 population. The early method of intermittent filtration, including settling tanks, sludge beds, and sand filters, would need a total of not less than 130 acres and 23 000 000 cu. ft.; the more modern Imhoff tank—

trickling filter plant, with sludge beds and appurtenances—would require about 10 acres and 3 000 000 cu. ft.; and a plant for the most recent activated sludge process would require about 2 acres and 1 000 000 cu. ft.

Operation of Treatment Plants for Sewage and Industrial Wastes.—Although much progress has been made in the art of sewage treatment, and many sewage treatment plants have been built, there remains considerable lack of realization, on the part of the public and of municipal officials, of the necessity for continuous, careful, and intelligent operation of such plants. Prior to 1900 only about two sewage treatment plants in the United States were under the control of resident technical operators, these plants being at Brockton, Mass., and Worcester. By 1910 several other treatment plants were under technical supervision, notably at Columbus, Ohio, Plainfield, and Reading. Since that time many new plants have been constructed, of which the larger have been provided almost invariably with technical operators. The smaller plants, however, in far too many instances, are operated without proper supervision.

Technical supervision of plants for the treatment of industrial wastes is even less common, largely because such plants are a source of outgo rather than of income, and, consequently, do not enlist the interest of the proprietors. On the other hand, some progressive manufacturers have provided for the expert technical supervision of intelligent non-technical operators, with excellent results.

Summary

Reviewing the history of the last 150 years, it is seen that the advance in the development and application of the art of sewerage and drainage of towns, although slow at first, has attained such an acceleration that there is a wide gap between the conditions as of the beginning and the ending of the sesqui-centennial period.

In the early years the privy, the cesspool, and the drain to the nearest watercourse prevailed. Cities were without water supplies and without sewers. The well and the cesspool or privy existed side by side. Visitations of cholera and yellow fever occurred from time to time, and typhoid and malarial fevers were prevalent. The relation to disease, of parasites conveyed by food and drink, or by insect hosts, was unknown. The general death rate was abnormally high, viewed in the light of present conditions, and little attention was given to the sanitation of such towns and cities as existed.

During the latter part of this period, discoveries in the science of bacteriology, relative to the causation of disease and the various methods of its transmittal, have resulted in rapid strides in the sanitation of the environment. The prevention of pollution of water supplies, their purification in case of contamination, and the proper removal and disposition of the waste products of human activities, have made remarkable progress. Resulting in large measure from the application of scientific knowledge, coupled with engineering skill in the control of man's environment, cholera and yellow fever have dis-

appeared, typhoid fever and other water-borne diseases have almost been eradicated, and the general death rate has been diminished materially.

Progress in the field of sewage disposal has been more spectacular than in those of sewerage and drainage, using these terms in a restricted sense. Even fifty years ago, the principles of sewage purification, either solely by natural means or by artificial processes utilizing natural agencies, were not known. To-day, many of these principles are known, and processes are available by which municipal sewage can be purified practically to any degree desired.

The fundamental reason for progress has been the ever-broadening development of science and its application to the art of sanitary engineering. Such application of knowledge has been greatly stimulated by the ever-increasing growth in population and the aggregation of this population into communities of restricted area.

The Future

If it were possible to project a curve of the accumulation of knowledge, it would be less hazardous to prophesy future developments.

In the field of sewerage and drainage there does not seem to be any reason to anticipate radical departure from the principles now established. Data useful as a basis of design, however, will become more complete, and the application of engineering skill will result in better design and construction as time goes on.

Household plumbing will be somewhat simplified, but there will be a still further increase in plumbing conveniences and a greater volume of household sewage. This increase, however, will be offset in some degree by general metering of water supplies and by greater economy in the use of water in the industries.

With continued increase in density of population there will be greater demand for the proper regulation of stream pollution. It is probable, however, that the comparatively recent tendency in some places to attempt a complete cleaning up of streams, will give way to a policy of reasonable use, subject, however, to far better control than is exercised in most localities at present.

With an increasing number of workers in the field, it is certain that better methods of sewage treatment will be devised and developed. The progress of the last fifty years has been confined primarily to the utilization of biological forces, the means of accomplishing which will be greatly improved in the future. The most promising opportunity for the development of new and better methods now appears to lie in the field of physical chemistry, research in which may show a way by which organic colloids can be removed from sewage without the aid of biological agencies. Such a development may lead to simpler methods, less susceptible to temporary derangement. Although it seems improbable that a net income will be derived from the recovery of the fertilizing ingredients of sewage, it is probable that sewage sludge will be utilized as fertilizer in an increasing degree.

The serious handicaps under which most sewage plants are operated to-day, due to lack of adequate funds and proper management, will be overcome in the course of time. The most promising means of accomplishing this is State legislation, of which the Ohio Act of April 5, 1923, is a forerunner. This provides for sewer rentals to cover the cost of operation and maintenance of sewerage works.

The work accomplished during the past 150 years in the field of sewerage and drainage of towns has been the result of the effort of relatively few individuals. Looking backward, the achievements appear to have been great, notwithstanding the difficulties resulting from lack of knowledge. The future increase in population and the raising of the standards of sanitation will afford large opportunities. Looking forward, it appears that the number of workers in the field is destined to increase, and that the accumulation of knowledge in science and in the arts may well enable the engineers of the future to accomplish results even more remarkable and beneficial than those of the past.

STREET CLEANING AND THE COLLECTION AND DISPOSAL OF REFUSE

By Samuel A. Greeley,* M. Am. Soc. C. E.

General Statement

The cleansing of cities involves the removal and disposal of the solid wastes resulting from the activities of the inhabitants. These wastes collect in various ways on the surfaces of streets, yards, vacant areas, and roofs. Such solid wastes, commonly termed refuse, include all the products of community life except sewage. Refuse materials comprise garbage, ashes, rubbish, street dirt, manure, trade refuse, dust, etc. By manual labor and by the use of wagons, trucks, and other special equipment, refuse materials are collected and disposed of.

In the absence of regular and frequent removal, such materials accumulate principally on streets and in alleys, and to a less extent on vacant areas and in yards. There has been, and still is, a marked tendency on the part of individuals to throw their refuse into the streets. In the early days, the hog was the common scavenger, and roamed about and partly cleaned the city. The following was written in the early Fifties:†

"Our streets and alleys should be cleaned everywhere, especially in and around the neighborhood of the square. The brick bats, trash, old hats, old boots and shoes, rags, bones, manure and many other things which grace our streets, should be hauled off, and hog holes filled up."

The need for final disposal was not yet clearly recognized. People in Quincy, Ill., considered geese better scavengers than hogs, and so let them roam the town.

The rapid growth of cities has made for a constantly changing problem in connection with city cleaning, and it has been difficult from the average point of view to keep pace with the necessary demands.

Gradually, people began to understand that the accumulation of refuse is unhealthy. Dr. Frank M. Wells, Health Officer of Cleveland, Ohio, in 1876, wrote:

"It is a sanitary necessity that cities should be kept clean and their refuse, which is organic matter in a state of decomposition, should be promptly removed. This can be accomplished with greater facility when streets are paved, and therefore the paving of streets demands the attention of sanitary bodies. * * * The importance of a constant and thorough cleaning of the streets can not be over-estimated. * * * Of more importance, perhaps, than the condition of the streets, is that of the yards connected with the dwellings, since they are in such close relation with the house that the effect of filth deposited in them is more readily felt."

Refuse left without removal promotes the breeding and growth of vermin, mosquitoes, flies, and rats, all of which tend to spread diseases among human

* (Pearse, Greeley & Hansen), Chicago, Ill.

† In *The Journal*, Springfield, Ill.

beings. During certain seasons, the refuse dries, and is pulverized to dust, which fills the atmosphere, to the annoyance of the people and often to the great damage of merchandise. Such influences are directly proportional to the quantity of refuse and the density of population. The quantity of refuse per unit or area in a community increases with the density of the population, and the effect of such accumulations on public health and comfort is greater in crowded, heavily populated districts than in open rural communities. Thus, the development of sanitary engineering in the field of city cleaning during the past 150 years follows closely the development of cities and the sharp increase in urban population.

Growth of Cities

The first considerable growth of cities in the United States began during the twenty years preceding the Civil War. The winning of the Mississippi Valley, the building of railroads, sundry improvements in farm machinery, and successful inventions earned an era of prosperity and stimulated industry. Cities grew. Following the Civil War and the development of the West, factories were built and people flocked to the cities. The increasing density of population in several large cities is shown by Table 3, the data for which are taken from the U. S. Census.

TABLE 3.—Density of Population in a Few American Cities.

City	Population per Acre.	
	1900	1924
New York, N. Y.	18.6	31.5
Philadelphia, Pa.	15.5	24.2
Boston, Mass.	21.4±	28.3
Chicago, Ill.	13.9±	24.1
St. Louis, Mo.	14.7	21.0
New Orleans, La.	2.3	3.6
Average	14.4	22.1

This concentration of population forced the adoption of special measures for city cleaning. In some notes on street cleaning in the Common Council Manual of New York City (1862), it is stated:

"In May, 1701, the assistant aldermen of the different wards were instructed to call on the several inhabitants in their respective wards and ascertain what they are willing to pay towards cleaning the streets and carrying away the dirt; but this method not meeting with a proper response on the part of the inhabitants, an order was made in the same month that the inhabitants of the city, on every Friday, sweep the dirt in heaps before their respective premises * * * for removal by the city cartmen."

In 1887, the Ladies Health Protective Association addressed a memorial to the Mayor of New York, stating that "Modern science has fully exposed the imminent dangers that beset health and life in a malodorous and dust covered

town" and, after reviewing methods of city cleaning, urged that "the street cleaning system of New York be wholly reorganized, or that a far different spirit of energy and efficiency should be infused into it."

Thus, if the need for city cleaning has grown with the cities, the effectiveness of city cleaning has developed more or less consistently with progress in municipal government and the enlightenment of public opinion. The contrast between the cleanliness of New York City under the administration of the late Colonel Waring and during the next four years under Tammany as described by a sanitary engineer, William F. Morse, of New York, may be cited as follows:

"Beginning in 1898, with the inheritance of a well-organized and thoroughly equipped service, with labor and money-saving devices and apparatus in running order, with plans and purposes well-defined for carrying on a practical and successful line of work in an honest and economical way; now at the end of four years, as the result of incompetent management and complete surrender to the machine politicians, the department is in a position of absolute contempt."

Progress has been secured in growing cities, despite periods of stagnation caused by incompetent management. The sharp reduction of the general death rate from around 25 per 1 000 about 50 years ago to less than 15 at present (1926), has been caused by improved city cleaning as well as by advances in water supply, sewerage, and public health administration.

Elements of Progress

Broadly speaking, progress in city cleaning depends on the degree of excellence of municipal government, and on the methods and equipment developed by sanitary engineers for use by city officials. It may be said, then, that two of the major elements of progress in this field are (*a*) the intelligence and character of public opinion, as it determines the character of the municipal government; and (*b*) the zeal and skill of outstanding individuals leading the way beyond their contemporaries. The latter provides the facilities for improved methods of city cleaning and the former marks the extent of efficiency in operation and results.

The excellence of municipal government is, of course, largely an outgrowth of public opinion. The more intelligent, experienced, and outspoken the public opinion, the better, in the long run, will be the municipal government. This, in turn, stimulates the science and practice of city cleaning. Outstanding events which picture clearly to the average person important factors of public health mark forward steps. The picturesque descriptions of the work of Pasteur among cattle and silk worms are typical. Perhaps in America the great losses from typhoid fever spread by flies from privies during the Spanish-American War stirred public opinion toward better standards of municipal cleanliness more than any other single event. The conquest of yellow fever by Gorgas resulted from improved cleaning of cities as well as through drainage, and demonstrated to the public the gain in public health through public hygiene. During the quarter century following the Spanish-

American War, progress in city cleaning was more marked by far than at any other time.

Among the names of those active in city cleaning work within memory are Wells, Waring, Landreth, Parsons, Goodnough, Whinery, Morse, and Hering. Such men conducted scientific investigations, studied experience here and abroad, and applied their knowledge to actual operation. One of the first comprehensive investigations of the subject was begun in 1887 by the Garbage Committee of the American Public Health Association, of which the late Rudolph Hering, M. Am. Soc. C. E., was Chairman. One of the best early efforts in this direction was by Dr. Frank M. Wells, Health Officer of Cleveland, in 1876. In a notable report to the Board of Police Commissioners entitled "Filth and Its Relation to Disease", Dr. Wells states the fundamental aspects of city cleaning. After limiting his subject matter to sewers and scavenging, he disposes of the then conflicting theories of disease—one holding that diseases spring spontaneously from filth, and the other that filth furnishes a favorable atmosphere for the multiplication of the organisms of disease—by the following statement:

"Practically these two theories are identical since there is but little difference, whether filth directly causes disease, or is an essential factor in the development of the organisms which produce disease.

"That unsanitary conditions bear a certain relation to a particular class of infections, is now the opinion of the majority of the medical profession."

Early Practice

The beginnings of city cleaning were undoubtedly in street cleaning. Residents deposited their refuse in piles in the street whence it was removed, by a public scavenger, to a public dump beyond occupied districts. Roaming hogs disposed of the garbage they could eat. Thus, hog feeding of garbage and land fill had their beginnings. Practice in Cleveland in 1876 is thus described by Dr. Wells:

"The refuse, which is usually deposited in the yards, consists of ashes, swill, and garbage, which, under the present ordinances governing these articles, form, I believe, a very prolific source of filth. These ordinances provide that no ashes shall be mingled with the swill and garbage (the very means which would render them inoffensive), and that they shall be removed by the Contractor not less than two times a week during the months of May, June, July, August, September, and October, and as many times oftener as may be necessary to prevent the swill deposited from becoming offensive; and not less than once a week during the rest of the year, upon notice from the householder being sent to him. By another section, every householder is obliged to provide water-tight receptacles for the swill and garbage which may accumulate during 48 hours."

Practice, prior to 1887, and its trend for the future, is outlined in the Memorial of the Ladies Health Protective Association as follows:

"Our third point is, that neither ashes nor garbage should ever be placed on the pavement, but that, like the mail carriers, the collectors of house refuse should have a whistle to warn of their coming, and that when they ring, the cans should at once be taken out of the house, emptied into the cart, and returned at once into the house. We think that refuse carts should have high sides and a sloping cover with a hopper in the center, and that every house-

holder should be required to own a galvanized iron receptacle fitted with a cover and with a sliding bottom, so that when placed over the hopper and the slide pulled out, the contents will be received into the closed cart, and the now intolerable blowing of ashes and dust about the streets from the carts be thus avoided. We are agreed that, to get rid of the house ashes and garbage, and of the street sweepings, crematories should be built, similar to the so-called 'Destructors' and 'Carbonizers' in use in England, and that the house ashes and garbage should be burned in the Destructors and the street sweepings in the Carbonizers, and the residuum used for making mortar in one case and fertilizers in the other, as is now so successfully done in Leeds and other English cities. The system at least pays for itself, and if adopted here, the wasteful, pernicious, and disgusting practice of dumping city refuse either inside or outside of the magnificent bay of New York, might be wholly discontinued."

Dr. Henry I. Bowditch, of Boston, Mass., gathered statistics for the Centennial Exposition in 1876 from about seventy cities in the United States, and summarized them as follows: In about twenty-five of the seventy cities, the house offal is moved in carts. The remaining forty-five places report a variety of methods, such as: (1) Thrown into cesspools; (2) fed to hogs; (3) thrown into river; (4) dumped in valley; and (5) used as fertilizer. Thus, less than one-half the cities reporting appeared to have a regular collection service.

The collection and disposal began with dumping refuse on the streets, whence it was gradually removed by hogs, scavengers, and the disintegration of traffic. Then came removal and dumping by the municipality, the householders being required to provide cans. Special methods of disposal began in the decade, 1880 to 1890. In 1873 a report to the American Public Health Association by Dr. C. A. Leas, of Baltimore, Md., states as follows:

"* * * Again, in other localities, the scavenging service is wholly or partly intrusted to Contractors, who mainly regard their own pecuniary interests rather than the public health. The municipal authorities of some towns and cities employ scavenging forces, but without fixed regulations. * * * In some cities the collection of kitchen offal and house ashes is made separately by two sets of carts, with a view to the utilization of the ashes for the filling of sunken lots, and the vegetable and animal offal for the feeding of swine. * * * Whilst in others it is collected together. * * *."

The report then describes a complicated system of composting the garbage with sifted ashes, a tank treatment of night-soil, with a decanting of the liquids to the compost pits, and the final preparation of a fertilizing material. This process appears to have been tried at Baltimore at about this time, but evidently was not continued.

General Development Since 1876

The condition of the streets and the collection of refuse are closely related to the habits and actions of the residents and housekeepers. Their co-operation is important. The general development of city cleaning has depended a great deal on the increased understanding of the public. Much educational work has been accomplished by street-cleaning departments and those charged with the collection and disposal of refuse. The growing familiarity of foreign sections of the population of American cities with city cleaning rules and regulations and the efforts of the cleansing departments have facilitated and

improved the work. Great numbers of kitchen cards, based on ordinances regulating the house treatment of refuse, have been distributed. The separation of refuse materials at the house, where ordered, is much better secured. Although not so readily landmarked, better co-operation by the public has contributed largely to the progress of city cleaning in the last half century.

Street cleaning and collection equipment has been developed with the advance in manufacturing and the development of motor vehicles. Perhaps even more important is the better understanding gained by experience in operation, of the fundamental principles involved. Frequent time studies of the work of collection units have been made, and careful consideration of the relations between the size of the wagon, its loading height, the location of the receptacles, the speed of loading, the length of haul, and means for secondary transportation have secured better economy and efficiency. Small single-horse carts have given way to larger wagons, the tractor-trailer system, and motor trucks. Long hauls have been handled better by secondary methods of transportation, such as trains of tractor-drawn vehicles, railroad cars of special design, barges, and large trucks. Street flushers, snow loaders, sweeping machines, and similar equipment have become available. The displacement of horses by automobiles has lessened the work of street cleaning, and the extension of pavements has made the work done more effective. Thus, a sounder balance between hand and machine work has been secured.

Development in Reduction Plants

The reduction of garbage into grease and fertilizer was first practiced on a working scale in Buffalo, N. Y., in 1887. The Merz process was used, in which the refuse was first dumped into a large hopper from which the free water was allowed to drain. It was then spread out, and cans, bottles, rags, metals, bones, etc., were picked out. The remaining garbage was then passed through hot-air dryers and the partly dried material treated with a solvent for the extraction of grease and the recovery of the solids as tankage or fertilizer base. This process, with some modifications, is still used in Chicago, Ill., Detroit, Mich. (in part), and elsewhere. Other processes for the recovery of grease and fertilizer were invented and plants built. In them the problem of odors and nuisance was difficult to solve.

A notable development in garbage reduction is known as the Cobwell process (1912). The garbage is first placed in a reducer, which is a round, flat-bottomed, covered, steam-jacketed tank, with a diameter of at least twice its height. In this, the garbage is flooded with naphtha and then cooked by admitting steam to the jacket under a pressure of 85 lb. per sq. in. Agitation arms in the reducer keep the contents in motion. The temperature of the garbage and naphtha is held at less than 200° Fahr., under which conditions the original moisture content is carried off with the vaporized solvent. Thus, the garbage is dried. When the water is gone, the temperature in the reducer rises, and the dried garbage is washed several times with naphtha (gasoline) to extract the grease. Finally, the residual material or tankage is dried in the reducer with live steam. Thus, the entire process is conducted in a single tank without exposure, and odor control is better secured. Recently, economies in

operation have been made by a partial preliminary drying in hot-air dryers, but with an increased odor hazard.

The greater unit value of the dried product (tankage) as a stock food instead of a fertilizer has led to further developments. At Indianapolis, Ind., Dayton, Ohio, and Michigan City, Ind., so-called "Morrison" plants have been built. In this process the garbage is first placed in vertical digesters or cookers, holding 4 or 5 tons, where it is cooked with live steam for several hours. It is then pressed in the tank under live steam, grease and water being drawn off to a settling tank where the grease is recovered. The tank or digester is then closed tightly and the residue dried further under a partial vacuum by admitting steam to the jacket. After drying, a door near the bottom of the digester is opened, and the dried material is discharged on a conveyor. The dried material or tankage is then separated, screened, and ground for the market. Some grease is recovered by skimming the liquid drained from the digester, but it is understood that a part of it remains in the residual tankage.

At present (1926), following operations at Toledo, Ohio, a so-called "Pan-American" process plant is being installed at Kansas City, Mo. This process involves a separation of foreign materials, such as metals and glass, from the garbage, with a drying operation. The dried material is then prepared for sale as a stock food.

Except as just stated, developments in garbage reduction plants have been chiefly in better equipment and machinery. Experience gained in operation with dryers, digesters, piping, and other apparatus has resulted in better and more durable design and construction. Materials better able to withstand the corrosive action of the hot liquids and gases are used. Thus, improvements have come in design and construction, rather than in the invention of new processes.

Incineration

Incineration of garbage in the United States was first practiced in 1885 when a plant to burn garbage with coal was designed by Lieut. H. J. Reilly, U. S. A., for the Federal Government, and built on Governors Island, New York. Designs by Engle, Dixon, Decarie, Lewis, Morse, and others, for burning chiefly garbage with an additional fuel followed, and plants were built by several cities. In the meantime, in England and on the Continent, many incinerators or so-called destructors were built for burning a mixture of garbage, ashes, and rubbish, and this was burned generally without additional fuel.

In 1908, J. T. Fetherston, M. Am. Soc. C. E., introduced mixed refuse incineration into America and built plants on Staten Island. Other plants of this type were built in Seattle, Wash., Milwaukee, Wis., Paterson, N. J., Memphis, Tenn., Atlanta and Savannah, Ga., and elsewhere, generally prior to 1915. In these plants a mixture of garbage, ashes, and rubbish was burned under boilers, and some power was developed. Such works were generally situated nearer the centers of the cities than was the case with reduction plants, as the odor hazard was less.

Recently, there has been an adaptation of incinerators of this type to the burning of garbage and rubbish only. Experience indicated that ashes added more to the cost of incineration than was justified by their fuel value, and, as they could be dumped satisfactorily, it was more expedient in many cases not to burn them. Adjustments in the design included a wider drying hearth, deeper grates, the use of occasional small quantities of additional fuel, and proper flue areas. Such furnaces operate generally with a forced draft of pre-heated air. Incinerators for this service have been built in New York, Brooklyn, N. Y., Philadelphia, Pa., Asheville, N. C., Muskegon, Mich., Charleston, W. Va., and elsewhere.

Perhaps the chief addition to English experience contributed by American designers has been the development of mechanical charging devices and ash-removal apparatus. Many plants are equipped with charging hoppers that are controlled by sliding doors operated by hydraulic pistons and worked by the fireman. The hoppers are filled from above by grab-buckets or by hand from storage hoppers. This arrangement permits 24-hour operation and the use of refuse of such quantity and quality as to maintain the best rate of combustion. A few plants have mechanical clinkering or ash-removal, but, with the omission of ashes from the mixture burned, there has been less need for this device.

Meanwhile, designs have been developed from the older garbage furnaces for burning rubbish with the garbage with a reduced quantity of additional fuel. Such furnaces are of larger internal capacity than the destructor type, and much of the material is discharged directly into them from the collection wagons. Such plants have been built in many Southern cities and in smaller and medium-sized cities of the North. Table 4 contains data indicating the furnace capacities of various types.

TABLE 4.—Data on Incinerator Furnaces.

(Approximate capacity, 100 tons.)

Type of plant.	Area, in Square Feet.		Inside volume of furnace, in cubic feet.	Combustion chamber volume, in cubic feet.	Outside storage hopper, in cubic yards.
	Burning grate.	Drying hearth.			
A	433	192	4 000	1 410	0
B	120	360	3 992	.....	0
C	100	62	976	1 006	290
D	120	80	1 110	924	152
E	181	142	2 296	1 464	150
F	120	....	1 280	2 110	218

Incinerators are still generally purchased by municipalities under general specifications requiring the fulfillment of stated guaranties covering capacities, temperatures of combustion, and operating costs. This practice opens the bidding to a variety of designers, and the selection of a contractor may be decided by a comparison of the total annual costs and the likelihood of satisfactory operation, as judged by records of routine service elsewhere. There is, at present, a tendency toward more detailed specifications and general plans.

Other Methods of Disposal

Perhaps feeding to hogs has changed from early practice more than any other method, although a wide range in operating still prevails. Hogs used to be allowed to roam over dumps (in Louisville as late as 1917) and even streets searching for garbage. Now, better house treatment is practiced, and cleaner, fresher material is hauled to the hogs at one or more farms. It is spread on concrete platforms, and the unconsumed parts and hog manure are gathered and disposed of generally by burial. Shelters and running yards are provided, and the animals are inoculated against cholera, which items have much improved this method of disposal.

Dumps continue to be a chief method for disposing of street sweepings, ashes, trade refuse, some rubbish, and some garbage, and great areas of low and submerged lands near cities have been reclaimed. Parts of Chicago, Boston, and other cities have been converted from low marsh land to drainable upland by filling with refuse. In Seattle, Portland, Ore., and other Pacific Coast cities, garbage has been dumped successfully with a proper cover of street sweepings, waste building materials, and other relatively inert substances. In the smaller cities some garbage is buried. Dumps are better regulated, with less miscellaneous scavenging, better control of fires, and more cover with inert materials. The use of other methods of garbage disposal has influenced the making of better dumps.

Odor Control

The growth of cities and the increased quantity of refuse has emphasized the dangers and discomforts caused by atmospheric pollution. Not only have odors been produced by the special methods of garbage disposal developed, but those from dumps and hog farms have become a nuisance to more people, and hence have demanded attention. Probably no other branch of sanitary engineering causes such frequent recourse to the Courts for the abatement of nuisance. Consequently, measures for odor control and elimination are a mark of progress in this field. Some of the steps which have been taken in America are:

a.—The separation of garbage from other refuse to be disposed of on dumps, so that dumps are more sanitary.

b.—The separation of rubbish from other refuse to prevent fires, smoke, and odors from dumps.

c.—The use of water-tight collection wagons, washed and painted more frequently.

d.—The careful covering of organic matter on dumps with soil or other relatively inert material.

e.—The use of concrete feeding platforms at hog farms, and the better disposal of residues.

f.—Not only the use of incinerators, but improved design and construction, including better facilities for receiving and handling refuse at the plant, and more ample combustion chambers.

g.—Chlorination, scrubbing, and other improved methods of treating dryer and digester gases from reduction plants.

h.—Better floors and buildings, and an appreciation of the advantages of general plant cleanliness.

i.—Careful selection of disposal plant locations, with reference to the cost of delivering refuse and the character of plant.

Summary

The cleansing of cities, including street cleaning and the collection and disposal of refuse, has thus progressed during the past 150 years with their growth and the development of sanitary science. During the first half of the period, there were few large cities, and the problem was not acute. Following the middle of the Nineteenth Century, cities enlarged rapidly and required cleansing. A full realization of the dangers of incomplete city cleansing, with means for its better accomplishment, did not appear, however, until after the Centennial year. Since that time the dangers and discomforts to the public from filth and dirt have been recognized, and sanitary engineering has made use of available appliances and has developed methods for the cleaning of streets, the collection of refuse, and its final disposal. The operation of these appliances and methods has called for skilled management and the employment and organization by public officials of a considerable number of men. Consequently, the efficiency with which appliances have been used and the excellence of the work done has depended very largely on the quality of the public administration. The cleansing of cities is thus interwoven so clearly with their management that efficiency of operation and progress in the future will depend in large measure on the character and training of municipal governments.

HISTORICAL NOTES ON LAND DRAINAGE IN THE UNITED STATES

By S. H. McCrory,* M. Am. Soc. C. E.

Land drainage in the past 150 years has had an important part in the development of American agriculture and in the improvement of the public health. Complete statistics of drainage have not been compiled, but 50 000 000 acres added to the cultivable land area in the United States and an equal amount made more productive and profitable doubtless would be a conservative estimate of the benefit to agriculture. The benefits to health would be exceedingly difficult to measure, but it is known from early records that malaria was generally prevalent in Illinois, Indiana, Michigan, and Ohio, where drainage is most complete, and that it is much less common in those States to-day. The experience in the South, also, has been that after drainage the extent and seriousness of malaria have generally diminished.

Early Drainage in America

Drainage of farm lands undoubtedly began in each of the Colonies soon after the first settlement was made. Early practices followed those in use in England at that time. Open ditches probably were most used, but blind drains made by digging a trench and filling the lower part with poles, brush, or stones, were used to some extent. In 1767, Elkington, of England, discovered his method of intercepting drainage; this was described in a treatise by John Johnston in 1797, and laid the foundation for modern under-drainage. It was reprinted in England several times, and in 1838 was first published in the United States at Petersburg, Va.† In 1804, drain tile was laid in England; perhaps James Graham was the first user, and tile laid by him were still giving good service in 1887. Deep, or "thorough", drainage was introduced in England by James Smith, of Devonston, Sterlingshire, Scotland; his views came under general notice about 1832, and had great influence on drainage work in England.

In America, under-drainage started in 1835 when John Johnston, of Seneca County, New York, brought over from Scotland patterns from which clay tiles were moulded by hand and laid on his farm near Geneva. By 1838, handmade tiles were manufactured at Waterford, N. Y., and sold for $24 per 1 000 pieces. In 1851, Mr. Johnston reported that he had laid 16 miles of tile drains on his farm; and in the meantime a number of other farmers, chiefly in New York State, had followed his example and reported success. Among these American pioneers in the art of draining was John Delafield, a neighbor of Johnston's, who in 1848 imported what was believed to be the first tile-making machine used in America. This operated on the same principle as

* Chf., Div. of Agricultural Eng., Bureau of Public Roads, U. S. Dept. of Agriculture, Washington, D. C.

† Supplement to the *Farmers' Register.*

the modern machines for making clay tile, and the work it could do has been described,* as follows:

"This improved tile machine produces drain tiles in the form of a horseshoe, rising 2½ and 4 inches; it makes pipes also for draining, from 1 inch bore up to 6 inches diameter, each size varying about half an inch. Soles or flat tiles are made on which to lay the tiles when desired. Semi-cylinders are made of 8 and 11 inches diameter. It also produces with equal readiness, pan tiles for roofing and ridge tiles."

The horseshoe-shaped tiles, 12 to 15 in. long and usually laid on the flat sole tiles, were the common kind in the beginning. The cylindrical tiles do not seem to have come much into use for drainage until about 1858.

The principles underlying successful under-drainage apparently were well understood by Johnston and his contemporary progressive farmers, for one finds, in the discussions and papers of that day, the current arguments advanced for under-drainage, such as soil aeration and warming, improvement of soil texture, and removal of injurious salts. Moreover, stress is laid on the necessity for "thorough" drainage, as contrasted with shallow drainage. As early as 1848 John Delafield stressed the value of drainage for much land that was already sufficiently dry to be producing cultivated crops.

Development of Tile Drainage

Stone and pole drains were still much in vogue after the middle of the Nineteenth Century, but perhaps no one since has better stated the present view as to the superiority of tile over these materials than did Henry D. French when he said:† "No system of drainage can be made sufficiently cheap and efficient for general adoption, with other materials than drain-tiles."

Modern drainage began in the United States when Johnston laid the first tile drains, in 1835. The Ohio and Mississippi Valleys were then just being settled. Much of this land, although very fertile, could not be cultivated until it was drained and malaria was prevalent throughout large sections. Following the importation of the first tile-making machine, in 1848, the use of tile for drainage spread rapidly. In 1853, Samuel Lillie, of Allen County, made the first tile in Indiana, and, in 1859, James Stewart started the first horse-power tile factory in that State. The number of tile factories established in the United States were as follows: from 1850 to 1859 inclusive, 66; from 1860 to 1869, 234; and from 1870 to 1879, 840.

On January 1, 1880, there were 1 140 factories in operation, as follows: Indiana, 486; Illinois, 320; Ohio, 230; Michigan, 63; Iowa, 18; Wisconsin, 13; New York, 8; and Pennsylvania, 2. Thus, at that date, the center of tile manufacture had already moved from the East to the Middle West. To May 1, 1882, there had been laid in Indiana, 9 798 256 rods (30 619.55 miles) of tile, with one county not included in the statistics.

The sizes manufactured increased steadily, and in the early Eighties some plants were able to make 24-in. tile. Machines for manufacturing concrete tile were placed on the market in the Eighties, and the use of this material

* *Transactions*, New York State Agricultural Soc., 1848.

† In his book "Farm Drainage," 1859.

increased gradually, especially for tile 18 in. in diameter or larger. The sizes used in farm drainage have increased gradually; very little tile smaller than 4 in. is now (1926) used, and in large sections of the Middle West, 5-in. tile is considered the minimum size. In Iowa and Minnesota, 36-in. tile outlet drains are now common and drains from 42 to 54 in. in diameter are constructed occasionally.

The hand tools used in constructing drains underwent much improvement during the period from 1840 to 1880. About 1873, Manley Miles invented a drain scoop which could be either pushed or pulled, and made grading the trench much more rapid and easy than it had been. The skeleton spade was also invented during this period.

As the sizes of tiles and the depth of drains increased, there came a demand for a machine that would dig trenches. Among the early types were the Blickenderfer ditching machine, the Hickok, the Rennie elevator ditcher (patented in 1869), and the Johnson tile ditcher, all operated by horses. In 1880, seven kinds of ditching machines were reported* in use, or as having been tested, but with unsatisfactory results. In 1883, the Plumb ditching machine was demonstrated. It was the first one operated by steam, and seems to have been fairly successful. Soon after this several other steam-operated machines came on the market, and from these the modern trenching machines were developed.

The problem of computing the carrying capacity of drain tile received serious consideration by the early drainage engineers. Poncelet's formulas were generally used. In 1916 and 1917, Yarnell conducted extensive experiments and developed formulas for the flow in drain tile.

Investigations of the run-off from drained areas and the relation of depth and spacing of tile to drainage, have been or are in progress in Alabama, Iowa, Illinois, North Carolina, and Minnesota. The problem is intricate and much additional work will be necessary before reaching a full understanding of the laws that control the movements of water to drains.

Construction of Open Ditches

It early became apparent that, if under-drains were to be successful, large outlet drains must be provided. These were mostly open ditches, constructed either by hand, or with teams and scrapers. Usually they were not more than 5 ft. deep, the bottom width only occasionally exceeding 4 ft. In Ohio, Indiana, and Michigan, and in the Upper Mississippi Valley States, the construction of such outlet drains increased rapidly as the States were settled. In January, 1884, the Drainage Committee of the Ohio Society of Engineers and Surveyors reported that, in Ohio, 20 000 miles of county and township ditches had been constructed, benefiting 11 000 000 acres of land. The report placed much emphasis on the benefit these drains had been to the health of the State. Most of these ditches were found to be too small, however, for providing the degree of drainage that was desired. There was need for an economical means of constructing large open ditches.

* *The Drainage Journal*, 1880.

In 1882 the Mason and Tazewell Special Drainage District was organized in Mason and Tazewell Counties, Illinois. The drainage plan of this district comprised a main ditch 14½ miles long, 10 ft. deep, varying in top width from 30 to 60 ft., with side slopes of 1 to 1; approximately 37 miles of lateral ditches, 10 feet deep; and 30 miles of spade and scraper ditches. About 7 miles of laterals were added later. Construction was started in 1883 and completed in 1886. The cost of the improvement was approximately $300 000. On this work five dipper dredges were used by the contractor, W. A. McGillis and Company. The dredges were constructed by the Bucyrus Foundry and Machinery Company, of Bucyrus, Ohio, and probably were patterned after dredges used in digging navigation canals. This was the first drainage district on which dredges were used, and the main ditch when constructed was the longest in the United States. Mr. Herbert Hamilton, of Petersburg, Ill., was the Engineer for the District. The *Engineering News,* in commenting on the work, stated: "This was the first work done with a dredge, and has been so satisfactory that it may be said to have worked a revolution in such matters."

Since this work was done the development of dredges has been rapid. The vertical spud was replaced by the bank spud, which permitted the use of a narrower hull, thus enabling the machine to dig smaller ditches. On the other hand, the design of larger and larger ditches led to the design of larger dredges, until at present (1926) floating dredges range in size from the small ½-yd. machine, with a 25- or 30-ft. boom, to the 5-yd. machine with a 100- to 125-ft. boom. The success of floating dredges led to the development of the dry-land dipper excavator for use where sufficient water was not obtainable for the floating type.

Soon after the first dipper-dredges were put in operation, dredges equipped with grab-buckets were used, their principal advantage being that they could be equipped with a longer boom. Machines of this type have been highly developed in California, where they are used for ditches and levees in peat lands.

In 1903 Page and Schnable built the first drag-scraper excavator, and this was used on the Hennepin Canal. It was first used on ditches in 1906, and was originally considered a dry-land excavator, but it has gradually supplanted the floating dipper-dredge for constructing drainage ditches. It is built in a wide variety of sizes, and various methods are used for moving it. The great advantage of the drag-line excavator over other types is its flexibility. There are well-defined limits to the size of ditches that can be constructed by floating dipper-dredges of a given size, but such limits do not apply so closely to the drag-line. It has the added advantage that on large ditches it is possible to provide a wider and cleaner berm than is possible with dipper excavators. Experience has shown that the securing of an ample berm is of much importance when large deep ditches are to be dug.

The early dredges were operated by steam engines fired with either wood or coal. Internal combustion engines began to be used on drag-line excavators soon after their introduction. Electric current, where readily available, now affords a convenient source of power.

Pumping for Drainage

The use of low-lift pumps to drain lands was early practiced along the coast. Drainage wheels were first used, and were operated probably by animal power or by windmills. About 1850 centrifugal pumps began to be used. In the late Sixties the Ivens pump was invented, and special designs for low-lift pumping were developed and used extensively. In 1880 the Menge pump was introduced. It could be easily and cheaply erected, and was used widely for drainage pumping.

As projects became larger, and centrifugal pumps were improved in efficiency, they gradually supplanted other types. Recently, screw pumps, giving still higher efficiency on low lifts, have been introduced. About 1900 drainage by pumping began to be practiced along the Upper Mississippi and Illinois Rivers. At present (1926), practically all the bottom-land along the Illinois River has been reclaimed in this way.

Drainage of Irrigated Land

Soon after irrigation was started in the West, some of the land began to be damaged by seepage and the accumulation of alkalies. As early as 1884, Mr. George C. Roeding, a nurseryman of Fresno, Calif., began drainage experiments to relieve this condition. He laid tile drains in 1893 which were said to be still working in 1909. As this trouble was becoming widespread, the Bureau of Soils, U. S. Department of Agriculture, built several experimental drainage systems in 1902. These experimental systems followed Eastern drainage practices as to depth and opening, but were not as effective as had been expected. In 1902 the position of Drainage Expert was created in the U. S. Department of Agriculture, and the late C. G. Elliott, M. Am. Soc. C. E., a prominent drainage engineer, was appointed. He gave much attention to the drainage of irrigated lands; and a small group of engineers was assembled to work on this problem It was found that shallow drains were ineffective, but that a deep drain, properly located, frequently would drain an entire field. From the work thus started has developed a method of drainage which has reclaimed or protected much irrigated land.

Lands containing calcium carbonate—commonly, called black alkali—have always been exceedingly difficult to reclaim by drainage. Chemists as well as engineers have devoted considerable study to this problem, but it has not yet been solved. Seepage and the accumulation of alkalies must be prevented if irrigation agriculture is to be made permanent. The engineers of the United States have developed and perfected methods of draining irrigated land to a greater extent than ever before.

Drainage District Laws

Even in small drainage undertakings several land owners frequently are interested, and it is often difficult to secure voluntary co-operation. When many land owners are concerned, it is practically impossible to secure unanimous action. This difficulty brought about the passage of laws which provide means of constructing necessary drains and forcing all land owners to pay their just share of the cost.

Almost every State now has a general law which permits the organization of drainage districts, provides the necessary means of securing co-operation among a number of land owners to construct the improvement, and specifies the manner of distributing the costs among the affected lands and of securing the privileges of long-time payments. These laws are based on early English laws for drainage and sewerage, which provide that a citizen shall consent to pay his proportional part of the cost of a public, local improvement in the same way that he consents to share in other expenses of government. The authority to enact such laws is exercised by the State Legislatures, and is subject to the limitations placed on legislation by State and Federal Constitutions. The history of drainage legislation in each State is a story of repeated attempts to enact laws which should conform to these constitutional requirements, and meet the changing needs of the owners of wet or overflowed lands.

The first drainage law in the United States of which there is authentic record was enacted by the Colony of New Jersey, on September 26, 1772, and it was re-enacted by the State when it adopted its Constitution, on July 2, 1776. This was an act drawn for the purpose of clearing obstructions in the free course of the waters of the Passaic River, near Little Falls.

The act provided for co-operation among a number of land owners to secure field protection, for a division of the costs, and for a method of collecting the costs; it established the public interest in such work by reason of the improvement of the public highways. It did not, however, provide for the inclusion and assessment of a minority of land owners who did not desire to co-operate in the project, nor did it provide for spreading the payments over a period of years.

One of the earliest general drainage acts was passed on April 9, 1804, in New York State. This act was declared unconstitutional, on the ground that it provided for the taking of private property for a private, rather than a public, use.

Another early general drainage law is found in the Revised Statutes of Massachusetts, 1836, Chapter 115. This act provided for the improvement of low lands by removing obstructions from streams and by ditching. It provided for a petition to be signed by a majority of land owners setting forth the proposed improvement, for notice to land owners who did not sign the petition, for a judicial hearing, for a board of commissioners to be appointed by the Court to construct the improvements, for an assessment of the expenses to be made on all proprietors according to the benefit each should receive from it, for damages to be paid to injured parties, and for appeals to high Courts. Thus, it is clear that this law was a marked advance over earlier ones in that it provided for the forced participation of non-petitioning land owners and for legal safeguards to prevent abuses of this power.

Under the earlier drainage acts the work to be done was small, and in many cases was performed by the land owners themselves, but, as the projects grew in size, and expensive machinery was required for economical construction, it was necessary to engage contractors, and these contractors had to be paid on the completion of the work. As it was impossible for the land

owners to raise the large sums thus required, drainage development, for a time, awaited legislation which would allow adequate and proper financing. In 1879, Illinois passed its Levee and Farm Drainage Acts, which permitted the district to issue bonds to be sold for cash to pay for the construction. These bonds were first liens on all assessed lands within the district, and arrangements were made whereby the land owners had a long time in which to pay the costs assessed against them and thus redeem the bonds.

Except for minor improvements and adjustments further to protect the interests of the bond buyers, this was the final step in the development of general drainage laws as now known. In almost every State laws have been developed, and approved by the Courts, by which drainage and flood protection districts can be established and financed under the supervision of the Courts, having the following characteristics:

1.—By law they are made a continuing form of corporation, and act through a board of officers.

2.—They can borrow money and issue bonds in the name of the district.

3.—They are financially responsible, and may sue and be sued in the district's name.

4.—They possess machinery for making an equitable distribution of costs in proportion to benefits conferred.

5.—They are authorized to levy taxes against each piece of land, to the extent of benefits conferred, and to use State machinery for collecting such taxes.

6.—They have the power of eminent domain, which gives them the right to condemn property needed for carrying out the purposes of the district.

7.—They possess the power to construct such improvements as are necessary to accomplish the reclamation of the lands in the district.

8.—They may hold and convey property.

Extent and Cost of Drainage

Statistics as to the growth of drainage by private individuals, firms, or corporations, have not been collected, but, in 1920, the Fourteenth Decennial Census gathered data as to the status of drainage on farms. These figures show that about 53 000 000 acres were drained by ditches or tile. This is equivalent to 10.5% of the improved lands in farms. Illinois has drained more than 8 000 000; Iowa and Ohio more than 7 000 000 acres. Farm lands still needing drainage were reported as 39 000 000 acres.

During the Census of 1920 statistics concerning land drained by drainage districts were also collected. In 1920, the area benefited and assessed for the cost of the drainage thus provided was more than 65 500 000 acres. These figures do not include statistics for levee districts which had not constructed drains. In addition, 3 900 000 acres were in organized drainage districts which had not begun construction. The area is probably not less than 75 000 000 acres in 1926, estimating conservatively from nearly complete data secured in 1923. There has been much overlapping of enterprises, particularly in Ohio, Michigan, and Indiana, chiefly because in some States the enlargement or clearing of an old drain required the establishment of a new drainage district.

According to the Census, the drainage works of the districts completed or under construction prior to 1920 comprised 111 770 miles of open ditch, 45 174 miles of tile drains, and 4 330 miles of levees, or a total of 161 274 miles. All but 7 974 miles had been completed on the Census date. The cost of this drainage cannot be determined accurately as records of the early work are incomplete in States where the most has been done by allotment to the land owner instead of by contract. The Census shows $183 000 as the cost of all enterprises prior to 1860; $10 000 000 to 1880; $60 800 000 to 1900; and $434 600 000 to 1920, including the cost of the completion of work under construction. The cost of drainage done by farmers is difficult to estimate. From fragmentary data available it is conservatively estimated that at least $600 000 000 has been spent for such improvements, and, if more complete information were available, it is possible that the figure might reach $1 000 000 000. Drainage work by districts and individuals had cost, to 1920, from $1 150 000 000 to $1 500 000 000.

What have these works accomplished? First, they have generally greatly improved the health of the communities in which they were constructed; second, they have made available to the farmers about 65 000 000 acres of the best land in the United States—land that, in its original condition, could not be cultivated profitably; third, they have increased yields, and made crops more certain on the lands drained; fourth, they have reduced the losses of crops due to floods and inadequate drainage; and, fifth, they have removed surplus water and thus made easier the construction and maintenance of roads and railroads.

Future Developments in Drainage

In the future benefits accruing to agriculture and health will cause much land to be underdrained that at present is not thought to need it. Within the next two decades the Middle, South Atlantic, and Gulf States will be practicing under-drainage on the same scale as that now followed in Iowa, Illinois, and Indiana.

As the density of population increases and more intensive farming is practiced, much land now drained will need more thorough drainage. This will require deeper and larger outlet ditches, with flatter side slopes than has been customary in the past; and detention reservoirs, to prevent damage by floods, will become practicable in many places where they are not now economically feasible.

Excavators capable of digging, without rehandling, ditches with a cross-sectional area of 6 000 sq. ft. and upward, to any desired section, with berms of any width desired, and capable of distributing the excavated material in such manner that the weight will not be unduly concentrated, will be developed.

Tidal marshes will be reclaimed. This will involve construction of embankments and pumping plants of a magnitude not yet attempted, particularly along the Gulf Coast, where, in addition to securing drainage, it will be necessary to provide protection from storm tides caused by tropical hurricanes.

The size of drainage districts will increase, and eventually districts will be organized co-extensive with the water-sheds on streams, such as the Saginaw in Michigan, or the Yazoo in Mississippi, with permanent staffs who will handle all problems involving water, such as drainage, flood control, water power, navigation, and control of erosion.

Drainage laws will be further simplified and made more effective. Simpler and less costly methods of organizing small districts will be developed. It is to be hoped that the administration of districts will eventually be entirely removed from the judiciary and assigned to men qualified by training and experience for such work.

HISTORICAL REVIEW OF DEVELOPMENT OF CONTROL OF DISEASE-BEARING MOSQUITOES

By J. A. LePrince,* Esq.

Disease-bearing mosquitoes have played an important part in the early settlement and development of all countries in the temperate and tropical zones of the Western Hemisphere. The second expedition of Columbus was nearly wrecked by them at Santo Domingo, and, later, Prescott wrote of mosquito-borne disease as follows: "The moment a town is founded, or a commercial center created, it is certain to cause the explosion of the latent malignity of poison in the air." In early days the Colonies suffered severely from both yellow fever and malaria. Quinine was scarce and costly, and other remedies used for malaria had little value.

Mosquito-Borne Disease a Menace of Importance

One is apt to consider yellow fever as a semi-tropical, or tropical, sea coast disease, but it has not always been so. It was intermittently present in the Southern States from Colonial days to 1905, and not entirely absent in the Northern States. In eight States north of Virginia, from 1693 to 1870, eighty yellow fever outbreaks are recorded.

In the records of New York, N. Y., yellow fever appeared during seventeen summers, and at Philadelphia, Pa., during fifteen summers. Reports show 2 086 deaths from yellow fever in New York in 1798, and 3 506 in Philadelphia in the same season. In the Philadelphia epidemic of 1793, in a population of about 40 000, more than 4 000 deaths were recorded, and reporting was not as complete then as it is to-day. Longfellow's "Evangeline" contains a description of one of these Philadelphia outbreaks.

The Colonists were painfully aware that malaria played a decidedly important part in retarding development. Jamestown, Va., was situated on low land close to a large wet depression. No attempt was made at drainage, and it is easy, to-day, to understand why this Colony was a failure. It is recorded that the original colony at Charleston, S. C., was first situated on the mainland near swampy areas like those around Jamestown, and two years later, due to sickness among the colonists, was moved to its present location, at the end of a peninsula, where health conditions were more satisfactory. In the early days at Savannah, Ga., malignant malaria fever was common, and the situation became so serious that the town authorities passed a law to forbid the maintenance of "wet culture," as rice was then called, and reimbursed land owners for loss of potential crops. This was probably the first serious early attempt at malaria reduction by an American city.

Following the Declaration of Independence, with the settling of new territory westward from the Atlantic Coastal Plain, malaria prevalence was common, even as far north as New England, Illinois, and Michigan. In fact, it

* Senior San. Engr., U. S. Public Health Service, Memphis, Tenn.

was widely distributed in the Northern States as late as the Eighties, and then began to decrease with the extension of intensive farm drainage, improved living conditions, the reduction in the cost of quinine and its more general use, and the provision of metallic screens for the protecton of homes.

During the Civil War one-fourth of all hospital admissions were due to malaria fever, and in military camps in the Southern States in the Spanish-American War period so many soldiers were infected by malaria before leaving for Cuba that only a small part of some regiments was fit for service.

The First Mosquito Campaign

During the Nineteenth Century the number of deaths from malaria among the native population of Havana, Cuba, in some years was greater than that of the total deaths caused by yellow fever. The first effective campaign against mosquito-borne disease was begun by Americans at Havana in 1901. At that time yellow fever had become so prevalent in that city as to affect seriously the military occupation of the Island. The cause of the transmission of the disease was then discovered; the mosquito that conveyed it was reduced below the danger point, and yellow fever was eliminated.

During the first yellow fever battle the campaigners felt so certain of the final outcome that they instituted an anti-malaria campaign, and reduced malaria prevalence about 80% before the first period of American occupation terminated. A few years later, due to the absence of yellow fever and the rarity of malaria, the city became a tourist resort, although previous to anti-mosquito measures, it was known as the cradle of yellow fever and malaria.

It is of interest to know that, during this historic campaign, an American sanitary engineer kept a chart, in connection with yellow fever control measures, and estimated the date when yellow fever would be eradicated. As he happened to be directing the field control measures, he became too enthusiastic over obtaining results, and yellow fever was eradicated 60 days earlier than his first estimate. His friends having told him that an engineer's estimate should be more accurate, he replied that it would be made so as soon as they could show him how to determine the existence and location of walking cases of yellow fever.

Although it was thus definitely proved in 1901 that both yellow fever and malaria could be eliminated at a reasonable cost, no serious and thorough effort was made to control disease-bearing mosquitoes in the United States until the outbreak of yellow fever in New Orleans, La., in 1905 and then only in that city until yellow fever had been eliminated.

The Panama Canal Zone was occupied by Americans in 1904; yellow fever was eliminated by 1905, and an extensive anti-malaria campaign was initiated and has since been continued.

English Suggestions and American Inventions

The mode of transmission of malaria was discovered by Sir Ronald Ross, who, during his visit to Panama in 1905, stated:

"What is most necessary for *Anopheles* control is for us to find a cheap powder to act as a larvacide that we can toss to the right or left, and also we should devise a trap we can bait to catch disease-bearing mosquitoes."

These two suggestions were developed later by American sanitarians. One of the most prolific sources of malaria mosquitoes known is on the Potomac River, and is now being treated by the application of dust clouds of Paris green from airplanes; and the mosquito trap has been perfected so that one trap, less than 2 cu. ft. in volume, has caught more than 1 100 malaria mosquitoes in a single night. The inventor used for bait the odor of the canal construction laborers whom these mosquitoes desired to bite.

The Public and a New Idea

It is surprising that no attempt was made to control disease-bearing mosquitoes in the United States until 1913, when malaria surveys were first made in Virginia and North Carolina by Dr. H. R. Carter, of the United States Public Health Service, on his return from Panama. Dr. Carter was a graduate civil engineer as well as a physician of international reputation, and, because of his education and experience as a public health officer in the control of yellow fever and malaria, was peculiarly fitted to define the malaria problem of the United States and outline a program for its solution. At that time it was estimated that the annual economic loss caused by malaria alone in this country was $100 000 000. The ravages of yellow fever in Southern ports had also caused many deaths, much suffering, and enormous financial losses. Even as late as 1922, when a dengue epidemic swept over the country from Florida to Texas, its rapid rate of travel indicated clearly the extensive prevalence of the yellow fever mosquito in towns and villages. This mosquito spreads both yellow fever and dengue, and breeds only in man-made water containers in or near occupied homes.

Malaria Control in Military Camps

In 1914, a Federal appropriation of $16 000 was made for malaria studies and investigations by the U. S. Public Health Service, and in conducting these investigational studies 22 surveys and 3 malaria control demonstrations were made in 7 States during that year. This appropriation and the investigational study were continued until the United States entered the World War, when the small personnel employed were assigned to control measures connected with war activities. At that time zones of health protection were established at all cantonment towns and in areas a mile wide surrounding each military cantonment and near-by town in all sections where malaria was prevalent.

If the same malaria sick rate and death rate that took place in Southern military camps during the Spanish-American War had prevailed during the World War, there would probably have been a loss of 5 000 men by deaths from malaria. By rapid training of engineers in malaria-control measures, and quick, hard work, the total deaths from malaria in Southern military camps throughout the war was held down to 36. This enormous reduction is worthy of consideration, yet more important is the fact that enlisted men were not sent to France saturated with malaria to unfit for duty a large part of the military forces, as was the case in the Spanish-American War before the method of malaria transmission and control measures were known. During the World War, 193 men were constantly incapacitated by malaria, but with the same

rate as obtained in the Civil and Spanish-American Wars, 38 000 would have been incapacitated each day of the war from April, 1917, to December, 1919.

At the termination of the World War, the U. S. Public Health Service co-operated with the International Health Board and the State Health Departments of Southern States, and succeeded in starting malaria-control activities in fourteen of such States. As soon as the State Health Departments were able to supervise their local control projects, Federal supervision was withdrawn, and, to-day, the State Health Departments are assisting counties and communities in mosquito-control activities.

Previous to 1914 probably less than six communities had undertaken malaria-control measures, and the results of such limited effort were unsatisfactory. Up to that time, not a single State health department was taking any action toward malaria elimination, although in many counties malaria was the most important health problem. No State or county had made any appropriation for malaria reduction. In 1916, the physicians of one State alone reported to the State Health Department 158 779 cases of malaria.

Public Demand for Mosquito Elimination

As an illustration of the change in the public attitude toward malaria control and mosquito elimination that has taken place since 1914, the U. S. Public Health Service has co-operated with State Health Departments in malaria-control measures in 343 communities in 216 counties in 17 States, and in activities connected with mosquito surveys, control measures, and investigations, in 667 communities in 376 counties in 24 States.

In addition, many communities have undertaken control measures that are not included in the recorded data, and the State Health Departments of Alabama, Georgia, and Texas, report that they are now overwhelmed with requests for advisory supervision from communities desiring to undertake mosquito-control activities.

It was the writer's good fortune to be present when the campaign against disease-bearing mosquitoes in the Western Hemisphere was inaugurated at Havana, Cuba, in 1901, to take part in the sanitation of that city, and then go with General Gorgas and Dr. Carter to the Canal Zone, where the fight against disease-bearing mosquitoes was inaugurated under even greater difficulties, but with equal success. In 1914, the writer returned to the United States, and since that time has followed the trail of the *Anopheles* all over the South.

As soon as the way was found, it was comparatively easy to control *Stegomyia* mosquitoes and eradicate yellow fever. The control of *Anopheles* and malaria is a much more complicated matter, but it can be done. Yellow fever has not been of any sanitary importance to any city in the United States since 1905, and within that time malaria has been greatly reduced. Who can say what the next 25 years will bring forth! Every indication points to a continued reduction in malaria throughout the United States at an equal or possibly even more rapid rate than has been attained in the past 25 years. Should this prove true, it needs no prophet to foretell the outcome.

CHANGING CONCEPTIONS OF VENTILATION SINCE THE EIGHTEENTH CENTURY

By George Truman Palmer, Esq.*

The history of ventilation is a chronicle of the effort to analyze accurately the causes of a harmful effect. The effect has been human discomfort, lowered efficiency, and, not infrequently, injury to health.

In general terms, the cause has been bad ventilation. For years, however, there has been difficulty in picking out the specific features that make for badness, and this has handicapped the engineer in designing proper corrective measures.

At the birth of the American Republic there was a consciousness that the air of an enclosure occupied by human beings had some real though intangible relation to health. It was the growing concentration of population, however, which really brought ventilation to the fore. Increasing numbers of children in school, the substitution of the factory system for isolated home manufacturing, the advent of many-storied dwellings and office buildings, the construction of commodious theatres and other meeting places, all these conditions have accentuated the necessity of lessening the discomfort inevitable from indoor crowding.

Vast changes have taken place, both in understanding the basic principles of ventilation and in methods of adapting indoor air to healthful uses.

A century and a half ago it took the most persuasive arguments of Benjamin Franklin to secure the opening of a sleeping-room window when he and John Adams had occasion to be bedfellows in an hostelry in New Brunswick, N. J. To-day, the open bedroom window is general practice.

The grate and the stove warmed habitations prior to 1800. To-day, a steam pipe serves this purpose, even if one's office may be on the fiftieth floor of a skyscraper.

In 1834 ventilation of the British House of Parliament was served by a tower on the roof, 110 ft. high, with a fire at the base for the purpose of creating a draft; and this pulled air into the room through thousands of small holes in the floor.

To-day, not only public buildings, but factories, theatres, eating places, and other inclosures are served by smoothly running direct-connected, electrically-driven, multi-vane blowers controlled by an insignificant looking switch.

The Unfolding of Ventilation Principles

Ventilation has had a more difficult course to pursue than bridge building. In addition to the laws of gravity, stresses, and strains, ventilation has had to satisfy the shifting theories of the hygienist and, worst of all, the discordant demands of human comfort.

* Director, Div. of Research, American Child Health Assoc., formerly Chf. of Investigating Staff, New York State Comm. on Ventilation, New York, N. Y.

Several things happen to the air in a crowded room: The temperature rises; humidity increases; oxygen diminishes; carbon dioxide increases; volatile organic matter and unpleasant odors are added; more dust is afloat and, largely in consequence, more floating bacteria can be detected.

Are all these changes identified with discomfort? If not, which are important and which are not? The job of the ventilating engineer is to restore comfort. Against what shall he direct his attack? It has taken a century and a half to tag these elements, and even to-day it can hardly be said that complete satisfaction has been attained.

The study of these ventilation factors began in the chemical laboratory. Prior to 1880, three main theories prevailed as to the causes of discomfort in a crowded room: First, that it was due to a diminution in oxygen; second, that it was caused by the poisoning effect of the accumulating carbon dioxide; and, third, that it was due to the toxic effect of organic matter given off in the breath.

The early suspicion against oxygen depletion arose from the then recent discovery (1774) of the existence and significance of oxygen in respiration. It was assumed that the amount of depletion was serious. It is now known that, owing to the multiple opportunities for leakage through walls and crevices, the oxygen content is actually lowered only an insignificant amount. In fact, the worst ventilated room has far more oxygen than a mountain health resort where the partial pressure of oxygen is greatly reduced by the high elevation.

It was Lavoisier who shifted the suspicion from oxygen to carbon dioxide. There was very little basis for this view, but, once enunciated, it has persisted even to this day. Brown, in 1870, refers to carbon dioxide as a "fatal gas". Even in 1913 the engineers, Hoffman and Raber, in their Handbook, class carbon dioxide with the other "impurities", and regret that some way has not been found for dissociating it from the remainder of the atmosphere.

Pettenkofer, in 1863, made it clear that carbon dioxide was not in itself poisonous, but that it served as a useful index of other harmful substances in respired air which he believed were instrumental in lowering resistance to disease. This suggestion gave birth to the carbon-dioxide standard of ventilation, and this, in turn, led to the most common air-flow standard of 30 cu. ft. per min. per person.

The worst ventilated room rarely reaches 50 parts of carbon dioxide in 10 000. Before unfavorable symptoms can be produced, under laboratory conditions, it is necessary for the carbon dioxide to be increased to 300 or 400 parts. The school child actually breathes more carbon dioxide when curled up on his sleeping porch than when sitting in the school room.

The organic-poison theory was sponsored by Brown-Sequard and d'Arsonval. Their viewpoint is represented by Russell in the "Smithsonian Miscellaneous Collections", who wrote as late as 1896, that organic matter in respired air "is a dangerous and pernicious element in all aggregations and, combined with carbon dioxide, produces, when in moderate quantity, depression, headache, sickness, and other ailments." The great majority of workers have

been quite unable to produce the slightest evidence of the existence of an organic poison in respired air.

The relative unimportance of the chemical factors in the air as a cause of discomfort and the primary significance of the thermal factors—temperature, moisture, and air motion—was first brought out clearly by Hermans in 1883. In 1896, Billings, Mitchell, and Bergy in America reviewed and repeated much of the experimental work previously reported. They voiced the conclusion that it is "very improbable that the minute quantity of organic matter contained in the air expired from human beings has any deleterious influence on men who inhale it in ordinary rooms, and, hence, it is probably unnecessary to take this factor into account in providing for the ventilation of such rooms". In their eyes, the two great causes of discomfort, although not the only ones, in crowded, ill-ventilated rooms, were excessive temperature and odors.

This viewpoint has been confirmed in substance again and again by Flügge and his associates in Germany, by Haldane, Pembrey, Leonard Hill, and others in England, and by Benedict, Crowder, the New York State Commission on Ventilation, and others in America.

Present-Day Conceptions of Ventilation

The present-day attitude with respect to the different elements in ventilation may be summed up as follows:

Elevated indoor temperature in the winter, even up to 75°, produces discomfort, lowers working efficiency, forces the heart to extra effort, and measurably elevates the body temperature. As far as possible, the air of an inclosure should be cool and fluctuating in temperature within narrow limits, rather than constant or unvarying.

Likewise, air motion should be variable or fitful, rather than of uniform velocity. Variability or pulsation in air motion stimulates the pleasant feeling of an outdoor breeze, cooling, but not sufficiently prolonged to be chilling.

Humidity may vary within rather wide limits and still be comfortable. In fact, there is little to justify humidities above 40% in the ordinary room in winter at temperatures around 70 degrees. Nor is there evidence that humidities as low as 20% are harmful or uncomfortable. There is a difference between dryness and "dryingness". A low humidity without marked air velocity may be dry, but not drying.

The present air-flow standard is undoubtedly excessive. This may be decreased by one-half in such places as school rooms without discomfort or harm to the occupants.

Except with very dirty clothing and people, there will not be volatilization of odors in cool rooms. One objection to higher humidities is that it accentuates odor.

Ordinarily, the bacterial content of indoor air is of no practical importance. The likelihood of disease being spread by bacteria that float about in the air is so remote as not to warrant serious consideration. In the ordinary room the dust content of the atmosphere is inconsequential to health.

Organic matter and carbon dioxide need not enter into the calculation, although measurements of the latter are useful as an indirect determination of the amount of air flow.

It is recognized, of course, that in special situations factors ordinarily unimportant loom large. In the submarine, oxygen depletion and excessive carbon dioxide are factors to be reckoned with. In certain industrial processes dust or fume removal is of the highest importance; and some situations require high humidity, as in the textile industry.

Changing Practices in Ventilation

Although theories relating to ventilation have shifted from time to time, their influence on practice has not been felt until recently. This is because no deliberate effort was made a century ago to ventilate the ordinarily occupied room. Efforts, to be sure, were made in special fields, such as the rotary fan for deep mines, used in Savoy and Bohemia, as far back as 1553, and the use of bellows for extracting air from the holds of ships, devised by Triewald, the Swedish architect, in 1741. Also, there is the application of bellows for hospitals and mines, described by Stephen Hales, an English clergyman, in 1758. Prior to 1850, however, the most commonly used method for securing air propulsion was the chimney draft. Tall towers with fire grates at the bottom were built specifically for the purpose of creating a circulation of air. A later development was the placing of hot water or steam pipes in the chimney or duct, to accelerate the draft.

Ventilation has always been closely associated with heating. Hot water, and particularly steam heating, paved the way for the development of indirect or hot-blast heating, which is so common to-day.

At the birth of the American Republic, rooms were warmed with grates and stoves. The heating and ventilating equipment of Independence Hall in 1776 consisted of two open stoves (which cost about $135) and wooden shutters or ventilators. Hot-water heating was being tried out for chicken incubators in France and England. James Watt was warming his study with an iron box connected to a boiler in the room below. The difficulties of this period had to do with the control of heating.

By 1850 steam had begun to find extensive use, and this opened the way for the rapid heating of air in quantity, in other words, indirect heating. This method, also known as the plenum, or the hot-blast, system grew in favor and, in 1867, Chicago installed its first mechanical plant with indirect heating, for a school building. From a main duct in the basement two tin ducts were carried up through the wardrobes, terminating in openings in the classroom about 12 in. above the floor. Deflectors over the openings directed the incoming air down toward the floor. Needless to say, there was considerable complaint of drafts.

Between 1850 and 1900 mechanical ventilation found greatly extended use, but there were no radical changes in methods or principles. In fact, in looking back over the history of the subject, it is rather striking that no particular method characterizes a particular period. In 1870 discussion waged over the relative merits of the hot blast and the split system. The same dis-

cussion is rife to-day. The Tobin tube and the Sherringham valve, of the early Nineteenth Century, were methods of introducing air directly through the wall of a room. This method is exemplified to-day in the window deflector and the unit ventilator, to which the fan has been added.

The problem of ventilation has been how to warm an inclosure in cold weather, or cool it in warm weather, and at the same time circulate air in such a manner as to remove odor, conserve heat or cold, and not cause unpleasant drafts. The matters at issue have been whether to heat directly or indirectly, whether to admit air at the top of the room or the bottom, whether there should be a single air inlet to the room or many, whether air should be forced through an inclosure or exhausted, or both.

The improvements that have taken place, in addition to artisanship, are largely refinements in control and increases in capacity, which have been made possible through developments in the use of steam and electricity.

Air Conditioning

Since 1900 the most notable changes have been in the field of air conditioning, humidification, and dehumidification. A form of humidification was practiced in 1838 when the air supplied to the British House of Commons was made to pass through a sheet of water dropping from perforated pipes. The development of humidification, however, took place mainly in the textile industries, where high moisture content was necessary to prevent the breaking of threads. Humidification by the release of steam from a jet gave way to the use of a pan of water heated by steam pipes, and known as an evaporating pan. This, in turn, was followed by the combined air washer and humidifier, consisting of spray nozzles, the water being circulated by a rotary pump. The degree of humidification was controlled by a thermostat in the wash-water or by a humidostat in the air duct.

Effect of Changing Theories on Recent Practices

In the last twenty-five years changing theories of ventilation have left their mark on progress. So long as respired air was supposed to be poisonous, there could be no let up in the amount of air change. This viewpoint led to unnecessary restrictions, and actually retarded progress. An illustration is the English weaving sheds where an upper carbon dioxide limit of 6 parts per 10 000 was specified. This did not bring comfort, for the places reeked with steam and were unbearably hot. After a thorough study of the situation —and even at the suggestion of the operatives—the air flow was cut down, the CO_2 limit was raised to 11 parts and, what was most important to comfort, an upper limit was placed on the wet bulb temperature.

Another instance is in mines, where an unnecessarily high standard of oxygen was specified. Later, it was learned that lower concentrations of oxygen were preferable as this reduced the danger of mine explosions.

For years a controversy has waged over the ventilation of school buildings, fresh-air enthusiasts speaking of mechanical ventilation as "canned air". Engineer extremists, on the other hand, would not even apply the term ventilation unless propulsion of air was by mechanical means. Once having

recognized the non-poisonous character of respired air, there should not be the slightest objection to window ventilation and gravity exhaust, although this method will not insure a continuous air flow equivalent to the 30-cu. ft. standard. For this reason, laws which require mechanical ventilation in school buildings, indirectly through the provision calling for 30 cu. ft. of air per min. per person, are unnecessarily severe, and should be amended.

A clearer understanding of the ventilation elements made possible also the practice of recirculating air, thus saving fuel cost. This would have been deemed impossible at a time when a different attitude prevailed with reference to carbon dioxide and organic matter. The Young Men's Christian Association Training School at Springfield, Mass., found this procedure entirely practical and economical, during the course of experiments in 1913. The method has now found application in theatres and factories, and to some extent in schools. The use of ozone to cut down odors has been tried in conjunction with recirculation, and has met with favor, particularly in the schools of St. Louis, Mo.

The unit ventilator, or combined blower, humidifier, and heater for individual rooms, has been a recent development. The apparatus is more costly, but it permits individual room control. This saves in the operation of a central plant when only one or two rooms need to be ventilated.

Ventilation Laws

Compulsory ventilating laws for public buildings and factories have been enacted largely since 1900. Regulations are to be found at an earlier period; Detroit, Mich., for instance, prescribed ventilation appliances for places of employment in 1881. State-wide acts were passed in New Jersey in 1903, and in Ohio and New York in 1905. In approximately twenty-four States there are now (1926) laws or regulations prescribing ventilation in schools and other places. For the most part, these laws require forced ventilation, with an allowance of 30 cu. ft. per min. per person. They also specify floor space and cubic space standards per occupant. To a lesser degree, temperature standards are also laid down.

Contributions of Ventilating Practice to Human Welfare

To-day ventilating engineering represents a distinct profession. Evidence of this is seen on all sides. Habitations are much more comfortable as a result, and the hazards of indoor life are unquestionably reduced thereby. The dust which used to becloud the worker in the polishing room is now removed locally. Steam vapors from vats, which formerly rendered their attendants invisible a few feet distant, may now be carried away through exhaust hoods. Basement and sub-basement space, which formerly had limited use, is utilized by cafeterias which, through the aid of electric lights, ventilating ducts, and a dehumidifying system, are made attractive and comfortable for thousands of people daily.

Ventilation, an ephemeral thing at the dawn of the century, now invades the theatre bill posters, where glaring letters give almost as much prominence

to the cooled, washed air, as to the names of the play and the comments of the critic.

The American Society of Heating and Ventilating Engineers, organized in 1895, has grown to large proportions, and now conducts a research laboratory, where the problems confronting the profession are being studied.

In spite of the advances made and the numerous illustrations of good ventilation, there is room for a much wider use of good equipment in such places as theatres and meeting halls. It is the rule and not the exception to leave a theatre after a 2 or 3-hour performance, hot, sticky, and thoroughly uncomfortable. Engineers have yet to learn how to counteract the heat production of a hall full of people so that temperatures at the close will be nearer 70 than 80 degrees.

Outlooks for Ventilation Progress

The changes in ventilation perceived in the immediate future are likely to include:

(*a*) Refinements in the control of temperature;
(*b*) The introduction of cyclic or variable air motion, as opposed to unvarying and monotonous air flow;
(*c*) The development of methods of cooling during warm weather;
(*d*) A more economical use of fuel through the medium of recirculation;
(*e*) Rewriting and modernizing legislative requirements; and
(*f*) More intensive study of plant operation.

From the wealth of evidence available, overheating is more threatening to human comfort, health, and efficiency than any other single ventilation element. There is need for continued improvement in thermostatic control and regulating instruments.

The oscillating wall fan is an improvement over the stationary type. It cools but does not chill. Intermittent air propulsion by blowers will soon be accomplished. One of the most justifiable criticisms against mechanical ventilation is its deadly uniformity. This is not an idle criticism. Outdoors one is used to the intermittent play of air on the skin. This is missing indoors, unless the windows are open. This is one of the attractive features of window ventilation, and is one of the reasons for the insistence on open windows. There is no reason why this condition cannot be quite successfully imitated mechanically. It is not the alternate starting and stopping that is wanted, but the actual reproduction of the irregular outdoor velocity cycle.

When this comes it will be possible to introduce air at lower temperatures, which will be more stimulating and fairer to the nose and throat. The intermittency of the action will produce the sensation of a breeze, but not that of a draft. It is this refreshing, draftless breeze which is more needed than anything to vitalize mechanical ventilation.

People are accustomed to think of ventilation as a winter problem, but are beginning to see its uses as a protection against the debilitating heat of summer. The circulating fan is growing in popularity. The cooled and dehumidified theatre is here. Who knows but what the gas compressor and expansion coils may cool the living and work rooms as well as the ice box?

The re-circulation of air will find wider and wider application, for this means fuel economy. Large spaces with relatively slight crowding are particularly suitable for this practice.

There are numerous examples of well-intentioned, but illy worded and unwarranted legislation bearing on ventilation. This distracts attention from the really important questions, provides a ground for controversy, and hinders progress. This situation is bound to be remedied.

The literature of the subject contains many more accounts of projected works than of impartial critical tests of operating results. In order to learn the most from experience, there must be careful observations of equipment in use. This is necessary in order to verify or disprove the practical success of engineering ideas which are constantly being introduced. It is to be hoped that the research staff of the American Society of Heating and Ventilating Engineers may find opportunity to enter this field and bring forth scientific data.

Most to be desired is air that is cool rather than warm, dry rather than damp, diverse in temperature in different parts and at different times rather than uniform and monotonous, moving rather than still, and, finally, free from annoying odors and floating matter. This is fresh air. It is the object of ventilation to reproduce this condition indoors as faithfully as possible.

DISCUSSION

JAMES W. ARMSTRONG,* M. AM. SOC. C. E.—Touching as it does almost every phase of the water-works problem this is an interesting paper. Mr. Fuller has shown very clearly the value, to humanity, of a pure water.

One or two points have recently come under the speaker's observation that might be of some interest in connection with pipe coating. He recently had occasion to inspect the inside of a 7-ft. steel water main that had been in service about eleven years. It is laid under 25th Street in Baltimore, Md., and is protected on the outside by a concrete casing and on the inside by a coating of bitumastic enamel.

A walk of about ½ mile and return through this line showed it to be entirely free from tuberculation. The only defects discovered, were around the rivet heads in the bottom of the pipe. The evidence is that workmen, in passing through the pipe line, had knocked the protective coating from some of the rivets and corrosion had set in at such places.

If bituminous enamels are properly put on they make an excellent waterproof coating for both steel and concrete, but as they have to be put on hot, it is necessary to have the surface to which they are applied clean and perfectly dry. Failure of bitumastic coatings can generally be traced to neglect on the part of workmen to comply with these precautions.

A piece of casting taken from a broken water main in New Orleans, La., revealed the fact that the interior was nearly free from corrosion and that a thin smooth coating of lime had been deposited, which formed a natural and effective protection. This would indicate that cities using lime for softening purposes have little to fear from tuberculation of cast-iron pipe.

In Baltimore, where the water is naturally corrosive, sufficient lime is added after filtration to maintain a pH value of about 8.2 for all water entering the city mains. The alkalinity is thus maintained at a point sufficiently high to reduce its corrosive qualities very greatly. Cities annoyed with the corrosion of pipes might avoid much of their trouble by raising the alkalinity of the water delivered to the city mains.

In tracing the history of the water-works pump, Mr. Fuller has shown that the electrically operated centrifugal pump has, after a long struggle, come into its own. There are three great advantages in pumps of this kind: (1) Low first cost; (2) very little repair work; and (3) an absolute minimum of labor for operation. At Montebello, the low-lift pumping station contains five electrically driven centrifugal pumps, having an aggregate capacity of about 250 000 000 gal. per day. For more than eleven years, practically all Baltimore's water supply has passed through this pumping station, and there is no other power available, should the electricity fail. For several years, after first placing the station in service, power was supplied over a single underground cable. On one occasion a blow-out in this cable caused considerable uneasiness, but it was repaired before the storage in the 15 000 000-gal. reservoir ran out. A second cable was afterward installed, and since then

* Filtration Engr., Baltimore City Water Dept., Baltimore, Md.

there have been only momentary interruptions in the power supply. During the entire time this station has been in operation, only one man has been employed on each shift of eight hours, except for repair work.

The cost of pumping water, neglecting fixed charges and overhead, from 1916 to 1919, against an average head of about 40 ft., was $1.62 per 1 000 000 gal. During the entire life of the plant, more than eleven years, the cost averaged about $2.10 per 1 000 000 gal. for pumping against heads ranging from 30 to 43 ft. The high price of coal during the World War was the principal cause of the increased total cost.

The plant at Little Falls, N. J., should be considered the prototype of all modern filter plants, as it was the first to be entirely constructed of reinforced concrete. The use of reinforced concrete for such purposes spread very rapidly. The great variety of forms and shapes into which it could be moulded, led many engineers to believe that its use was the solution of most of their structural problems and has made them a bit slow about recognizing its limitations. Lately, many have learned that concrete, passing as excellent when fully protected from the elements, may fail utterly when exposed to the weather for a few years.

It has also been learned that concrete through which water is leaching, is doomed; that the passage of water through concrete will, in turn, dissolve both the calcium and aluminum compounds; and that the dissolving of these compounds robs the concrete of its strength and leaves it an easy prey to the action of frost and the elements. To secure imperviousness for all water-bearing or exposed concrete is of the utmost importance.

If field operations could be carried on with the precision of laboratory work, it might be possible to secure satisfactory concrete, but the difficulty of controlling the human factor may make futile the most painstaking and careful work in securing a proper quality, grading, and mixing of materials. Unless some method of securing denser concrete can be obtained, engineers of the future may come to rely more on some outer coating to render concrete impervious.

In the ordinary distribution system valves are not operated often, and an old superintendent might, after years of service, not have had experience enough to judge rightly the merits of a particular valve. With the advent of large mechanical filter plants where valves are opened and closed every day, certain weaknesses have developed that had not been realized. Special efforts should be made to improve the details of valves designed to operate in a horizontal position.

J. W. Ellms,* M. Am. Soc. C. E. (by letter).—The survey by Mr. Fuller of the progress made in the past half century in the water-works field, is both interesting and instructive. To the older members of the Society, whose professional activities have run parallel with the development of the art, this record may seem commonplace. However, does it not naturally raise the question of how such improvements have been made possible, and to what specific cause the advance may be attributed?

* Engr., Water Purification and Sewage Disposal Dept., Public Utilities; Cons. San. Engr., Cleveland, Ohio.

The general increase in scientific knowledge is doubtless a partial answer to the question; but is it not more specifically answered by the vast amount of research work which has been carried on in this field during the past fifty years by professional men? The labor of individuals and of associated groups for the solution of specific problems has furnished the real basis for these improvements. The large sums of money expended in research work have not always been appreciated; but without these funds the present status of the art could not possibly have been reached. State, municipal, and private funds have enabled scientists to cope with the problems arising in this field of applied science. The benefits that have been derived from systematic research in the past is a sufficient guaranty of what may be accomplished in the future. Co-operative research during the World War certainly proved what can be done under the stress of necessity.

While the writer realizes that much is now being done by National engineering societies in furthering research work, he believes that more may be accomplished and greater advances in the art secured by more active and properly directed group action. The field is broad and the rewards ample for all those who have a genuine interest in the progress of applied science in water-works engineering. The problems to be solved involve the fundamental branches of science, such as physics, chemistry, and biology; and in applied science, the arts of civil, mechanical, and electrical engineering. Where among human activities could one find a more fascinating or varied field for labor? To the younger members of the profession, it should offer a life work of usefulness.

Caleb Mills Saville,* M. Am. Soc. C. E. (by letter).—Mr. Fuller has performed a notable service to engineers and others specializing in water supply work in bringing together in such a concise but comprehensive manner this critique of water-works practice during the past century and a half.

While probably the great fires in Chicago, Ill., and Boston, Mass., in the early Seventies furnished an impetus to water-works construction, it is notable that many of the works in Northern cities were started about ten to fifteen years earlier. For some reason, the late Fifties and early Sixties seems to have been a time of considerable water supply work in this section, possibly because of growth in population and increase in value of property.

Apparently, the largest increase in public water supply works came after 1880. Of the 9 850 plants estimated as in service in 1924 and given in Mr. Fuller's Table 1, 6.1% were installed prior to 1880; 32.5% prior to 1896; and 67.5% since that date. That is, about two-thirds of the total number of water supply systems in the United States, as estimated in the "Manual of American Water Works", were installed between 1896 and 1924.

The use of house cisterns or tanks connected with the public supply was a very common mode of supply for individual buildings, because they could be filled at night when the city draft decreased. This reserve helped during the day when the city supply, due to inadequacy of trunk lines, was unsatisfactory on the higher elevations. Previous to this, and in the transition period from

* Mgr. and Chf. Engr., Hartford Water-Works, Hartford, Conn.

dug wells to public supply, many private houses had water-tight cisterns in their cellars, in which rain water from the roof was stored and pumped by hand-operated force pumps to tanks in the upper part of the house. Often these cisterns were supplied with charcoal filters through which the water was passed before being used. In many towns and cities, about a century ago, large public cisterns were located in various parts of the municipality, in which water was stored for fire protection purposes. Such cisterns were existent in Malden, Mass., and Hartford, Conn., up to within a few years, although abandoned many years ago, probably with the introduction of aqueduct water. The locations of these cisterns were often forgotten and only recalled when they were accidentally uncovered or broken through by heavy loading.

Wooden pipes of bored logs were used in many localities. They were in service for some years in Boston and elsewhere. In Hartford, such pipes were used as early as 1803 in at least two supply systems bringing water to the center of the city from springs several miles away. On Fig. 1 is shown a photograph of one of these wooden pipes removed in 1926 in the center of the city during the construction of a large building. On Fig. 2 is shown a 42-in. cast-iron pipe for purposes of comparison.

The use of cement-lined pipes seems to deserve somewhat more attention than Mr. Fuller was able to accord it. As he states, this pipe had considerable vogue, particularly in New England, and its value then and now seems not to have been fully appreciated. The best treatise on the subject of cement-lined water pipes known to the writer, is found in a paper* entitled "Wrought-Iron Cement-Lined Water Pipe" by the late Leonard Metcalf, M. Am. Soc. C. E. A perusal of this paper indicates the widest variation in experience, from good to bad.

As an example of satisfactory use, it is of interest to note the 30-in. cement-lined main of the old Charlestown, Mass., Water-Works, laid from the reservoir on Walnut Hill through Broadway, Somerville, Mass., for a distance of several miles. Installed in July, 1871, it is still in service as an integral part of the present Metropolitan (Boston) Water Supply System. Possibly, in systems where so much trouble was experienced with this kind of pipe, the makers and not the material were most to blame.

The reliance on linings and coatings to protect both cast-iron and steel pipes is mentioned very briefly by Mr. Fuller. The absolute dependence on the integrity of a covering to protect cast-iron pipes from rust tubercles that reduce flow and form corrosion that soon destroys steel pipe when exposed to "aggressive" waters is, however, worthy of more than a passing comment. The importance of the work of the committees of the several water-works associations now considering this matter of pipe covering, is realized when one recalls the steel pipes that have completely failed within a few years after being laid in adverse conditions of soil or exposed on the interior to corrosive water. Steel pipes undoubtedly have a large place in water-works construction, but that place must be suitable for their use.

* *Journal*, New England Water Works Assoc., March, 1909, p. 1.

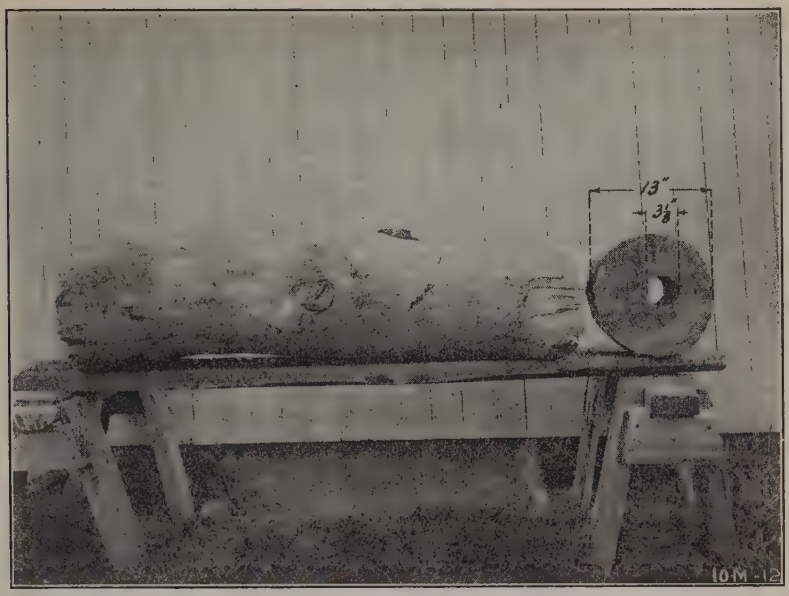

FIG. 1.—WOOD PIPE, ORIGINAL WATER SUPPLY LINE, HARTFORD, CONN.

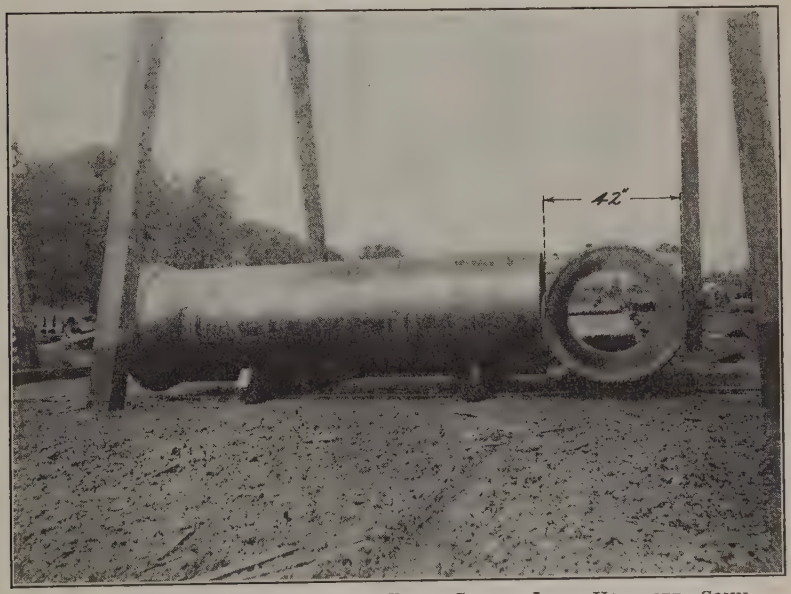

FIG. 2.—CAST-IRON PIPE, PRESENT WATER SUPPLY LINE, HARTFORD, CONN.

In the matter of "distribution economics," it seems desirable to record the vast improvement that has resulted from the intensive work of the National Board of Fire Underwriters, under the able leadership of George W. Booth, M. Am. Soc. C. E., Chief Engineer, in developing such adequacy of supply and delivery systems that it has been possible to reduce rates for insurance considerably; which is only another way of stating that the fire hazard has been greatly diminished by the advancement in water supply work. Present conditions in a large Western city indicate that if one is searching for information concerning the "bitterness of the opposition to metering" it is unnecessary to revert to the Eighties.

The methods used in Philadelphia, Pa., and New York, N. Y., in securing a source of water supply were similar to those in Boston, when the first water supply was brought in through the "ancient conduit" installed by a company of citizens under authority of an Act of the May Session of the General Court of the Massachusetts Colony in 1652, or six years previous to the dug wells of the Dutch in 1658 and 141 years prior to the Manhattan Company of Aaron Burr, chartered by the New York Legislature in 1799. Two years earlier than that date, 1797, the Hartford Aqueduct Company was given a charter by the General Assembly of Connecticut. In February, 1795, the General Court of Massachusetts gave a charter to the "Jamaica Pond Aqueduct Corporation" to bring water from "any part of the Town of Roxbury into the Town of Boston."

In skimming the history of the development of pumping engines, the performance of the E. D. Leavitt triple expansion engine, installed at the Chestnut Hill Pumping Station of the Boston Water-Works in 1895, should not be overlooked. This pumping engine, on the authority of the late Desmond FitzGerald, Past-President, Am. Soc. C. E., is said to be "one of the most remarkable in existence in respect to duty and workmanship." Its three cylinders are 13.7 in., 24.375 in., and 39 in. in diameter, respectively. High speed was made possible by use of Riedler valve construction. The normal speed of the engine is 50 rev. per min., at which the pump capacity is 20 000 000 U. S. gal. per 24 hours. The duty of this engine was 145 000 000 ft-lb. per 1 000 000 B. t. u. It is stated that this engine has been run at a speed of 70 rev. per min., or 40% in excess of the contract, with smooth and economical operation.

The epoch-making Louisville, Ky., investigations and their result in directing future work in water purification, was due almost entirely to the minute attention to detail, the untiring enthusiasm and good judgment of Mr. Fuller.

It would seem desirable to call more attention to the two types of filtration works on which dependence is placed for safe-guarding public health and supplying attractive water; and especially to the advance made since 1895 in the art of clarifying the turbid waters of the South and West; due, first to the hit-or-miss methods of commercial exploitation and, finally, placed on a sound scientific basis by the technical work of the late E. B. Weston, M. Am. Soc. C. E., Mr. Fuller, and Robert Spurr Weston, M. Am. Soc. C. E.

The failure of the slow sand filter, in many cases, was due not to the type of filter, but to its limited application and inadaptability to meet some conditions imposed. To overcome these difficulties, modern art has developed a much more efficient machine than the slow sand filter. The largest slow sand plants in this country are those at Pittsburgh, Pa., Philadelphia, and Washington, D. C. Slow sand plants giving most satisfactory results as to quality of effluent and cost of production are in operation at Springfield, Mass., and at Hartford. In these places, as in many others in the north and east portions of the United States, where the natural waters carry little turbidity and only a moderate amount of color, the slow sand filter is particularly well adapted. Where this type can be used, the resulting effluent generally is much more satisfactory. After-sterilization is usually unnecessary and the operation of the plant is more "fool proof" than the rapid sand type. The latest of the larger filter plants of the rapid sand type is the installation at Providence, R. I., designed and constructed under the advice of Allen Hazen, M. Am. Soc. C. E.

The rise in regulation of public utility works in the past two decades seems well worth comment and has demonstrated the wisdom of this method of control of water supply as well as other utility business. This regulation has injected into utility operation business methods which have been almost as efficacious in producing satisfactory working conditions as the improvement in technique has advanced the quality of the water supplied. In fact, these two are interdependent, for without economical financial control, the improvements in supply and purification would have been much less available for public use.

In a statement of this kind covering as it does a period of many years, it seems desirable to give brief note of some of the leaders in this branch of engineering who have now passed on. Among these may be mentioned James B. Francis, J. James R. Croes, Alphonse Fteley, Frederic P. Stearns, and Desmond FitzGerald, Past-Presidents, Am. Soc. C. E.; Hiram F. Mills, Hon. M. Am. Soc. C. E.; and Joseph P. Davis, Dexter Brackett, and George C. Whipple, Members, Am. Soc. C. E.

It is of interest to note also that most, if not all these names, as well as those of many others eminent in water supply work, were associated at times either with the Boston Water-Works, or that institute of public health work administered so efficiently by Dr. Thomas M. Drown, William T. Sedgwick, and Dr. Henry P. Walcott, the Massachusetts State Board of Health.

M. M. O'Shaughnessy,* M. Am. Soc. C. E. (by letter).—Mr. Fuller is to be complimented on the exhaustive handling of the subject of water-works, included in his brief summary. The most valuable tabulation is the great increase in number of publicly owned water systems *versus* privately owned (Table 1). The United States is to be congratulated on making the greatest advance in the science of water distribution and measurement as indicated by the Venturi meter developed by Clemens Herschel, Past-President, Am. Soc. C. E.

* City Engr., San Francisco, Calif.

In describing hydraulic-fill dams Mr. Fuller ignored the credit that belongs to the late Julius M. Howells, M. Am. Soc. C. E. He successfully constructed the first two hydraulic-fill dams in the United States; the first in Texas and the second at La Mesa, San Diego, about 70 ft. high. The latter has since been submerged by a higher buttressed arch concrete dam immediately below it. The late James D. Schuyler, M. Am. Soc. C. E., had the discretion to pick up Mr. Howells' ideas and methods and, with a broader practice, develop the subject of hydraulic-fill dams more exhaustively.

Mr. Fuller ignores the importance of the rock-fill dam, devoting less than one sentence to it. It is entitled to more consideration, as the largest dam east of the Mississippi River is the rock-fill dam, more than 280 ft. high, across the Dix River in Kentucky, which was completed in 1925 as a restraining reservoir for power uses. The water-tight curtain is properly on the water face of the dam where it belongs, and not on the back.

He contributes a very valuable section toward the history of pumping water, including a description of the Worthington pumps. Modern electrically operated centrifugal pumps have displaced all the heavy, cumbersome machinery and equipment in vogue thirty years ago.

The Medical and Engineering Professions are to be complimented on the improved sanitary condition of water supplies for drinking purposes, as indicated by the lowering typhoid fever death rates in American cities. Table 2 shows at once that there is at present only one-twentieth of the deaths from this disease that there were 20 years ago. This shows progress.

The City of San Francisco has taken elaborate precautions for the preservation and purification of its water supply by extensive land ownership around reservoirs. This is a wise precaution. It is a foolish idea for water companies and cities to encourage pleasure-seeking people to enjoy the fishing or boating on domestic water supplies, and the only safe rule for public health is exclusion. In this regulation the San Francisco engineers are supported by the public health authorities.

Morris Knowles,* M. Am. Soc. C. E. (by letter).—In discussing Mr. Fuller's paper, there is little fundamental information that can be added. The author covers the subject completely and concisely, and any addition must necessarily be an expansion of some item already mentioned.

The trends of the demand of people, as regards quality of water, is one factor which is seldom mentioned, but which has played an important part in the history of public water supply systems. As in everything else, the people are demanding an improved quality of water for their use. The time when it was necessary that a water be safe for drinking purposes only, has passed. Even during the past 10 to 20 years, the demand of the people as regards quality of water has grown. The people of New England dislike mud and hardness, but will put up with color. Western people have put up with turbidity and hardness, but dislike color. The time is not far distant when a water that has turbidity, color, or hardness will not be tolerated anywhere.

* Pres. and Chf. Engr., Morris Knowles, Inc., Pittsburgh, Pa.

In other words, water must not only be safe for drinking purposes, but must be pleasing in appearance and pleasant and easy to use.

It has been known for a long time that one of the prime requisites of an industrial community is soft water. This is being more and more realized and, consequently, the demand for such water is increasing. The importance of this factor is well shown by the number of softening plants that are being installed. In the State of Pennsylvania, there are twelve such plants, four of which supply a population of more than 50 000.

Another quality of water that is becoming important is its temperature. This is indicated by the fact that many plants equipped with condensers of the water-works type have had to discontinue their use, due to the fact that the few degrees rise in temperature of the water that results has been the cause of many complaints.

The demand for improved quality of water has been almost in direct ratio with the education of the people on the subject of water supply. As soon as they know that they can get a good quality of water, they will demand it. Although the people are better informed on the question of water supply than they have been in the past, there is still room for more education. In every line of endeavor, be it industry, art, or other activity, it is necessary that education of the people proceed with the progress that is made, or the progress will soon cease.

A great number of people, knowing nothing about water, revolt against drinking purified water that has come originally from a known rather polluted stream. In order to overcome that difficulty, either the pollution will have to be removed, or the people will have to be educated to the idea that the water is satisfactory in spite of its antecedents. In almost any city in the country where good water may be obtained by turning a tap, there is also a company engaged in the business of selling so-called "spring", well or distilled water for drinking purposes. This may be an indication that the public water supply is not what it should be, but more often it is simply lack of education on the part of the people relative to the subject of water supply and safety of the water from public systems, as compared to the doubtful quality of other water.

The water-works engineer now has many problems dealing with the art and details of public water supply and the education of the people. He will probably always have these, but he has, and will have, assistance that will tend to make the solution of the problems less difficult. This aid is, and will be, given through the agencies of supervision, co-operation, and consolidation.

The developments during recent years in the fields of governmental supervision and inspection of drainage areas, of interstate agreements, and of consolidation of public water supplies, are of particular interest to, and should be welcomed by, the water-works engineer. It is in this direction that people must look for the solution of problems that have to do with the increasing pollution of streams by such material as industrial wastes and mine drainage that cannot be dealt with by present water purification methods. In order to solve these problems, engineers must either correct conditions at the source of the pollution, or go to one of the few remaining unpolluted streams for water.

Since about 1890, there has been a gradual change in the United States in conditions as regards sources of public water supply. Previous to that time, practically all American streams were relatively unpolluted, and the problem of locating a surface source for public water supply purposes consisted of locating a convenient stream having the necessary flow. With the greater stream pollution of the present day and the greater demand for sources of public water supply, the problem has become more complicated. In order to find a source of supply, a city, in many cases, must go outside its own jurisdiction and must look to State and even Federal administrative bodies for assistance.

State assistance and supervision of public water supply has become available through Sanitary Divisions of State Health Departments. In 1890, Massachusetts had about the only effective State Health Department in this respect in the country. Since that time practically all States have provided for Sanitary Bureaus and in more than one-half the States it is necessary to obtain the approval of these agencies on water supply and sewerage projects. People must look largely to these governmental agencies for the preservation of present sources of public water supply.

In the cases of large sources of water supply, Sanitary Divisions of State Health Departments are not capable of handling the question, as most large streams flow from one State to another. In such instances they must look to interstate agreements and sometimes Federal supervision, such as the U. S. Public Health Service. Interstate agreements are usually the result of meetings in which the interested State Governments, manufacturers, and others concerned are represented. The Interstate Stream Conservation Agreement concerning the Ohio River, in which Pennsylvania, Ohio, West Virginia, Maryland, New York, Indiana, Illinois, Kentucky, and Tennessee are represented, is one example of the effectiveness of such procedure. The success of this co-operative group will probably lead to the development of other similar agencies and agreements, in an effort to solve other similar problems.

In solving the question of mine drainage pollution in Pennsylvania, the ultimate answer will probably be the preservation of certain drainage areas against such pollution for use as sources of public water supply. This is about the only satisfactory solution in sight and the Court decision in the Indian Creek case would indicate that this procedure is feasible. Such solution will involve not only activity and increased power on the part of the State Government, but also the probable formation of regional and other combined water supply districts, inasmuch as it would be impossible for the smaller cities to have their own protected drainage areas.

The development of the art and of the details of public water supply has been extensive and should continue, but one of the more important developments as regards public water supply will probably be in the field of co-operation and consolidation.

George H. Fenkell,* M. Am. Soc. C. E. (by letter).—Mr. Fuller has made a very complete and interesting résumé of the advance in water supply prac-

* Supt. and Gen. Mgr., Dept. of Water Supply, Detroit, Mich.

tice during practically the full life of water supply systems in the United States. To the student, historian, and others, who may wish to pursue the subject in further detail this paper will serve as an authoritative reference and starting point.

The author's quotation from a paper by the late J. James R. Croes, Past-President, Am. Soc. C. E., regarding the development of a method of pumping water direct to a distribution system and of controlling pressures at the point of pumping, is very interesting, as this method is still in common use in many cities and towns, particularly in the Middle West. The development of the motor-driven fire-pump has eliminated, to a great extent, the necessity for excess ranges of pressure on the distribution system, which pressures were apt to have a bad effect on the plumbing systems of the buildings served with water. The increasing use of elevated storage tanks, and the gradually increased capacity of those being built, also tend to smooth out some of the pressure variations which always accompany the use of this system of distribution.

For the purpose of completing the record it is to be regretted that Mr. Fuller did not extend the data on maximum steam pressures used for pumping water beyond the year 1906, and, at the same time, add information relative to pump efficiency and duty. For completeness, some recent performance of steam turbine and electric motor-driven centrifugal pumps would have been interesting, as these are fast coming into more general use.

The development of intakes for lakes and rivers having small variations in level has probably been more marked on the Great Lakes and in tributary waters than elsewhere. This has been due to the great extent of this region and the large population making use of these waters. Throughout this district, winter weather is generally severe, and serious trouble from ice may be expected even in the southernmost part. Frazil, or needle ice, and the grounding or piling up of surface ice are usually most troublesome, and dangers arising from the heavy lake traffic must also be considered. These factors materially affect the design and maintenance of intakes on the Great Lakes.

The simplest intakes consist only of a pipe line laid on the lake bottom, and may terminate in an upturned elbow, or tee, covered with a screen or straining device of some kind. The elbow may have no support, or rip-rap may be piled around it. In some cases the pipe terminates in two or three elbows. A more elaborate design of the inlet end of the pipe (and this type was used by the City of Detroit, Mich., in 1858) consists of a boiler-plate cylinder having a dome top perforated with a great number of $\frac{1}{2}$-in. holes. Another variation has a cast-iron or steel hood or cage placed over the inlet elbow or toe of the pipe line, which is pierced with holes $\frac{1}{2}$ in. or more in diameter. Designs which included no protecting crib were probably in more extensive use formerly than now.

At Toronto, Ont., Canada, the inlet is carried above a protecting crib and, for the older intake, is protected by a cone consisting essentially of twenty-eight $1\frac{1}{4}$-in. round bars, spaced equally around the circumference, and for

the new intake by a steel plate supported 30 in. above the lip by 1¼-in. round rods, spaced 8½ in. on centers.

For the larger intake pipes it is customary to protect the inlet end by a submerged crib. There is considerable variation in the construction of these cribs. The larger ones have usually taken the form of a square or octagonal timber crib having a solid floor. They are divided into compartments by the cross-timbering. The conduit is carried through the cribbing above or below the floor to the central compartment or well, terminating in an elbow. In some cases, to provide for future extension, the conduit is carried across the entire crib, the end being closed with a blank flange outside the crib and a tee provided at the central well. The crib is towed out to its final position and sunk, and as many compartments as are necessary to hold it down are filled with broken stone or concrete, or both. The usual practice is to cover the central well, and often the four compartments adjoining the sides of the well, with a grating of plank placed on edge and spaced about 2 in. in the clear. In some cases, as at Toronto, the pipe is carried above the crib and the inlet protected.

The submerged type of intake structure is usually built in connection with a pipe conduit, but at Gary, Ind., Crib No. 5 at Cleveland, Ohio, and the new intake at Milwaukee, Wis., the conduit is a tunnel. Practically all exposed intake structures have been built in connection with tunnels, but that at Montreal appears to be the exception. These structures are usually limited to depths of 40 ft., or less. Crib No. 3 at Cleveland is in the deepest water, about 49 ft.

An exposed crib consists essentially of a central well enclosed by massive walls of sufficient thickness to give strength and stability to resist the forces of wind, wave, and ice action. The intake shaft of the tunnel draws the water from this well, and ports in the crib walls admit the water to the well. These cribs are built on shore, launched, towed to position, and sunk on a bottom which had been previously leveled off by dredging.

There has been considerable change in the design of exposed intake cribs. The City of Chicago, Ill., with its large population and heavy shore pollution requiring the location of its intakes at increasing distances from shore, has taken the lead in developing exposed intake structures. Two-Mile Crib, completed in 1867, was the first. It was built entirely of timber, pentagonal in shape, with 58-ft. sides, and a height of 40 ft. The central well was of similar shape, and the seven compartments of the wall space were filled with rubble during sinking. The Hyde Park or 68th Street Crib is of similar construction, but hexagonal in plan. These two intakes are peculiar in that they are enclosed by a heavy breakwater. Crib No. 4, the first exposed crib at Cleveland, built prior to 1890, was pentagonal and was constructed entirely of timber. The Four-Mile Crib, built during 1890-94, the Lake View Crib, completed in 1896, and the Carter M. Harrison Crib, built about the same time, at Chicago, mark a change in construction. They are all circular or polygonic in plan and have a base of heavy timber grillage through which the ports pass. On this base are two concentric steel shells with radial bulkheads

forming compartments which, in the case of the Four-Mile Crib, were filled with concrete. Crib No. 3, at Cleveland, built about 1898, is very similar in construction.

The Detroit intake crib, built during 1905-06, was constructed entirely of timber and the compartments were filled with concrete. Its shape is an elongated octagon. The City of Buffalo, N. Y., completed a crib in 1910 having two concentric steel shells with no bottom. It was divided radially into compartments, a number of which were closed at the bottom with timber for buoyancy when towing the crib to position. The crib was landed on a concrete foundation ring resting on rock, and then filled with concrete.

The Wilson Avenue Crib, at Chicago, completed about 1918, presents another variant. There were two concentric steel shells with radial compartments, but no floor. The bottom of each shell had a cutting edge. For buoyancy, the ports were bulkheaded, and buoyancy tanks were built between the shells. When sunk, the steel shoes entered the clay and sealed the bottom. Concrete was used for filling.

Exposed cribs are usually provided with a more or less elaborate superstructure with quarters for attendants. Except for the Wilson Avenue Intake, Chicago, the Linwood Avenue Intake, Milwaukee, and the Buffalo Intake, the tunnels have been driven through clay.

Ice is a source of much anxiety and trouble for many who maintain intakes on the Great Lakes, because it may greatly reduce, and, at times, cut off the flow. Sheet ice and frazil ice are usually the source of trouble, sheet ice chiefly after breaking up, for it is then carried by wind and current and may form ice jams obstructing the flow to the conduit. Frazil ice, by adhering to the sides of inlet openings and ports, gradually builds up and becomes a serious obstruction, often cutting off the flow entirely.

Various remedial measures have been used to overcome ice troubles, particularly from frazil ice, but none has been uniformly successful. Experience has shown that the depth of the port opening below the surface has a marked effect. The depth depends on local conditions, but 35 to 40 ft. will usually give freedom from trouble with frazil ice. The velocity of flow through the ports has also been reduced on various intakes in an effort to minimize the tendency of frazil ice being drawn into the ports. Velocities of less than 0.5 ft. per sec. have been used, but there are no available data as to the maximum velocity which will not overcome the buoyancy of this ice.

Back pressure on the intake ports of submerged cribs has been used more or less effectively to remove adhering frazil ice. Steam and compressed air have also been used, and dependence, in some cases, is placed on sufficient storage to tide over the demand until natural causes assist in removing the obstructing ice. On exposed intakes, particularly at Chicago, a crew of men is stationed on the crib to combat the ice. Pike poles, steam, and small charges of dynamite are used for this purpose.

In shore wells where ice frequently clogged the screens, traveling screens replacing the former stationary screens, have eliminated trouble in many cases.

The steam-operated power plants on the Great Lakes also use large quantities of water for condensing. The maximum consumption per plant of the Detroit Edison Company ranges from 184 000 to 500 000 gal. per min. The average is more than 2 gal. per min. per kw. The intake arrangements of the power plants are quite different from those of the water supply plants. The water usually comes through a short canal, or a forebay, which may or may not have a boom across the entrance to deflect floating débris and ice. At the Avon Plant of the Cleveland Electrical Illuminating Company, and at a plant in Milwaukee, a lagoon has been built on the lake shore using heavy rip-rap for the enclosing dikes.

Traveling screens are usually installed at power plants to remove débris and ice. These plants are also arranged so that the heated cooling water can be discharged into the forebay and thus prevent trouble from ice.

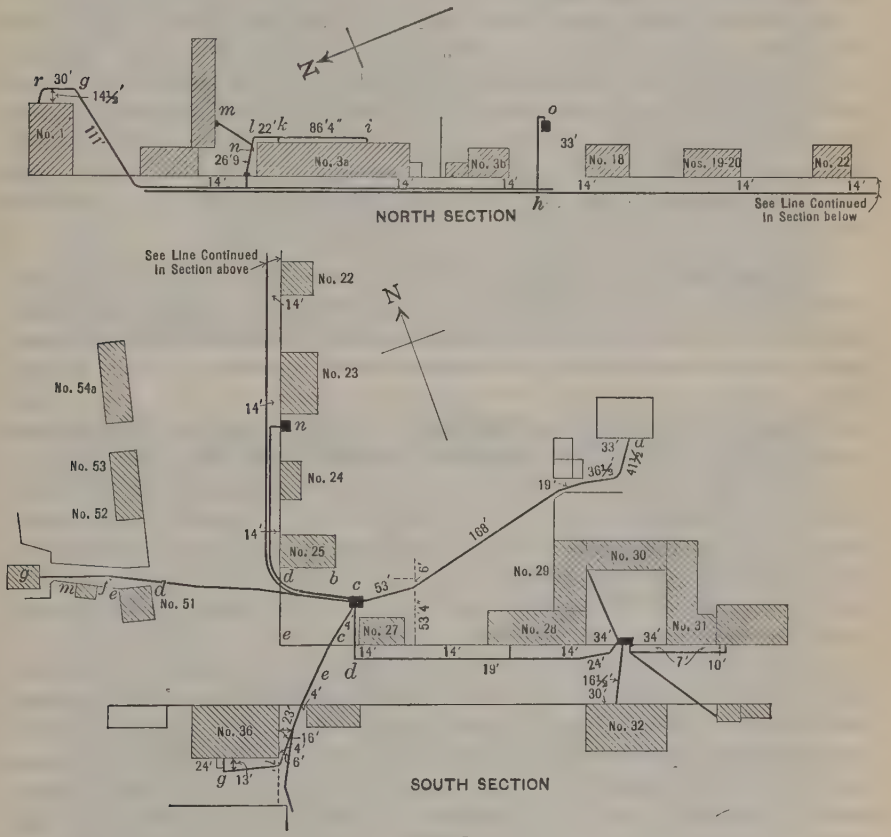

FIG. 3.

HARRY G. PAYROW,* M. AM. SOC. C. E. (by letter).—As a resident of Bethlehem, Pa., the writer was interested in Mr. Fuller's reference to the first water-works pumping plant in the United States, which was operated

* Asst. Prof., Civ. Eng. Dept., Lehigh Univ., Bethlehem, Pa.

there. A few years ago he saw the original plans of both the pumping station and a layout of the distributing system. Both plans were well executed, the lettering being in German script. Fig. 3 is a traced copy of the distributing system that may be of some interest, at least as to its comprehensiveness.

The lignum-vitæ pump first successfully forced water from a spring up to a wooden tank on May 27, 1755, and on June 27 of that year, the regular operation of the Bethlehem Water-Works was commenced (see Fig. 4). The pump lift was about 45 ft. The pipes were generally bored logs of hemlock, although some that were recently excavated, were gum and walnut. Fig. 5 shows a bored hemlock water pipe, laid about 1754, which was excavated in 1927. Apparently, a considerable length of lead pipe was used for connections to cisterns and buildings. As the pipe was laid, offsets were taken, chiefly to buildings, thus showing considerable foresight on the part of the builders in locating the water mains permanently.

It might be further stated that these early Moravian settlers fully appreciated the value of protecting their famous spring from pollution. As early as 1747 some concern was expressed as to the purity of Bethlehem's water supply. The Village Board ordered the spring to be enclosed with a fence, and it was to be cleaned "in the light of the moon". Later, it was ordered that only those who understood it should attempt to clean the spring. This may have referred to the folk notion that the state of the moon must be heeded.

W. Kiersted,* M. Am. Soc. C. E. (by letter).—Mr. Fuller's interesting historical sketch of water-works development reminds the writer of the situation in the Middle West in the Eighties and early Nineties, when promoters enthusiastically sought franchises for water-works construction. Due to their efforts, doubtless many small cities acquired water-works much sooner than would have been the case had the matter been left entirely to municipal initiative. The utility bonds offered by these promoters, for a time, seemed to have a ready sale, particularly for properties in the larger cities. However, with some of the promoters the essential aim was to increase their regular material and supply business through sales to the water-works constructor while accepting bonds in payment. The outcome of this policy, when the bonds issued against the utility failed to find a ready market, was sometimes disastrous and caused serious financial embarrassment.

Improvements were made from time to time as the method of purifying and distributing water became better understood, particularly in localities depending on a river as the source of supply. Mechanical filtration, one of the methods advanced through commercial channels as offering great prospects for improving the quality of river water, had its capabilities greatly overrated at first, which resulted in numerous failures in efforts to clarify muddy water. Through all this period a few important cities like St. Louis and Kansas City, Mo., and Omaha, Nebr., located on the Missouri River, continued to rely on sedimentation as a means of water clarification; and of these three cities, Kansas City was the last to construct what are termed modern purifica-

* Cons. Engr., Kansas City, Mo.

Fig. 4.—Pump-House as It Looks To-Day.

Fig. 5.—Bored Hemlock Water Pipe, Laid About 1754.

tion works. Mr. Fuller could have consistently added a paragraph with regard to the evolution of the sedimentation process, particularly as it is the main dependence of successful filtration. The experience of Kansas City is a good illustration of what can be accomplished in clarifying water by sedimentation and of rendering a water safe and potable through the aid of chlorination. It is worth while to give the experience of this city during the fiscal years, 1921 to 1926. These general results are given in Table 5.

TABLE 5.—Physical Characteristics of Kansas City, Mo., Water Supply.

Fiscal year.	Average turbidity of water distributed, in parts per million.	Percentage of turbidity removed.	Typhoid deaths per 100 000.
1921	23	96.68	11.5
1922	23	98.28	4.6
1923	29	97.7	4.8
1924	16	95.5	3.6
1925	11	99.54	1.9
1926	8	99.68	3.46

In a large measure these highly gratifying results are due to the efficient effort of Dr. George F. Gilkison, although he was compelled to use settling basins not altogether scientifically designed. The results of sedimentation considered in connection with the low typhoid death rate seem to be conclusive evidence that the mechanical filter is, in fact, of secondary importance in clarifying and purifying the river waters of the Central West. Future development of the art of water purification should see more attention given to the design of the settling basin and to methods of breaking up the colloidal condition of sediment in the preparation of water for the filter. Further development of the filter itself should be directed toward simplifying and cheapening its construction. The topic of sedimentation is too important to be obscured by the prominence of an associated topic of less real importance, namely, that of mechanical filtration. The latter process must rely on the settling basin to prepare the water for filtration and on chlorination to sterilize the filtrate.

Mr. Fuller's suggestion that the collection and digestion of available information relating to the engineering aspects of underground supplies, is a valuable one because this source of supply is greatly under-rated in localities where underground water supplies are abundant. Lack of an appreciation of the value of the underground source of water supply is perhaps the reason for advising cities, in a few instances, to abandon an available and abundant underground water supply for one from a polluted and muddy river. Propaganda relating to the mechanical filter may be responsible indirectly in no small measure for the obscurity surrounding the underground water supply in that it has engrossed, so completely, the minds of engineers.

It is worthy of note, however, that late developments show that a large quantity of water can be pumped from a single well sunk in fine water-bearing sand. This is certainly an achievement, particularly in the method by which wells in such material can be successfully constructed, operated, and

maintained. Success in this particular direction has greatly broadened the range of development of underground water and has added a new stimulus to further effort along similar lines.

Referring to Mr. Eddy's paper the developing stage through which the disposal of sewage is now passing is quite likely to leave in its wake many abandoned or transformed structures formerly erected in compliance with some theory or principle which, at the time, appeared promising. The septic tank is now of the past for community use. The Imhoff tank, although still a recognized device for treating sewage, will likewise become a thing of the past, except for small towns, because experience has shown the insurmountable difficulties of attempting to combine, successfully, the purely mechanical process of sedimentation with the biological process of sludge digestion. A sacrifice of essential principles of one or the other of the processes is likely to follow attempts to co-ordinate them in a single structure.

Preliminary sedimentation is an essential factor for consideration in any method of sewage purification, and its importance is so great as to entitle it to an independent structure wherein the governing principles of sedimentation can be applied without interference with those of an entirely different process. This treatment cannot accomplish all that is desired, however, because it does not remove the colloids and, therefore, does not reduce the sewage to a condition suitable for application to either land or sprinkling filter. The desirable intermediate treatment is one that will break up the colloidal condition of the remaining sediment and reduce the sewage to a state susceptible of further improvement in a secondary settling basin. The writer regards this intermediate treatment of sewage as the most important phase. It invites the closest attention of the chemist and the engineer in arriving at the best and most economical process by which a maximum percentage of suspended matter can be removed from sewage, before attempting to purify it still further by any natural process. When this end is accomplished the final disposal of sewage by irrigation in the arid and semi-arid sections of the United States, or by intermittent filtration in other sections of the country more generously watered by Nature, will receive well merited consideration. Neither method of land disposal should be considered obsolete as long as a natural process of sewage purification remains acceptable.

The sprinkling filter, notwithstanding its many merits, must disgorge itself of organic accumulations periodically or become clogged. The usual offensiveness of the disgorging process can be alleviated in a great measure through the previously mentioned intermediate treatment. Then the danger of overburdening the natural activities will be decreased; there will be less occasion for the use of after-sedimentation; and the area of the filter, always expensive to construct, can be materially reduced.

The method of sludge disposal, which is of secondary importance, should be adapted, of course, to local surroundings. Although they are accompanied with some odor, reservoirs cheaply constructed of earth offer a satisfactory solution in isolated places. In other localities, open or closed separate

digestion tanks may be required, wherein some kind of treatment will probably be needed.

In short, it is the writer's belief that future development should be directed toward a larger removal of suspended matter before sewage is applied to land or sprinkling filters.

JOHN H. GREGORY,* M. AM. SOC. C. E.—Mr. Eddy has presented an exceedingly interesting paper on the history of the sewerage and drainage of towns. There are many phases of the subject that might be discussed at length, but the speaker will confine his discussion to one phase only; that is, the question of the separate or combined system of sewers for cities. There is much to be said for both systems. The speaker holds no brief for either type, but there are some phases of the subject that should be considered rather carefully. Take, for example, the question of storm overflows from a combined system. When a large city is located on a stream which has a large volume of flow, the question of storm overflows may not be of much importance; whereas, if the city is located on a stream the flow of which during dry weather may be almost nothing, storm overflows become of great importance.

With reference to maintenance and operation, both systems present certain difficulties. With the combined system there are catch-basins and, with the separate system, surreptitious connections of rain-water leaders to the sanitary sewers, sometimes causing flooding of cellars, and also surreptitious connections whereby sewage is discharged into storm-water drains.

However, it seems that there is very much to be said for the separate system in the case of a large city located on a stream that has a very low stream flow in summer, especially if the stream runs through the heart of the city. The speaker has in mind one city having a population of about 300 000 which is sewered mainly on the combined system. The city happens to be located on a stream having a water-shed of 1 500 sq. miles and a dry-weather flow in the stream of less than 10 cu. ft. per sec.; which is almost nothing. Under such conditions storm-water overflows are of great importance, and the volume of overflow must be kept at a minimum if nuisance in the stream is to be avoided. If the city was sewered on the separate system, the problem of keeping the stream clean would be much simpler.

The tendency in the country is for cleaner streams, and if streams are to be kept clean it is a question whether the advantages do not lie with the separate system, rather than with the combined system, if the sewage is to be treated.

KARL IMHOFF,† M. AM. SOC. C. E.—The scientific conditions of the digestion of sewage sludge in separate tanks (separated from the flowing sewage) were first studied by Mr. H. W. Clark, in Boston, Mass., in 1899. Since 1906 sludge digestion has been successfully carried out in the lower chamber of two-story settling and sludge-digesting tanks. Later, sanitary engineers learned also to digest sludge successfully in entirely separate tanks by the same alka-

* Cons. Engr.; Prof. of Civ. and San. Eng., The Johns Hopkins Univ., Baltimore, Md.
† Chf. Engr., "Ruhr-Verband," Ruhrverband, Essen, Germany.

line methane fermentation that is observed in the lower chamber of good two-story tanks.

The digestion depends only on two factors: Mixing and temperature. The fresh sludge is mixed with ripe alkaline sludge in order to avoid acid fermentation in the former. The pH value of ripe sludge is 7.3 to 7.6.

The temperature should be between 6° and 25° cent., the higher the better. In the Southern States the natural temperature of separate tanks may be sufficient. In the Northern States, two-story tanks are better because the sludge tank is kept warm by the flowing sewage of the upper chamber. Artificial heating is easier in separate tanks.

Liming (against acid fermentation) was first tried in 1913 by W. L. Stevenson, M. Am. Soc. C. E., and K. Thumm, in Berlin. It is also recommended by Dr. W. Rudolfs. It may have value in ripening time, or for special acid trade waste; but, ordinarily, it is not necessary.

Kenneth Allen,* M. Am. Soc. C. E. (by letter).—Mr. Eddy has presented an adequate and comprehensive review of progress made in salient features of sewerage and sewage disposal practice in a few pages of print to which little of importance can be added. Nevertheless, the following notes may be of enough interest to be mentioned.

The separate system of sewers was advocated by Edwin Chadwick in England in 1842 and by John Phillips in 1847, more than thirty years before its introduction in the United States by the late Col. George E. Waring. The City of Paris built its first modern sewer in the rue de Rivoli in 1851. The practice of flushing to remove deposits in the crudely designed sewers of the period by damming and then releasing the flow had been used to a considerable extent in London, England, and in Germany; but with the advent of the separate system, in which deposits were liable to occur because of the small diameters used and the intermittent flows of sewage near the upper ends of laterals, the Rogers-Field automatic flush tank came into use as a more practicable device. These tanks were deemed an essential accessory to such systems by Waring, who introduced them at Memphis, Tenn., and, with later modifications, they were largely adopted in the design of separate systems during the latter part of the Nineteenth Century, until it became apparent that their effect was more limited and their use of water more costly than at first supposed. They still find a legitimate field of usefulness under restricted conditions.

Concerning the introduction of sewerage in New York, it may be remarked that the first "Public Necessity House", or comfort station, was built in 1691, while the first public sewer is said to have been laid in Broad Street, as a result of a petition to the Town Council, in 1696; but it probably was not until 1805-07 that an important sewer, still incorporated in the existing system, was built in Canal Street. In 1860 egg-shaped sewers were introduced and, in 1864, vitrified pipe.

The first sewer in Chicago, Ill., is said to have been laid in 1835, but it was not until 1856 that construction under a systematic plan was put into effect.

* San. Engr., Office of Chf. Engr., Board of Estimate and Apportionment, New York, N. Y.

It is said that water-closets existed in Herculaneum in 400 B. C., but in spite of the precedent it was not until 1776 that a patent was issued for this device. In 1846, plumbing was introduced in America as a special luxury. Siphon traps were suggested for water-closets by the Metropolitan Sanitary Commission in England in 1847 and by 1852 they were being introduced in that country. A quarter of a century intervened, however, before the use of water-closets became common in the United States.

The question of sewer ventilation has received more attention in England and on the Continent than in this country, where reliance has been usually placed on holes in the manhole covers. These were introduced in New York in 1875. Where the sewers are designed or operated so that they keep clean, this seems to meet the sanitary demands of the case. It was just before this (1873) that Baldwin Latham published his "Sanitary Engineering", which is probably the first comprehensive treatise on the subject of sewerage in the English language.

Mr. Eddy has referred to the screw pumps at Milwaukee, Wis., Chicago, Ill., and New Orleans, La. A similar pump was installed about fifteen years ago at the head of Gowanus Canal, Brooklyn, N. Y., to flush the waters of that stream by pumping, either from it into a 12-ft. tunnel, 6 270 ft. long, leading to Buttermilk Channel, or *vice versa*. The capacity of the pump is 14 000 000 gal. per hour.

The practice of discharging sewage or sewage effluents from submerged outlets has met with increasing favor since the construction of this type at Hamburg, Germany, Boston, Mass., and Washington, D. C., about 1900. The advantage is very apparent where the depth is more than 30 ft. and where, as in more recent construction at Cleveland, Ohio, Deer Island (Boston), and in the case of the Passaic Valley sewage, discharge is distributed by means of multiple outlets.

In 1647, an Act to Prevent Pollution of Boston Harbor was passed, but for more than two and a half centuries nothing of importance was done to preserve the purity of American rivers, lakes, and harbors.

In 1876, the Massachusetts State Board of Health issued a special report dealing with the "Pollution of Rivers", the "Water Supply, Drainage, and Sewerage of the State", and on the "Disposal of Sewage", calling attention to methods used abroad and to the necessity of adopting similar measures in the interests of sanitation. This, and a report the following year, on "Pollution of Streams", were notable in rendering the results of foreign experience available to American sanitarians and engineers.

The first comprehensive report on methods of disposal, presenting definite recommendations for construction, was submitted by the late Samuel M. Gray, M. Am. Soc. C. E., to the City Council of Providence, R. I., in 1884, although a few attempts at disposal on a small scale had already been made. The first attempt, involving irrigation, had been made at an insane asylum at Augusta, Me., in 1876, and at Cheyenne, Wyo., in 1883.

The water-closet was by that time being introduced and the condition of watercourses in the more densely populated districts was becoming more serious. Land disposal was in vogue as a method, and chemical precipitation

was coming into favor. The plant recommended by Mr. Gray was built at Providence and was followed by others elsewhere, as mentioned by Mr. Eddy. Among the smaller plants was that utilizing the Dortmund type of tank designed by Allen Hazen, M. Am. Soc. C. E., and operated at the World's Columbian Exposition in Chicago, in 1893.

During the two decades following 1880, irrigation or intermittent filtration was introduced at Pullman, Ill., South Framingham, and Brockton, Mass., Plainfield, N. J., Pawtucket, R. I., Canton, Ohio, and elsewhere. The experiments on filtration, conducted by the Massachusetts State Board of Health, at Lawrence, during and subsequent to the late Nineties, under the direction of the late Hiram F. Mills, Hon. M. Am. Soc. C. E., added emphasis to the important part played by air, and were followed by the development of the contact bed and trickling filter. At Reading, Pa., a double-deck filter was constructed above ground, where screened sewage was first strained through a bed of coke and delivered to a filter of sand resting on cinders. After percolating through this bed the sewage fell about 10 ft., in the form of rain, to a second filter consisting of sand resting on slag. The process provided a good effluent, but proved expensive and, later, was abandoned.

In 1909, aerators, leading the air caught by cowls to the bottom of trickling filters, were introduced by the late Rudolph Hering, M. Am. Soc. C. E., at Atlanta, Ga.

Among the more recent applications of air to filtration should be mentioned that of Strogonoff, at Moscow, where oxidation is hastened by introducing air in the bottom of an enclosed filter of fine material about 11 ft. deep. In this way it is claimed that ten times the volume of sewage can be treated per acre as by the ordinary trickling filter.

Meanwhile, the septic tank came into favor for sedimentation, followed by the Imhoff tank, of which type the Calumet Plant at Chicago deserves mention, while methods of artificial aeration were being attempted in a small way.

The important rôle played by the free contact with air in the treatment of sewage was recognized in England by Angus Smith as early as 1882. In 1891, Col. Waring began experiments at Newport, R. I., by forcing air into a bed of gravel or broken stone, which process he patented and introduced at small plants in Brooklyn, N. Y., Philadelphia, and Wayne, Pa., and elsewhere. In 1892, Lowcock came out with a somewhat similar process in England. In 1910, Black and Phelps conducted experiments in forcing air through colloider tanks at the 26th Ward Plant, Brooklyn, and, in 1913-14, the activated sludge process was developed by Fowler and his associates at Manchester, England. It was patented in America in 1915 by Mr. Leslie C. Frank.

A recent development along the lines of activated sludge has been made by Karl Imhoff, M. Am. Soc. C. E., in what is called an "Emscher" filter, or "contact aerator", introduced at Kettwig, Germany, in 1925. In this a certain degree of activation is brought about through the artificial aeration of the biological growth on filter media submerged in the upper compartment of an Imhoff tank, resulting in the elimination of separate aeration tanks.

Disinfection of sewage by calcium hypochlorite was tried out in 1884 in London by Dibdin and was investigated in Germany by Proskauer, Elsner, and Dunbar, and in the United States by Phelps, who, in 1907, applied it on a practical scale at Red Bank, N. J. More recently liquid chlorine has largely supplanted hypochlorite, and its use has extended rapidly for the protection of shellfish and bathing beaches. It has also been advocated to defer the oxygen demand of effluents.

Reviewing the development of sewerage and sewage treatment in America, experience, first in England and, later, in Germany, has been freely utilized; but it has been modified to the different climatic demands and in accord with independent research, of which the outstanding example was the early work of the Massachusetts State Board of Health. Irrigation, intermittent filtration, chemical precipitation, the contact filter, and the septic tank, have all seen their day; while fine screening, the Imhoff tank, sedimentation tanks with mechanical sludge removal, the activated sludge process, and chlorination, hold their own as standard and reliable methods of treatment.

George S. Webster,* Past-President, Am. Soc. C. E.—Relative to Mr. Eddy's paper, the speaker has been asked to discuss briefly the growth of the sewerage system in Philadelphia, Pa. Philadelphia was one of the first of the large cities in the United States to be laid out on a systematic plan. This was done in 1682 by Thomas Holme, Surveyor to William Penn, the first proprietor of the Commonwealth of Pennsylvania. In the development of these early plans, provision was made for drainage systems.

The first of these drainage channels was built about 100 years ago. They were built of bricks laid with dry inverts, that is, without mortar joints; were generally 7 or 8 ft. deep and were intended to carry off both surface and ground-water. No buildings were connected with them at that time. Later, many of these drainage channels became part of the combined system of sewers of the city. The first effort to determine the size of sewers for run-off was made by the Board of Aldermen and not by the City Engineer. The Aldermen decreed that all branch sewers should be 3 ft. in diameter.

In 1875, the speaker was in charge of a Field Corps of Engineers at the Centennial Exposition Grounds in Philadelphia and, under direction of those in authority, gave lines and grades, and supervised the construction of sanitary sewers discharging directly into the Schuylkill River above the dam and into the pool from which a part of the City's water supply was taken and furnished without treatment to the citizens. This resulted in typhoid fever in October and November, 1876—a serious epidemic in Philadelphia.

This instance indicates the state of the science of Sanitary Engineering at that date and emphasizes the great advancement that has been made in the last 50 years.

At the time of the Centennial Exposition in 1876, the late Rudolph Hering, M. Am. Soc. C. E., obtained from the Swiss Exhibit, a diagram showing the Ganguillet and Kutter curves for the flow of water in channels and the speaker made a tracing of it for the use of the City Engineering Department and for the Engineering Profession in general.

* Cons. Engr., Philadelphia, Pa.

The first empirical formula of which the speaker has any knowledge, that was used for determining run-off when designing sewers in Philadelphia, was "one cubic foot per acre per second", which is equivalent to 1 in. of rainfall per hour, all reaching the sewer. This is not a bad rule for an engineer to use as a rough check on his assistants in calculating run-off for large sewers.

In 1880, the American Public Health Association sent Mr. Hering to Europe to investigate sewerage practice, and his report thereon marks one of the turning points in sewer design in this country as it placed such design on a scientific basis rather than by rule-of-thumb. He brought back with him the Burkli-Ziegler formula. This was thought to be the last word in determining the run-off for storm-water sewers. It was soon found, however, that in a city like Philadelphia, with street grades varying from 1 ft. in 1 000 ft. in the flat sections to 10%, or more, in high suburbs, this formula did not give acceptable results in all cases.

The McMath or St. Louis formula, a modification of the Burkli-Ziegler, was tried for a time. It gave better results, but did not prove satisfactory. The City then established 6 pluviometer stations for recording intensity, duration, and the amount of rainfall in the city limits and also installed automatic recording flow gauges in a number of sewers; and from the information thus collected, a new formula known as the "Philadelphia formula" was evolved. It was in reality an extension or modification of the Burkli-Ziegler and McMath formulas. This was an advance over previous methods of determining run-off, but did not give correct results under all conditions.

All these investigations led to the adoption of what is called "the rational method of designing sewers" which is based on data collected in Philadelphia and on facts evolved by the late Emil Kuichling, M. Am. Soc. C. E., in his work at Rochester, N. Y.

Finding that the streams into which sewers discharged were becoming very heavily polluted and that the maintenance of public health demanded that some corrective steps should be taken, the City of Philadelphia has adopted a comprehensive plan and has entered on the treatment of its sewage on a large scale. There is in operation a treatment plant on the Delaware River near the Torresdale intake to the City's water supply. At this plant, Imhoff tanks, sprinkling filters, chlorination, and sedimentation are successfully used. In the northeast section of the city, a series of Imhoff tanks have been installed and are in operation, while in the southwestern section, preparations are under way for the erection of a large plant for sewage treatment.

L. L. Tribus,* M. Am. Soc. C. E.—Mr. Greeley's paper relating 150 years of municipal history, has naturally included many items of interest, but of necessity has had to omit enlargement where it sometimes would have proved very interesting.

No one can remember conditions farther back than perhaps one-third of the period, but the important phases of municipal housekeeping that comprise the cleaning of streets, gathering of waste products, and disposing of them, have all been developed in the past 50 years.

* Cons. Engr. (Tribus & Massa), New York, N. Y.

The perfection of pavement cleanliness now demanded, was impossible (even if wanted), prior to the advent of hard and smooth pavements. Macadam could not be machine-swept without risk of injury to the surface coat, unless maintained with greater care and at larger cost than cities would sanction. Cobble-stones, which covered so many miles of some city streets, afforded ideal gathering places for innumerable filth germs.

So far as the speaker recalls, the only place on earth where cobble pavements had any real excuse for existence is at Funchal, in the Madeira Islands, where transportation is by ox teams drawing sleds with well-greased wooden runners.

As people advance in desires, their demand is for larger municipal operations; and *vice versa,* larger operations re-act on the people. The speaker well remembers certain experiments of about 20 years ago. He selected three ill-paved, ill-kept, slum streets in different parts of a city. The buildings were largely devoid of paint; windows were rarely fully glazed; shutters hung by one hinge; house refuse was thrown in the gutters; children abounded and, equally with their parents, were a slovenly lot.

The curbing was then straightened; good curb-to-curb pavements were laid; a street sweeper in white uniform was assigned to each street; and notices were served asking house occupants to put refuse in sound receptacles, for regular daily collection by the city. What happened? Within six months windows were glazed; shutters hung; painting had begun; sidewalks were being repaired or renewed; garbage and wastes were almost completely placed in metal containers; some plate-glass store fronts appeared; children were less tattered and more frequently actually washed; and the parents began to be self-respecting. In one year the transformation was complete, and has been lasting.

Mr. Greeley has called attention to the basic fact in municipal house-cleaning problems, that only when those at the head take a real interest in their jobs, does efficiency show in the work itself. An enthusiastic head, honest and capable, will secure, out of even poor raw material, results that will bring credit and community praise.

The inter-relationship of pavements and street cleanliness is so vital that only with the former in first-class shape can the latter obtain. Street cleanliness usually re-acts on the maintenance of properties, but not always.

Municipalizing garbage and refuse collection and treatment systems is rather the last great step, aside from transportation, in city life. Waterworks, sewage systems, and various other utilities reach approximate perfection, but private ash collection continues, with its greater per capita cost, until places for dumping refuse or for feeding garbage to hogs, and for reduction processes, cannot be readily obtained. Then municipal relief is demanded.

The Oriental and near-Oriental sensibility to smell and sight does not seem as keen as that of the conglomerate and amalgamated American with its Anglo-Saxon predominance; so the dog and vulture scavengers that comprise the street-cleaning personnel of many populous cities are even yet tolerated.

The speaker is glad that he visited Constantinople before the thousands of street dogs were destroyed, and saw the groups of mangy curs, large and small, appropriating the sidewalks, while pedestrians walked in the streets. These

groups knew their own districts, perhaps by virtue of dog vote and determination, for it was immediate destruction for any dog to step outside his own territory. Not a scrap of any edible refuse could long be found in the streets of that wonderful cosmopolitan city. The unpaid, non-uniformed, four-footed corps did the trick, until finally banished to a neighboring island. They are said to have disappeared through the process of killing and eating each other. Lack of general sanitation, however, produces a terrible death toll when epidemic breaks out in Oriental cities.

Mr. Greeley has outlined the types of treatment plants with some of their respective merits, but on the economic side has not had time to emphasize sufficiently two points: (*a*) The relationship of costs of collection and haul, to the locations, sizes, and types of disposal systems; and (*b*) the possible market, if any, and means of reaching it, for recoveries of by-products and residues.

As a general principle, a large community must consider the whole services as one of net expense, with perhaps opportunity for some returns by the way.

For historical accuracy as to the introduction of the English furnace into this country, the speaker desires to give large credit to Mr. George Cromwell, who as President of the Borough of Richmond, City of New York, by his broad-gauged intelligent co-operation and authorizations permitted the completion of a long course of experiments. These were conducted by the writer, with Mr. Richard T. Fox (later of Chicago, Ill.), and John T. Fetherston, M. Am. Soc. C. E. (later, Commissioner of Street Cleaning of the three larger boroughs of New York), as chief assistants.

The findings were confirmed by Mr. Fetherston in a visit to Great Britain and the English type of high-temperature incinerator was subsequently adopted to serve the needs of Staten Island.

The speaker's special contribution to the change from the original English type of furnace, was the joint cooling of the clinker and heating of the forced-draft air, by driving it through the hot clinker while held on a lower grate. Mr. Fetherston's very valuable and useful patent was the making of a ridged grate, which formed breakage lines in the clinker, rendering its removal simple. The hydraulic charging pan was first perfected in the West New Brighton, Staten Island, N. Y., station.

Concurrently, with the Staten Island experiments and independently therefrom, the City Engineer of Seattle, Wash., reached the same conclusion, namely, that high-temperature incineration was the best form where utilization was not expedient and where the early destruction of organic matters was essential.

Staten Island seems to have been, not only the early nursery of scientific garbage treatment, following its first two Dixon furnaces, but the site of a very large Cobwell reduction plant that furnished cause for much litigation, throughout the course of which the speaker was consultant to those in opposition, led by the District Attorney and committees of the people. Briefly, the proven excessive nuisance from odors caused the final closing of the plant, not condemning the Cobwell system *per se,* but rather the operation of that particular installation.

Smooth, hard pavements, rubber tires, and horseless vehicles have lessened street noise and pavement wear, making street cleaning much simpler, more efficient, and cheaper than formerly. Municipal garbage and refuse collection, with treatment in high-temperature furnaces, has made for betterment.

Snow removal is a factor in large city housekeeping in the temperate zones. "Old Sol" looks after the situation in the southern range of cities where snow occasionally falls. "Jack Frost" largely holds the snow in place in the northern communities, until spring thawing attends to the matter; sidewalks are cleared, adding to the depth of snow in the roadways where sleigh and sled traffic soon packs it down.

More of the largely populated places come within the first series, and the problems have been many. Gathering by scrapers, and hand-shoveling, with carting to water-front dumps, have been most generally adopted; but probably the most efficient method, where sewers are large enough, is gathering and dumping into sewer manholes, aided, if the weather be not too cold, with urge of water from fire hose lines. A light fall may even be wholly flushed by hose into corner basins. The total of annual expense runs into many millions of dollars.

What the next 150 years may bring forth is hard to predict. Perhaps boneless synthetic foods will be prepared that will entirely eliminate garbage wastes, and only the containers will require disposal! The imagination might well run riot, as to the future, in view of past achievements—so well reviewed by Mr. Greeley. In general, however, engineers had better report upon accomplishment, rather than prophesy.

N. T. Veatch, Jr.,* M. Am. Soc. C. E. (by letter).—The subject of street cleaning and the disposal of refuse, discussed by Mr. Greeley, is one which, in a way, may be termed an "orphan child" of the Engineering Profession. Few engineers have had the desire, or perhaps the nerve, to make any effort to study the subject from its engineering or scientific angles, and, as a consequence, the profession does not have the wealth of engineering data and background of precedents in this particular field that it enjoys in many others. An engineering writer who is usually well informed on the subject once offered, in substance, the following statement, as one of the reasons for its present status from an engineering standpoint: "The question of collection and disposal of refuse has been made a 'political football' so to speak, and there is an almost universal lack of realization on the part of city officials that the subject is really an engineering matter."

This assertion is undoubtedly true, as is evidenced by the fact that, generally speaking, this particular division of municipal service is handled by branches of the city government not connected with the engineering department, and with comparatively few exceptions it is given no engineering advice or supervision. As a result, there are numerous examples of failures in practically every method of handling the problem, and practically every city official, in whose department the refuse collection and disposal is controlled, feels that he has started his duties as a public official with a veritable "stone hung around his neck".

* Cons. Engr. (Black and Veatch), Kansas City, Mo.

The lack of proper methods in street cleaning and the collection and disposal of refuse has been, and still is, responsible for the loss of many lives among the urban populations of this and other countries. This is true to a degree sufficient to challenge the interest and effort of every one interested in sanitary science. The fact that, at best, the refuse problem is a difficult and unpleasant one, due to its very nature and its political entanglements, is perhaps one of the causes for its not receiving the attention it should from the Engineering Profession in general. However, the difficulties that the problem seems to carry with it are causes only, and should not be made into excuses. In spite of difficulties, an immense amount of scientific engineering thought and study has been given to the problem, and there are numerous examples of outstanding service on the part of conscientious city officials and members of the Medical and Engineering Professions. There are also numerous examples of cities having efficient and successful handling of their street cleaning and refuse problems, and it is pleasing to note that most of them have had scientific and technical advice, and that they have followed it.

Much valuable data have been accumulated both in this country and abroad, valuable service has been rendered, and valuable results have been obtained by a rather small coterie of the Engineering Profession. Mr. Greeley is one of that number, and the profession is indebted to him as well as many other contributors. He is undoubtedly correct when he states that, "efficiency of operation and progress in the future will depend in large measure on the character and training of municipal governments."

In Kansas City, Mo., the question of garbage collection and disposal was for years a "thorn in the side" of the city officials. The service has been, and still is, obtained through private contract. For a long period, the contractor was paid a lump sum per year, the amount being increased from time to time as the city increased in population. This plan did not give the best results, as the house service was unsatisfactory. The contractor fed the collected garbage to hogs, and in consequence a considerable amount of material that goes into the usual house garbage was rejected by the collectors, and numerous complaints of non-collection were made. Such results, perhaps, could be expected where the contractor's co-operation depended in no way on the amount of garbage collected.

In an attempt to solve the problem, the city officials found themselves confronted, not only with the question of proper collection, but also with one of disposal, because the location of the hog-feeding pens was unsatisfactory. Due, somewhat, to lack of proper engineering guidance, the city at one time tried to enter into contract with a private disposal company on the basis of building, at the city's expense, a plant to dispose of the garbage by a patented process, which to that time had not demonstrated its feasibility. This action was stopped by injunction. Later, the city had engineering specifications prepared, and called for bids including those for both collection and disposal. The contractor was to select his own method in the latter. The successful bidder turned the matter of mechanical garbage disposal over to a sub-contractor and agreed to assume all expense of installation and responsibility for the operation of the plant.

As soon as the contractor had his work under way, and his routes organized in a preliminary manner, the city had an engineering survey made, and a report prepared covering the services included in the contract. This report included a careful study of the city, its population distribution and concentration, character, and quantities of garbage from different sections of the city, manner of house treatment, operation and routing of collection units, together with all other features entering into the problem. As a result of this engineering study, and a rather unusual effort in co-operation on the part of the contractor, marked improvement in the collection service was soon noted.

The contract calls for payment by the city on the basis of tons of garbage collected, and carries with it a definite penalty clause covering complaints for lack of service. This plan has resulted in continued good service.

The patented process used for garbage disposal is known as the "Pan-American process", mentioned by Mr. Greeley. While the plant has not been in operation long enough to prove its practicability definitely, the process, if successful, will be a decided benefit, and its feasibility is looked forward to with a great deal of interest.

Although there may be considerable question as to whether the best service can be given under municipal operation or private contract, there is no question but what Kansas City benefited materially from the scientific manner in which its garbage disposal problem was handled.

Arthur E. Morgan,* M. Am. Soc. C. E.—In every phase of the development outlined by Mr. McCrory is seen the same characteristic of gradual growth from crude and simple origins to great and complicated operations. The author describes the beginning of tile drainage in New York State 50 years ago with the use of 1, 2, and 3-in. tiles, and the beginning of open drainage with small farm ditches. From these have developed the extensive systems of underground drains in the Middle West, laid with great tile 2 or 3 ft. in diameter, and the open channels, sometimes 100 ft., or more, in width, in systems draining hundreds of square miles. In the development of excavating machinery there has been the same gradual growth, from the time when all work was done by hand, to the present day of dipper-dredges, drag-lines, cableway excavators, and suction dredges.

In the associated legal developments can be seen the same trend from the old primitive laws, enabling a few farmers to co-operate, each digging his share of the neighborhood ditch, to some of the modern codes, under which as many as 50 000 tracts of land have been assessed to pay the cost of a single improvement.

In most of that legal development it has been characteristic that lawmakers have seen but a little way ahead. The speaker has been interested in following the history of drainage law. As a rule each statute that has been passed, has been in the interest of some single project or type of project, and reflects the particular experiences of those who drafted it. Each law generally accepts the code that has gone before, and makes modifications of particular features. The process has been a step-by-step development, each

* Pres., Antioch Coll.; Pres., Dayton Morgan Eng. Co., Dayton, Ohio.

new code carrying along the vestiges and appendages of obsolete legal and administrative procedure. Land drainage engineers are only beginning to devise and create codes that are new in their general structure, based on comprehensive study of needs and of legal and administrative procedure.

The progress of drainage has depended, not upon the improvement of any single factor, but upon the co-ordinate development of all factors, technical, mechanical, legal, and administrative, that enter into such a development. If a single factor falls behind, the whole development must suffer.

Some years ago the speaker saw a drainage canal recently excavated by a dipper-dredge to drain part of the Dismal Swamp in Virginia. The work was done from plans made by George Washington. In his early days he had dreamed of draining the Dismal Swamp, but his plans waited 150 years because no equipment was available for their execution. The speaker first worked with Mr. McCrory in 1907, in Colorado. There they made plans for reclaiming "alkali" lands which, if executed, would reclaim a large waste area; but because of inadequate legislation 15 years passed before any substantial progress was made.

The process of reclamation does not depend on engineering design or on excavating equipment alone, but on the co-ordinate development of every factor that is involved. In his proper function the engineer is the person who co-ordinates and synchronizes all these factors. Anything that affects the ultimate success of the project is a proper part of his work. Sometimes, the engineer sees himself as concerned only with technical design. Until he can rise above that concept, and can see his work to include all factors necessary for the proper development and co-ordination of all elements, he will not come into his own.

When the speaker first planned extensive drainage work in Minnesota before 1905, the drainage laws were very inadequate. He spent a year in revising the Drainage Code and in getting his revision approved by engineers and lawyers, and passed by the Legislature. There was no suitable power equipment in the State and there were no experienced contractors to operate the equipment; so he searched the entire country for both. In his opinion, these efforts were normal and proper elements of engineering.

In the subsequent 20 years of practice this conviction has been strengthened. Is it not true that the factor most lacking to-day in the control of water is a larger concept of his functions by the engineer? There are great projects in this country that never can be fully realized until the engineer has a picture of the possibilities, and until he possesses the co-ordinating mind that brings together all necessary factors.

The engineer must see himself as the center of these developments. He must be enough of a lawyer to appraise the legal factors; enough of an engineer to plan the destinies of streams rather than the expediency of particular cases; enough of a business man to co-ordinate and define policies; enough of a developer to bring about the necessary adaptation of mechanical equipment; and enough of an administrator to bring all these factors together to effect his purposes.

The time is coming when the co-ordinating work of the drainage and reclamation engineer must extend beyond State lines. On the Colorado River there is a deadlock because of the lack of interstate machinery. There are great projects in Missouri and Arkansas similarly waiting for the technique of interstate co-operation. The compact now being worked out between New York, Pennsylvania, and New Jersey to give unified control to the Delaware River is a step in the right direction.

The control of water should not be exercised with reference to any one interest, but all probable uses and effects of water must be considered in engineering programs. About 1915 the speaker endeavored to outline, for the Water Supply Division of the State of Pennsylvania, a statement of policy for the use of its waters for all purposes.* An effort was made to consider the water supply of the State as one of its major resources, to be administered for all its uses by a department of the State Government, that should pass upon conflicts of interest.

Water is one of the prime essentials of civilization, and must be controlled and used with recognition of all the interests involved, and not of one alone. Sanitation, agriculture, power development, navigation, fisheries, or water supply must not be considered alone, but each one in relation to all the others. Organization and design must replace the present anarchy.

A striking example is the control and use of the waters of the Great Lakes. Navigation interests assume that they are all-important; power interests endeavor to direct events to further their own ends; the City of Chicago thinks chiefly of the Great Lakes as furnishing water for waste disposal; and public sentiment inclines to the attitude that the flow from the Lakes should first of all be conserved to maintain scenic effects at Niagara. The Great Lakes present a single problem in the control and use of water. To realize that, a single co-ordinated system of control, with all interests and uses taken into account, must replace the present conflict of interests.

To bring about such changes as this, the development of engineering statesmanship is needed. The engineer, more than any one else, is able to see the whole problem, and to bring the comprehensive control of waters to a level with the best phases of present civilization. Just as efforts for the control of water have grown in importance from the farmer's ditch to the control of the Great Lakes, so the work of the hydraulic engineer must lead from the country drain surveyor to the engineering statesman who devises and administers the control and use of great water resources.

Arthur M. Shaw,† M. Am. Soc. C. E. (by letter).—Mr. McCrory presents, in an interesting manner, the evolution of the modern system of drainage, especially sub-drainage, as an adjunct to agricultural development. Few people who live in cities realize the vital importance of controlling soil moisture by drainage. Irrigation, being frequently more spectacular, appeals to the imagination although infinitely more agricultural products come from lands that have been drained artificially (to a greater or less extent) than are produced by irrigated lands.

* Report of 1916.

† Cons. Engr., New Orleans, La.

The various steps in drainage became synchronized with the growth of the country, although it is doubtful whether artificial drainage ever was practiced to any great extent by the early New England colonists. With important exceptions, the practice of sub-drainage, originating in England, jumped the more rugged lands of New England and came to its greatest early development in Western New York. From there, the idea was taken into the "Western Reserve" and, later, into Indiana, Illinois, Iowa, and farther west and north.

By the time that these newer areas were brought under cultivation, it had been found that clay drain tile were so superior to the pioneer "blind drain", made of stones or brush, that few of the latter were used; but some temporary substitute was found necessary to serve the sections where tile could not be secured or where the farmers were not able to bear the initial expense. Such substitutes were the "Mole" and the "Bull Ditcher."

The original "mole" was a crude but heavily constructed sled with a steel plate extending down from the bottom of the sled to a depth of about 30 in. The plate was placed in such a position that, in pulling the sled along, a slit was cut in the ground by the edge of the plate, the lower end being given a sufficient "lead" to insure its remaining in the ground to its full depth. At the rear edge of the plate, near its bottom, was attached a short piece of chain, at the other end of which was a 4-in. forged iron ball; or, if available, an old cannon ball. The "machine" required about twenty yoke of oxen to pull it, although it frequently was pulled by one team of horses operating a home-made windlass.

The "bull ditcher" resembled a giant, double mold-board plow and was used in digging open ditches. In its later form, it could dig a ditch of 3 ft., or more, in depth. To avoid excessive draft, it usually was designed to construct a V-shaped ditch with side slopes of 2 on 1, or flatter. This equipment was used in the drainage of thousands of acres of prairie and marsh lands, principally in Northern Iowa and in Minnesota. The writer used an adaptation of the idea a few years ago in the preliminary ditching of a 1 500-acre tract of Louisiana "trembling prairie". A huge cypress log was sharpened at one end and provided with a stiff coulter and a pair of heavy plank wings for spreading the dirt. This crude appliance was pulled through the soft muck by a cable running to a donkey engine which was mounted on a barge. Canals had been dug at ¼-mile intervals and these served for transferring the power equipment.

Except under very favorable soil conditions, the useful life of the "mole" drain did not extend over a period of more than two or three years, but the "bull ditcher" proved to be a real success for its time. In digging comparatively shallow, flat slope ditches in suitable soil, free from rocks or stumps, it is doubtful if any modern machine could compete with it in its low cost of operation and upkeep.

A history of land drainage in the United States would not be complete without reference to the thousands of miles of open ditches still used in the drainage of the sugar plantations of Louisiana. Until recently they were dug and maintained by hand labor and this method is still utilized on the

majority of the plantations, although machine ditchers of the wheel, or the endless chain and bucket type, are coming into use. Many experiments have been made in the sugar belt with tile sub-drains, but they have not been as successful as in other sections.

W. B. GREGORY,* M. AM. SOC. C. E. (by letter).—The paper by Mr. McCrory presents the main points in the history of modern drainage and, of necessity, the author has omitted many points of local interest.

To the inhabitants of the State of Louisiana the problem of drainage will always claim a lively interest. This State ranks second in area of swamp lands, the State of Florida alone having a greater area. The City of New Orleans, the metropolis of the South, is built on alluvial land, a portion of which is below mean Gulf level. Except for narrow strips along the Mississippi River, the lands of Southeast Louisiana are at or near the level of the waters of the Gulf.

Under these conditions the problem of drainage by pumps becomes of considerable importance. The sugar plantations, with high lands near the river, were first drained by means of open ditches. Later, the amount of cultivable land was extended by building levees around the rear of the plantations and pumping out the drainage water. The pumps first used (as noted on page 1254), were drainage wheels, modeled after scoop wheels, used hundreds of years ago in Spain and other parts of Europe. In its later development these wheels were 28 to 30 ft. in diameter, with widths of from 6 to 8 ft. They were used to pump large volumes of water through small lifts, usually not more than one-fourth the diameter of the wheel.

One difficulty encountered with the scoop wheel was in the foundations, which were expensive and difficult to maintain. With the development of centrifugal pumps, the Ivens or the Menge pump was used because of the lower cost of installation, but not because of more efficient operation.

In turn, the centrifugal pump has found a competitor in the screw pump. The City of New Orleans is an example of the change in methods of pumping. The first pumps were of the scoop type, then the centrifugal, and now screw pumps are largely used.

Practically the same changes have taken place in the pumping of drainage water from agricultural lands, for while a few drainage wheels are still to be found on plantations, there are many more centrifugal pumps and some modern installations use screw pumps.

A notable example of drainage of swamp lands is to be found in the Fourth Jefferson Drainage District, comprising about 30 000 acres of Jefferson Parish, just west of the Parish of Orleans—the City of New Orleans. A large part of the area is swamp land, but the run-off from the high lands along the river is also to be pumped by four large pumping plants, each having two units of screw pumps, each of which is capable of removing approximately 120 000 gal. per min., at low lifts, the capacity falling off slightly at higher lifts. Each pump is driven by a 330-h.p., 4-cycle, Diesel engine. The net capacity of the pumps is sufficient to remove a run-off of 1.5 in. in 24 hours.

* Cons. Engr.; Irrig. Engr., U. S. Dept. of Agriculture; Prof. of Experimental Eng., Tulane Univ. of Louisiana, New Orleans, La.

The drainage of swamp lands is highly desirable in Southern Louisiana for many reasons, among which may be mentioned the elimination of mosquito-breeding areas and the additional area of very fertile lands to be used as homes. There was an ambitious beginning of this work in the first decade of the Twentieth Century, but the work was halted by the World War and its attending economic conditions. With vast areas of uplands in this section, that may be drained by gravity and yet are uncultivated (although not as fertile as alluvial lands), there is little incentive at present to drain swamp lands unless they are near enough to a city to promise returns that are not of a purely agricultural nature. However, some economists are discussing the approach of an era when the production of food for a vastly increasing population will be one of the gigantic problems. When the time comes that an agricultural return will justify the outlay for swamp-land reclamation, this State and many other sections of the South will come into its own and will drain these wet lands which are among the most fertile and productive to be found in the world.

R. A. Hart,* M. Am. Soc. C. E. (by letter).—The paper by Mr. McCrory leaves little to be desired. It is not made exactly clear that the work of the late Charles G. Elliott, M. Am. Soc. C. E., as Chief of Drainage Investigations, extended throughout the United States, and that his staff was concerned with the drainage problems of the humid as well as the arid regions.

With characteristic modesty, the author has refrained from mentioning his own contribution to the history of land drainage in the United States, but it is a well-known fact that he and his staff have played a dominant part in establishing land drainage on a scientific basis and have been directly instrumental in forwarding large drainage developments.

With respect to drainage of irrigated lands, one additional thought is worthy of consideration. Such drainage has to do with colonized, improved lands, in which large investments have been made, and which represents redemption of lands formerly highly productive, or the protection of lands now highly productive, rather than the reclamation of lands of relatively low market value and productiveness, as is the case with humid lands susceptible of drainage. The redemption or protection of irrigated lands by drainage often is the sole method of saving the original investment.

L. L. Hidinger,† M. Am. Soc. C. E. (by letter).—Mr. McCrory has assembled interesting and fairly complete data on the most important phases of the subject. However, it occurs to the writer that the section, "Construction of Open Ditches" might have covered a somewhat wider field.

Mr. McCrory refers to the fact that floating dipper-dredges have been largely replaced by drag-line excavators. This change has made the construction of more stable side slopes possible. Prior to 1920 practically all the dredging for open drainage channels was accomplished by floating dipper dredges. This type of dredge is a very unwieldy machine. It is impracticable to dig side slopes flatter than 1 on 1 with this type of equipment and,

* Secy.-Mgr., Western Clay Products Assoc., Salt Lake City, Utah.

† Pres., Morgan Eng. Cos., Memphis, Tenn.

as a rule, the slopes are left considerably steeper. Some of the first work was laid out with side slopes of 1 on ½, because it is not economically practicable to dig flatter slopes with a floating dipper-dredge. This was done with the expectation that the banks would weather down to a flatter slope and still leave sufficient capacity in the drainage channel. The floating dredge was almost invariably too large to dig short laterals to a properly designed cross-section, so that deterioration from the side slopes was not considered a serious defect, provided they were laid out deep enough to allow some sedimentation in the bottom without impairing the drainage of adjacent lands.

The substitution of drag-line excavating equipment for floating dredges has made possible the construction of drainage channels with any side slope that may be considered stable. Since the common use of this type of equipment, side slopes have been changed from 1 on ½ to 1 on 1½, or flatter, as may be deemed necessary. The present tendency is to dredge open drainage channels with 1 on 2 side slopes where they are located in ordinary alluvial soils, and flatter where the material is unstable.

Another important change in the construction of open drainage channels that has come about through the use of drag-line equipment, is a better balanced drainage system. When floating equipment was in common use it was cheaper to excavate small laterals with the dredge than by other means. This resulted in over-sized laterals that left an unbalanced drainage system. It is a recognized fact, among well informed reclamation engineers, that it is not economically feasible to construct channels for land drainage purposes large enough to carry off rainfall as fast as it is precipitated, and that part of it must be stored temporarily. Such being the case, it is imperative that a drainage system be balanced as carefully as possible so that lateral drains will not have excess capacity and thus overload the outlet channels. The drag-line has made possible the construction of drainage channels in accordance with the design, so that a better balanced drainage system can be installed and the flooding of lower lying lands can be largely prevented.

TABLE 6.—Capacity of Drainage Systems.

Location.	Year.	Cubic feet per second per square mile.
Southeast Missouri	1910	7.4
Northeast Arkansas	1912	8.8
Southeast Arkansas	1918	13.5
Southeast Missouri	1924	15.4
Northeast Arkansas	1925	17.4
Southwest Arkansas	1925	20.0

There has been a steady increase in the designed capacity of drainage channels. The first run-off curves provided only about one-third the capacity that is now used. Table 6 shows the increase in capacity of drainage systems located in the Lower Mississippi River Valley within the last 18 years. It is based on an area of 300 sq. miles.

Roy N. Towl,* M. Am. Soc. C. E. (by letter).—It has been the writer's privilege during recent years to study silting problems affecting the maintenance of drainage ditches in the Missouri River Valley from Yankton, S. Dak. to St. Louis, Mo. The average fall of the river is about 0.8 ft. per mile. The banks are several feet higher than the sag of the valley between the river and the bluffs, which latter rise to an elevation of 200 to 300 ft. The natural drainage of the valley is generally parallel with the river for a distance of 10 to 20 miles before finding a natural outlet or making an artificial ditch outlet. Hence, it is necessary to receive small tributaries directly into the drainage system and, consequently, many drainage systems have been destroyed with silt deposits, or seriously burdened, requiring frequent and expensive clean-out operations.

About 1905, W. E. Pratt, County Surveyor at Tekamah, Nebr., protested to the County Board against allowing Silver Creek, with a water-shed of 25 sq. miles, consisting of loess bluff formation, to enter the main drainage system without first spreading over its delta and partly de-silting its flood waters. Also, in the same water-shed, York Creek having a like drainage area, filled the main drainage ditch with silt to about 65% of its carrying capacity in one flood. In both these cases, the silt-laden flood waters have been diverted from the drainage system and carried directly to the Missouri River across the natural line of drainage. The drainage ditches are carried through undersluice-ways at crossing points. The floodway for the silt-laden stream must have a silt-transporting velocity. It is also found desirable to provide a spillway at or near the point of diversion to relieve the floodway of excess waters which may be clarified in a relatively small area before reaching the drainage system. Such diversion ditches and settling basins, separately or combined, have been used by a number of drainage districts in Iowa, Nebraska, and Missouri since 1915, with very satisfactory results.

In most cases artificial delta formation is limited to a small area for a period of 6 to 10 years and then transferred to another limited area, etc. It is desirable to de-silt flood waters on a natural or artificial flood-plain. This may be readily accomplished by removing levee embankments on one or both sides of the offending tributary stream and permitting the overflow to be distributed at a shallow depth for a considerable distance, and flooding the adjoining land, as in irrigation, and then providing for drainage of clarified waters into the main system. In certain cases of this kind, corn has been successfully raised without any loss from flooding and with a gradual deposit of rich soil on a well-drained slope on account of the inundation. This result may be expected if standing water is removed in a reasonable length of time.

Undoubtedly, this is the oldest chapter in drainage and flood regulation found in the book of Nature. The writer anticipates that it may be adapted successfully as a part of the program even for streams of the magnitude of the Colorado River. In support of this proposition he would suggest a study of the stabilized channel below Yuma, Ariz., which existed for possibly fifty years prior to attempted regulation.

* Civ. Engr. (Towl, Nelson and Schwartz), Omaha, Nebr.

Desirable channel conditions, especially with respect to maintaining drainage ditches, have been and always will be subjects for careful consideration. In this connection the writer has observed many natural and artificial drainage outlets subject to submergence and back-water from the Missouri River, which apparently were adverse; but actually the hydraulic flood grade line indicated better flowage characteristics than would seem possible. In fact, submerged silt deposits are carried out in flood time and the coefficient of roughness is very much less than that found in upper portions of the same channel not subject to back-water, but which are invaded with growth of vegetation.

Increased low-water flow in the Illinois River at Beardstown, Ill., which maintains a wider and smoother channel than would otherwise be possible, has a beneficial effect. The increased discharge at low stages has been approximately equivalent to the increased flowage from Lake Michigan during the past 20 years without any increase in stage for said increment of inflow. Thus, it may be expected that, in connection with detention and storage reservoirs, better channels will result on account of improved low-water cross-sections. The writer is also studying the problem of slack low-water flow in its relation to maintaining wider and better cross-sections in drainage channels. In this case he has found many natural examples of channels with irregular bottom profiles and fairly good, uniform flood profiles.

In conclusion, the writer must admit that his best lessons are exemplified in natural streams and more forcibly in artificial construction that refuses to become stabilized in conformity with the adopted plans and specifications for the project.

E. R. Jones,* Esq. (by letter).—The drainage policy throughout the United States has changed since 1920 from one of extensive to one of intensive drainage. By the former method is meant the practice of constructing large outlet drains for great undeveloped areas for the purpose of creating more farms. Intensive drainage means the drainage, usually by means of drain tile, of the wet spots within or at the edges of existing farms and fields.

Prior to 1920 both types of drainage were making steady progress. The agricultural depression beginning then made extensive drainage unprofitable. The demand for land, particularly new land, became less, the price of land fell, and new reclamation practically ceased.

This was not true of intensive drainage. In the face of high labor costs, and low prices for agricultural products, the farmer had to look around for means of reducing the cost of production in order to keep up his profits. He found that he had to keep two hired men during the cultivating season to give adequate cultivation to a 40-acre cornfield if it was mutilated with wet spots and swales. The fields were too wet so much of the time that he had to have a double crew ready to work fast when these spots did dry up.

Then he got tired of feeding and paying the extra hired man. He began to tile-drain the wet swales in those fields for the chief purpose of reducing the cost of cultivation. Increasing the yield was a mere incident. He found

* State Drainage Engr., Madison, Wis.

that there were commonly twice as many hours during June when a well-drained cornfield could be cultivated than were available in a field mutilated by wet swales. This meant that one man could cultivate as much corn in a well-drained field as two in a poorly drained one. That is why farmers are draining the wet spots in their fields.

One of those farmers is a resident of Reedsburg, Wis. He can use a tractor on his farm after draining the wet spots in his fields. He has paid for the tractor with the money he saved by discharging the extra hired man and with the increased yield of corn. The drain tile is his remedy for the high cost of farming. Fifty-eight carloads of tile were laid in his township in 1926.

Fortunately, intensive drainage does not cost as much as extensive drainage. With the latter, 200 rods of 5-in. tile, laid in trenches 3 ft. deep, discharging into a ready creek, at a total cost of $2 per rod, will commonly dry up all the wet swales in a 40-acre field. This $400 expenditure reflects a value on the entire field, because the wet swales made the slopes between them inaccessible in stormy weather. On extensive areas of wet land, not only do outlet ditches have to be dredged, but lines of tile 4 rods apart on the whole area may be necessary, at a total cost of $100 per acre instead of $10. That does throw the dredge or big-tile outlets into the discard. They are still necessary, however, in many old communities where a sluggish creek now forms an inadequate outlet for the lines of tile on the wet swales in the cultivated fields. Likewise, the three-cornered fields west of Brodhead, Wis., can be made rectangular and economical only by improving the channel of Juda Creek for 4 miles. This project is now under way. Because of the flashy run-off from the surrounding hills, a big ditch is better in that case than a big tile.

H. F. Gray,* M. Am. Soc. C. E. (by letter).—At the beginning of his paragraph on "The Public and a New Idea", Mr. LePrince states that no attempt was made to control disease-bearing mosquitoes in the United States until 1913.

Pioneer work was done in California as early as 1910, and has continued since that time.† The initiative was taken by William B. Herms, now Professor of Parasitology, College of Agriculture, University of California. Under his direction, what was probably the first campaign in the United States for malaria control through the prevention of mosquito breeding was undertaken at Penryn, Calif., beginning early in March, 1910. Late in the same month, another campaign for the same purpose was begun at Oroville, Calif. In August, 1910, Bakersfield, Calif., began an anti-mosquito campaign. The first malaria-control campaign on an irrigation district was carried on at Los Molinos, Calif., in 1912, as related‡ by Thomas H. Means, M. Am. Soc. C. E.

Although these early campaigns were intended primarily as practical demonstrations of the possibility of malaria control through mosquito reduc-

* Cons. San. and Hydr. Engr., Berkeley, Calif.

† *Am. Journal of Public Health*, Vol. 2, No. 6, pp. 452–455.

‡ *Transactions*, Am. Soc. C. E., Vol. LXXVI (1913), p. 778.

tion, were handicapped by inadequate funds, and lacked official recognition through statute authority, they were so successful that the work was continued under various auspices, and extended to many other communities in the State. Finally, in 1915, the California Legislature passed a bill* authorizing the formation of mosquito-abatement districts, and providing for funds through taxation of the lands benefited. At present (1927), there are approximately twenty organized mosquito-abatement districts in the State, of which six or seven are primarily concerned with the control of salt-marsh mosquitoes; the remainder are concerned primarily with malaria control.

James E. Brooks,† Esq.—The human mind is generally so burdened with the things of the present that it forgets the things of the past; especially so if the things of the past have not been personal experiences. People think very little about the terrors and horrors of smallpox and yellow fever epidemics. In this part of the world they are things of the past, and few communities have experienced them. However, the victory over yellow fever came so much later than that over smallpox that some of those who took part in the victory over yellow fever at Havana are still living.

Mr. LePrince, who is a civil engineer, was with the late General Gorgas at Havana, and, subsequently, at Panama. He is a pioneer in the fight against disease-carrying mosquitoes, and he is still carrying on the fight.

Mr. LePrince has not painted the picture of yellow fever black enough. Of the epidemic of 1878, Gorgas says: "In this epidemic over 13 000 people in the Mississippi valley alone lost their lives, and the loss of wealth is estimated at considerably more than a hundred million dollars." Yellow fever has been epidemic as far north as Quebec, Canada, and Swansea, in Wales.

In the fight against disease-carrying mosquitoes the physician, the biologist, and the engineer should work together, hand in hand. The late Dr. Henry R. Carter was not only a physician, but a graduate civil engineer. In 1898, while he was a surgeon in the U. S. Marine Hospital Service, Dr. Carter wrote a paper on his observations upon the extrinsic incubation of yellow fever, made at Orwood and Taylor, Miss. It has been said that,

"Measured by the results produced, this was one of the most important papers ever written. * * * It was one of the great steps in establishing the true method of the transmission of yellow fever."

The life habits of the different species of mosquitoes vary greatly. While in the larva and pupa stage they all live in water, but some develop in salt water and some in fresh water; some require clean water, while others will thrive in water so polluted that fish die in it within a few minutes. Some pass the winter in the adult or winged stage, some as eggs, and a few in the larval form.

It is fortunate that warfare against mosquitoes began with a species that is readily brought under control. The successful fight against the yellow fever carrying mosquito at Havana and Panama encouraged people to fight other species without a realization of the greater difficulties to be encountered.

* Chapter 584, Statutes of 1915.

† Cons. Engr., Essex County Mosquito Extermination Comm., Newark, N. J.

The mosquito which carries yellow fever is called *Stegomyia fasciata* by some and *Aëdes ægypti* by others. Malaria is carried from person to person by mosquitoes of the genus *Anopheles*.

Mr. LePrince speaks of the rapidity with which yellow fever was brought under control, but he makes no such statement about malaria. The war against *Anopheles* will be long and expensive, but the victory will be worth the price.

In New Jersey the fight began at South Orange in 1901, and it has been going on with increasing intensity ever since. It was started to get rid of an intolerable nuisance, and was directed against mosquitoes in general without regard to species.

To-day (1928) the nine counties along the eastern border, from Bergen to Cape May, and Passaic County, have mosquito commissions acting under a law passed in 1912, and their total annual appropriations amount to more than $300 000. In only one or two of these ten counties does the control work cover the entire county. Essex County, with an area of about 125 sq. miles, and 500 000 population, spends $75 000 per year for mosquito control. This is approximately 15 cents per person. There are still eleven counties without mosquito commissions, and of all the salt marsh in the State a little more than one-half has been drained. The work is being advanced each year. Most of the undrained salt marsh is in the southern part of the State.

Methods of Mosquito Control.—All mosquitoes, in their larval stage, live in water. At present, the attack is directed against the larva; and obviously, the elimination of standing water is the most effective method. This may be accomplished either by drainage or filling.

On the salt marsh, filling is expensive and is proceeding slowly, while drainage has been accomplished rapidly. Three methods are used: Open ditches connected with tide-water; dikes with automatic tide-gates; and pumping.

On the upland, the practice of draining and filling is followed wherever it is feasible. Where water cannot be removed it may be stocked with some top-feeding fish, or treated with some chemical called a larvæcide, or the surface of the water may be covered with a film of oil. In warm weather the larvæcide or oil film must be renewed at intervals of from 8 to 10 days. As an example of routine work, in Essex County about 10 500 sewer catch-basins are treated with oil once every 10 days from the middle of June to the end of September. A cheap, safe, effective, and lasting larvæcide has not been discovered.

Results.—The relief obtained through mosquito control work in New Jersey has been very great, and has more than justified the expenditures made, both from the standpoint of increased personal health and comfort, and the increase in taxable ratables.

Failures.—A female mosquito of the genus *Aëdes* will fly about laying eggs, one at a time, on the surface of the ground where some day they may be covered with water. This may be near a pool of water or in a depression in some field or woods. Months, or even years, may pass, when a heavy

rain during the warmer half of the year changes the dry ground to a pool of water, and in a few minutes the eggs have hatched. If the pool of water disappears before the larvæ have time to mature they die. The water may run off; it may seep into the ground; it may be evaporated; or it may remain a week or so and permit a brood of mosquitoes to reach the adult or winged stage.

Occasionally the time comes when rains follow each other at such short intervals, and the evaporation is so slight, that the hundreds and thousands of large and small pools and pockets of water (too numerous to be drained or covered with oil within the short time allowable) will turn out vast numbers of adult mosquitoes.

In 1926 the control work in New Jersey during May, June, and July, was more effective than ever before, but during August and September weather conditions were so unfavorable that, in spite of all that the mosquito commissions could do with the means and methods at hand, a large brood of *Aëdes* mosquitoes reached maturity.

Additional drainage and the greater use of machinery for digging and cleaning ditches, and a way of increasing the working force temporarily, following rainy periods, are needed to increase the efficiency of mosquito control in New Jersey.

W. G. Stromquist,* Assoc. M. Am. Soc. C. E. (by letter).—Because of the many factors involved in his review of the control of disease-bearing mosquitoes, Mr. LePrince said very little about the relation of artificial lakes to malaria. This is a subject of growing importance which should be given more attention by engineers than has been done in the past.

In former years, when water power projects were on a small scale only, there were many relatively small constant-level ponds which were frequently the cause of severe outbreaks of malaria; or, as they were often termed, "serious epidemicals". More recent developments of hydro-electric power are on a large scale, with immense impounding reservoirs. The danger of malaria is greatly increased. This is particularly true in the Southern States, where there is a combination of prevalent malaria with a rapid and extensive increase in hydro-electric projects.

Fortunately, the Engineering Profession is beginning to understand the possible relation of these projects to malaria outbreaks of serious importance that result in damage suits against the power company, or against the municipality developing a surface water supply. However, in too many cases the necessary precautions, under experienced supervision, are not taken until they are required by health authorities or threatened damage suits. Preventive measures are generally less expensive than corrective measures.

The production of *Anopheles* (malaria-carrying mosquitoes) is most prolific in bights or indentations of constant-level reservoirs where floatage protects the mosquito larvæ against its natural enemies. Aquatic or semi-aquatic growths in shallow parts of reservoirs also favor mosquito production, as does any protection against, or lack of, severe wave action.

* Director, Bureau of San. Eng. and Div. of Rural Sanitation, Jefferson County Board of Health, Birmingham, Ala.

Some of the conditions inimical to the development of *Anopheles* are: Distinct wave action against a clean shore; the presence of *Gambusia* (top-water minnows) which eat mosquito larvæ if they are not protected by floatage, vegetation, etc.; and pronounced fluctuations of water level at 10-day intervals during the mosquito season (from 2 ft. on steep slopes to 4 ft. on flat slopes).

Having recognized the danger of building reservoirs without proper precautions against malaria, the State Boards of Health in several States have established regulations governing reservoir construction. The rules imposed are adjusted to local conditions, but, in general, they require:

(1) Clearing the reservoir site of all trees, brush, and undergrowth that would extend above the surface at low-water level, in order to prevent the collection and anchorage of floatage.
(2) Clearing the shore line at a specified distance beyond high-water level to prevent the collection of floatage along the shore.
(3) Establishing hatcheries for *Gambusia* prior to impounding the water so that, as the reservoir is filled, the branches and indentations will be well stocked with these enemies of the mosquito.
(4) Other supplementary control measures, such as removing floatage, clearing shallow parts of vegetation, oiling, etc., under trained supervision, for the first few years after the reservoir is built and until the proper biological balance is obtained in it.

With clearing charges of from $25 to $40 per acre, the necessary work of preparing a reservoir site may cost several hundred thousand dollars. In an effort to develop less expensive methods of control, the U. S. Public Health Service has, since 1926, conducted some very interesting experiments to determine the feasibility of controlling the production of *Anopheles* in large reservoirs by means of Paris green distributed from airplanes. The development of this new control measure may in time eliminate from many projects the need of costly clearing operations.

It is advisable for any engineer connected with an impounded water project, be it a water supply or hydro-electric development, where there is potential danger of malaria, to consult with the Engineering Division of the State Board of Health, or with the U. S. Public Health Service, before he goes far with his plans, so that serious errors will not be made.*

It is worthy of note that, of the three men who were most prominent in originating and developing malaria control—the late General W. C. Gorgas, U. S. A., Dr. H. R. Carter, and Mr. LePrince—the latter two were graduate Civil Engineers. The control of malaria in cantonments and extra-cantonment zones, with the remarkable results mentioned by Mr. LePrince, was directed mainly by engineers.

THORNTON LEWIS,† ESQ.—Due to the fact that the Society is the oldest National Engineering Society in existence in the United States, it is fitting that its members should be interested in the very important subject of ventilation, for it is not only an engineering question, but one that vitally affects

* Possible errors that engineers may make in the construction of impounding reservoirs have been outlined in the *Proceedings* of the National Malaria Committee, 1927.

† Pres., York Heating and Ventilating Corporation, Philadelphia, Pa.

the health and comfort of all human beings. Dr. Palmer's paper is a real contribution to the literature of this subject. It is sane and well balanced. Unfortunately, only a few of the men who have attempted to discuss this subject in recent years, have had such a broad and comprehensive view of ventilation.

As a matter of fact there is a controversy raging at present between what might be called the open-window theorists and the mechanical ventilation advocates. It is not really for engineering bodies to decide this question. The Medical Profession should determine what is proper for man's health so far as air conditions are concerned. Then, the duty of the engineer is to provide these conditions. Technically speaking, the engineer should not take part in the determination of what is necessary for public health and the medical man should not concern himself with the method by which these conditions are obtained by the engineer. Unfortunately, neither of these professions has entirely done its duty in this respect.

The ventilating engineers, however, have established a research laboratory at Pittsburgh, Pa., which is operated in co-operation with the U. S. Bureau of Mines for the determination of basic facts relating to ventilation and heating. This work has been proceeding since 1919 and some very valuable results have been obtained, but the end is not yet in sight.

In this work the engineers have been ably assisted by the U. S. Public Health Service, which has made the physiological determinations, and one of the results of this very fine co-operative work has been the comfort chart. This chart shows what temperature and percentage of relative humidity gives the greatest degree of comfort. This has been termed "effective temperature". Scientists and those interested in heating and ventilating from commercial standpoints have been awaiting this chart for years. This is only the beginning, however, and with further co-operation from the Medical Profession still more light can be thrown on the troublesome question of ventilation.

Dr. Palmer mentions the common standard of 30 cu. ft. of air per min. per person, which has been written into most of the State laws governing the ventilation of school buildings. He states that this provision is unnecessarily severe, and should be amended. Perhaps he is right. Let it not be forgotten, however, that it has taken years to secure any standard of ventilation in school buildings of the various States and before efforts are made to destroy the standards that have been set up, let the correct standard first be determined.

The proponents of open-window ventilation also state that the 30-cu. ft. standard is too large, but they do not indicate the correct amount. They fail to recognize that with the method they offer, there will be times when no ventilation will be secured, for the wind does not always blow. If there is a school building with rooms on the four sides, the wind can blow on only one or two sides, at most, at the same time. The open-window ventilation is not positive ventilation.

One prominent engineer, and an authority on the subject of ventilation, has compared open-window ventilation to the old sailing ships, which were

governed purely by the whim of the wind, and mechanical ventilation to the steam-driven modern palace of the sea. Certainly, there is some analogy in this comparison.

No engineer in the country to-day, who is familiar with the question of ventilation, would oppose a change in existing laws to lower the amount of air per person introduced into schools or other buildings where human beings are assembled, provided the change was made to some standard that had a scientific basis.

Most ventilating engineers feel very much as the Civil Engineering Profession would feel if a physician came along and said that the factors of safety used for steel structures were wasteful and that, instead of 10, some other factor of safety, lower than this, was all that was needed. If he did not accompany this statement with any definite scientific information as to what the lower factor should be, the engineer would feel that it was better to adhere to the higher one which was known to be safe, and which certainly could not produce harm, than to allow some law to be passed that would reduce it below that where the safety of the public was assured. That is the position of most ventilating engineers to-day. They welcome any scientific information on this subject, but they will oppose the tearing down of the progressive standards already built up until those standards can be replaced with new ones based on facts and not on theories.

The speaker is forced to disagree with Dr. Palmer when he states: "Engineers have yet to learn how to counteract the heat production of a hall full of people so that temperatures at the close will be nearer 70 than 80 degrees." The absorption of this heat production has already been solved, not only in theory, but in practice, and is being used in a great many theatres and other buildings to-day. The reason it is not more generally used is that such a system is not only costly to install, but also expensive to operate. The theatre owner, however, who is largely interested in the box-office receipts, has found that in summer it will pay to use this costly system to give comfort. The further use of this system is limited only by its commercial value and not by the ability of the ventilating or air-conditioning engineer to produce these results. In the manufacture of many products, such as capsules, photographic films, artificial silk, etc., it has been found that air conditioning, even if expensive, is profitable and, therefore, it is being used. When the general public considers its own health and comfort equal in value to a manufactured article, it will be able to secure the proper air-conditioning equipment to produce the desired result.

The speaker does not mean to suggest by this latter statement that he disagrees with Dr. Palmer in his forecast of the progress to be made in ventilation; for certainly there will come tremendous improvements in this art as well as in others. However, a more intelligent public opinion is needed on the subject of ventilation and public health and a great deal more interest on the part of medical men than in the past. It is very encouraging to see the Society considering a paper of this character. It is also encouraging to observe several co-operative efforts being made by members of the medical

fraternity, public health associations, and the ventilating engineers. It is only through such movements that an early solution of this very complex question can be reached.

In the last 100 years there have been radical changes. Formerly, people lived out-of-doors most of their lives, but now they have become an indoor people. Even transportation systems, such as subways and closed automobiles, do not allow them to be outdoors as much as they need to be. It is, therefore, necessary, as Dr. Palmer points out, to furnish fresh air for indoor conditions. The ventilating engineer needs the assistance of the physician and the chemist to tell him what quality there is in the outdoor air that makes it "fresh". He can undoubtedly provide "fresh air" if he knows what it is.

Samuel R. Lewis,* Esq. (by letter).—The writer agrees in general with Dr. Palmer, except in his statement that:

"The present air-flow standard is undoubtedly excessive. This may be decreased by one-half in such places as school rooms without discomfort or harm to the occupants".

It is hardly fair or in keeping with the temperate statements of the remainder of the paper, to imply that these sentences express the consensus of present-day opinion in regard to ventilation.

In many cases, the present air-flow standard may be excessive. The air volume required is believed now to be governed by requirements of temperature and odor control, rather than by chemical or organic substances in the air.

There is evidence to support the belief, now held by many students of the subject, that an increase in health and comfort in school rooms may be gained by a supply of air per pupil per minute considerably less than the usual 30 cu. ft.

Leonard Greenburg,† Esq. (by letter).—The steps by which progress has been measured in the field of heating and ventilating during the last one hundred and fifty years are clearly described by Dr. Palmer.

It seemed certain in the earlier days that the discomfort one felt when placed in a poorly ventilated room was due to the vitiation of the atmosphere, brought about either by the production of subtle exhaled toxins, or by the accumulation of carbon dioxide. It has since been proved that these theories are incorrect and to-day most people are convinced that the discomfort is due primarily to overheating.

Every one must eat food in order to obtain the energy necessary for bodily activity. This energy is obtained from the oxidation of an amount of foodstuff capable of yielding approximately 1 to 3 000, or more, calories per day. The heat of this oxidation is liberated within the human body and in the body tissues. Some of it is needed to keep the body warm (98.6°), but a large portion must be wasted. This is done by the usual means (conduction, convection, radiation, and evaporation) from the lungs and the surfaces of the body.

* Chairman, Comm. on Research, Am. Soc. Heating and Ventilating Engrs., Chicago, Ill.
† Associate San. Engr., U. S. Public Health Service, and Lecturer in Public Health, Yale Medical School, New Haven, Conn.

If the environment is too warm, the body will have a difficult or almost impossible task in dissipating its excess heat, the heat-regulating and vascular systems of the body will be overtaxed, and discomfort will ensue. The problem of ventilation, in the light of present knowledge, resolves itself chiefly into the task of warming rooms without overheating them. To be sure, the problem of air supply is still of importance, for it is by this means that the heat is removed from large spaces, such as auditoria or theatres. To be specific the room must be comfortable when people enter it, and must remain so, in spite of the continuous contribution of heat from the people, as well as that from the heating sources which are in use. It is the regulation of these heating sources and, if necessary, the removal of body heat which must be accomplished if the environment is to be kept at the proper temperature. All this must be accomplished, as Dr. Palmer states, without the production of unpleasant drafts of cool air.

The engineer has been accustomed to deal with physical structures and materials which he can measure and weigh. To him the problem of ventilation presents one peculiar aspect, for the test of ventilation in the room is the production of a condition which shall feel comfortable to the majority of the occupants. Feeling is something new to the engineer; it is a yardstick that is more familiar to the physician. Fortunately, it is possible to translate feeling into temperature for it has been found that healthy sedentary people usually feel uncomfortable indoors in the winter when the air temperature is more than 70 degrees.

In addition to the importance of the subjective sense of comfort as a criterion of ventilation there appears to be one other aspect of the problem to which the ventilating engineer attaches insufficient importance, namely, the necessity for variability in the atmospheric conditions to which the body is exposed. The human body is peculiar, in that conditions which are continuously uniform are monotonous and distasteful to it. For this reason, the window method of ventilation with its intermittent breezes of cool and warm air, is much more pleasant than the method of closing windows and ventilating by means of the fan in the basement.

One of the real stumbling blocks in the progress of ventilation has been the indifference of the ventilating engineer to the advances which have been made in the field of physiological research. In spite of established facts there are still many ventilating engineers who demand an air change of 30 cu. ft. per person per min. It is important to note that if this change is supplied at a higher temperature than 70°, it may serve to overheat the room and produce discomfort, whereas if it is too cold, it will chill the occupants of the room. The temperature of the air is the important consideration which many still overlook.

Ventilation laws prescribe the supply of 30 cu. ft. per person per min. Few of them definitely state the temperature at which the environment should be maintained. It is obvious that they overlook the all important part of the problem. In addition, they actually impose a financial burden on the owners of the buildings and, in return, yield atmospheric conditions which, accord-

ing to the studies of the New York State Commission on Ventilation, are responsible for many respiratory diseases.

Dr. Palmer's tabulation of the changes in ventilation likely to take place in the immediate future, is excellent. The writer suggests a slight change in the order of importance of these developments. To a very great degree engineers lack an understanding of what ventilating systems, once installed, will accomplish. In order to design new systems which will work with the utmost efficiency it is necessary to know the working characteristics of those now in use. On a basis of such studies, engineers will be enabled to alter designs and take into account some factors which, perhaps, are now overlooked and, what is still more important, they will learn how to operate existing plants. It will be possible to instruct those in charge of operation just what to do, when atmospheric conditions arrive at the optimum, in order to maintain these conditions. A ventilation plant should not be compared with a bridge or a building designed by an engineer because these structures usually require little or no operation, but it should be compared with the water purification or sewage treatment plant; these require expert operation and receive it as a matter of course.

It is to be hoped that, in the future, the ventilating system will be given more expert supervision and operation. If this is lacking one naturally turns his attention to the use of automatic temperature control apparatus and, without question, the improvements to be expected in this field should do much to increase operating efficiency. At first glance the problem may appear to be a simple one, but more careful study and reflection will prove it to be complicated. It must be borne in mind that direct sources of heat, such as radiators, are large heat reservoirs, and when the steam is cut off they still continue to give off heat to the room atmosphere. This suggests, at once, that radiators should be turned off somewhat below the upper limit of the comfort temperature. The satisfactory operation of thermostatic control devices depends in a large measure on adjustment and maintenance, which again emphasizes the need of trained personnel.

The field of industry presents the most interesting and important tasks for the ventilating engineer. The ventilating problems of industry are manifold, and they continue to grow in number each year. Plants for the removal of heat, for refrigeration by means of cold air, and for the removal of noxious gases, dusts, and poisons, require the services of the ablest workers. Exact knowledge of the necessary elements in designs of this type are in the hands of relatively few, and new data are essential as newer problems arise. Furthermore, these problems are complicated by industrial conditions and plant processes. They are important both from the health and economic standpoint, and should receive increased attention from the Engineering Profession.

Problems of cooling in the warm months of the year and re-circulation during the heating season depend in a large measure for their solution on the economics involved. It appears to the writer that the ventilating engineer can cool the ordinary auditorium very satisfactorily, provided the rather large expense involved is no handicap. Re-circulation can well be practiced if the

economic return is justified by the design required. That improvements in this latter type of system are required there is no doubt, but these are largely of the nature of thermostatic temperature control discussed previously. The odor problem, which is of importance in this connection, may be solved partly by the careful control of temperature and humidity (odors are more pronounced at higher temperatures and humidities) and, in some measure, by the admission of outdoor air.

The chemical and not the physical viewpoint of the problem of ventilation may be regarded as the one single important obstacle in the way of ventilation progress. When this is completely eradicated progress in this field will be more rapid than it has been in the past.

George W. Fuller,* M. Am. Soc. C. E. (by letter).—The writer is appreciative of the several discussions amplifying the paper, which at best could only be brief and fragmentary on a subject with so many ramifications. As Mr. Fenkell indicates, it is to be regretted that recent performances of steam turbines and electric motor-driven centrifugal pumps, as well as data on maximum steam pressures used, were not included in the paper. However, it is probably best now to deal with them by reference rather than to include them in this discussion. These and a number of statistical and other data of interest will be found in the Manual of Water Works Practice issued by the American Water Works Association in 1925.

Harrison P. Eddy,† M. Am. Soc. C. E. (by letter).—It is always difficult to be sure of the accuracy and completeness of historical data. In presenting his paper, the writer felt that, while the information given therein was based on good authority, much other material of interest was preserved in local records or in the memories of a few. For this reason, it is gratifying that Mr. Allen and Mr. Webster have added interesting data relative to the early history of sewerage in this country, particularly as regards New York, N. Y., and Philadelphia, Pa.

The writer is inclined to believe that Mr. Kiersted has put it a little too strongly when he refers to "the insurmountable difficulties of attempting to combine, successfully, the purely mechanical process of sedimentation with the biological process of sludge digestion" in the Imhoff tank. The successful operation of Imhoff tank installations indicates that the difficulties are not insurmountable, and it is likely that Imhoff tanks will continue to occupy an important place among the devices for the treatment of sewage. The writer agrees with Mr. Kiersted in the matter of adequate preliminary sedimentation with the view of removing as large a proportion of suspended solids as possible, prior to subsequent treatment. The trickling filter functions excellently with well clarified tank effluent, although the removal of colloidal solids will materially increase its capacity, particularly with strong sewage. The periodic unloading of trickling filters is an established phenomenon, but the material unloaded by no means consists of the solids applied. Much of it is composed of

* Cons. Engr. (Fuller & McClintock), New York, N. Y.
† Cons. Engr. (Metcalf & Eddy), Boston, Mass.

organisms having their origin in the filter and would occur irrespective of the degree of removal of colloids. Sludge disposal is still a problem of importance and is often difficult to accomplish satisfactorily. As Mr. Kiersted notes, lagooning of sludge at isolated sites is often both economical and satisfactory; in other cases, however, the problem cannot be solved so easily.

Professor Gregory's emphasis of the advantages of the separate system of sewers will appeal to many engineers. Under certain conditions separate sewers are advisable and frequently decision between the two systems is difficult and is dictated by local conditions rather than by general principles. In the case of large streams, storm-water overflows may not cause serious pollution; but, as Professor Gregory indicates, such overflows may cause decidedly objectionable conditions in small streams. The common misuse of separate sewers and storm-water drains is a reflection on American municipal conditions.

Dr. Imhoff's references to sludge digestion are of interest, although data from the Imhoff tanks at Schenectady, N. Y., indicate slightly higher temperatures in the sludge compartments than in the sedimentation compartments. This fact suggests thermolytic action as a result of the digestion processes. Confirmatory evidence from other installations is desirable in this connection.

The several discussions emphasize two points: First, the great advance made in sewerage and drainage since the middle of the Nineteenth Century; and, second, the fact that much remains to be established in the scientific principles underlying proper sewage treatment and disposal.

S. H. McCrory,* M. Am. Soc. C. E. (by letter).—The writer is grateful to those who have taken part in the discussion. The development of drainage laws has been a slow process. Frequently, as Mr. Morgan suggests, laws have been passed to meet the immediate purpose. At times, emphasis perhaps has been placed on legal and engineering technicalities, and the agricultural side of the problem has been neglected. The tendency in recent laws has been to make the organization of the districts easier. It is probable that such laws have been too liberal in this respect, and that in future laws the organization of districts will be made more difficult. In considering new drainage projects there is an increasing appreciation of the importance of examining all possible uses to which the land can be put, and selecting the use for which it is best adapted.

Under-drainage is needed over a large area in the United States. Its advantages are well described by Mr. Jones. The mole drain described by Mr. Shaw had been almost abandoned when changed economic conditions made it necessary to find a cheaper method of under-drainage than the use of tile, and the mole drain came into use again. By substituting the tractor for the capstan and thus speeding up the work it is possible to construct drains 2 rods apart at the rate of 30 acres per day, at an approximate cost of about $2 per acre. Where the soil is of such texture that these drains can be used, they afford fairly adequate drainage at low cost.

Mr. Hidinger emphasizes the importance of proper balance in designing drainage systems with modern excavating machinery. Drains can be cut to

* Chf., Div. of Agricultural Eng., Bureau of Public Roads, U. S. Dept. of Agriculture, Washington, D. C.

specified size, and slopes can be adjusted to the materials through which the drains pass. The control of silt brought down by small hill streams by settling basins, as suggested by Mr. Towl, can be used to advantage on many streams. Studies now in progress under the writer's direction indicate that such basins should usually be proportioned so as to have, within the basin, from 1% to 2% of the area of the water-sheds.

The permanence of irrigated agriculture depends to a large extent on the establishment and maintenance of satisfactory drainage. As Mr. Hart states, these drains must often be constructed to prevent the loss of large areas of productive land which, under irrigation, are becoming water-logged and alkaline.

J. A. LePrince,* Esq. (by letter).—The California State Board of Health has issued a *Bulletin*† of value to those who are interested in prevalence or elimination of malaria. To a considerable extent this prevalence of malaria is due to irrigation, mining, and other operations of an engineering nature. Irrigation with inadequate drainage, seepage waters, and irrigation canals overgrown with vegetation demand attention and treatment by engineers. In the engineering schools of South Carolina, the students are taught to appreciate the importance of this phase of their work.

With regard to the mosquito control activities of New Jersey, all "mosquitologists" agree that it would be financially advantageous for all States with mosquito problems of economic importance to follow the lead and methods taken by New Jersey. Within the past year (1927) some unjustifiable criticism relative to anti-mosquito work in New Jersey and on Cape Cod, Massachusetts, was published in a prominent American engineering journal. The writer investigated the situation on Cape Cod and found that the total appropriation made for mosquito control was $1 000. Yet some one expected mosquito freedom over all the Cape Cod territory for that sum and stated that the enormous sums spent, had been wasted. Such news items in engineering journals are at least misleading.

Mr. Brooks states that the annual appropriations now made by the counties of New Jersey exceed $300 000 and it is probable that less than $500 000 are being appropriated by the counties of all other States taken together for mosquito control.

If such a sum were available for a few years exclusively for the control of malaria, this disease would soon disappear from the country, assuming that the elimination work was directed by competent specialists applying the newer control methods that have been devised and are being developed by the U. S. Public Health Service. These new methods are now being used in a number of countries of both hemispheres.

In connection with the elimination of pestiferous mosquitoes, the time will soon come when the public will expect the Engineering Profession to avoid building mosquito-breeding places in thickly settled communities. It means that storm-water catch-basins must be designed so that they will be dry except at time of rain.

* Senior San. Engr., U. S. Public Health Service, Memphis, Tenn.
† *Bulletin No. 44*, State Board of Health, Sacramento, Calif.

Mr. Brooks has shown unusual foresight in the general plan of ditching of the meadows of New Jersey. To have used additional smaller ditches to care for the unusually rainy seasons would have increased first costs as well as maintenance costs and, since emergency control measures are now being investigated, it is probable that sanitary engineers will be able to use the new and satisfactory supplementary measures in the years when the rains are spaced so as to be particularly favorable to mosquito life.

In regard to the statement that it is fortunate that warfare against mosquitoes began with a species (*Aedes aegypti*) that can be readily brought under control, it should be remembered that when the first campaign started it was not known that such was the case, and the public press of Havana claimed the efforts of the sanitary engineers were useless because all mosquitoes destroyed would be replaced by "others carried in from the yellow fever districts by favorable winds."

This pioneer work done in Cuba in 1901 had little effect on the reduction of the yellow fever mosquito in the Southern States, as is evidenced by the rapid spread of dengue fever in 1922. In that year there were more cases of dengue than have ever existed at any time in American history.

The relation of impounded water to malaria prevalence is now being studied by malariologists of other countries and they are sending to America for information, because the State health regulations in regard to the subject in this country have been published, and are based on scientific investigations conducted by the U. S. Public Health Service.

George Truman Palmer, Esq.* (by letter).—In closing the discussion on ventilation, the writer would like to call attention to certain mitigating circumstances which have tended to retard ventilation progress.

People can exercise choice in what they drink, what they eat, and what they wear; but, in the matter of air, they are forced to be communistic. At least, the occupants of the same enclosure are forced to share the same air environment. Within the same room, one person cannot have low temperature and another a higher temperature at the same time. So long as "some like it hot and some like it cold" there will continue to be differences of opinion on air comfort, and, in consequence, a certain amount of dissatisfaction. In the effort to eliminate the objectionable and the unhealthful in ventilation, sanitary experts can never hope to surmount entirely this question of personal preference and individual idiosyncracies.

The writer's criticism of certain existing legal requirements as to ventilation are made on the ground that they hinder progress. The 30-cu. ft. requirement obstructs the development of new methods. Window ventilation with gravity exhaust has its application. There is scientific evidence and practical experience to support this method. Many State laws, however, prohibit this practice. It is fully believed that there is less evidence to justify these laws than there is to sustain them.

If the laws were altered to permit real competitive development of ventilation methods, the better methods would eventually reveal themselves by their

* Director, Div. of Research, American Child Health Assoc., New York, N. Y.

survival. The substitution of the 15-cu. ft. requirement in place of 30 cu. ft., would make this competition possible and the experimental evidence is surely sufficient to provide assurance that health would not suffer by the change.

Mr. Samuel Lewis is quite right in criticizing the writer's statement about the desirability of reducing air-flow requirements as not representing the consensus of opinion. This should have been stated more carefully. The writer feels, however, that even if a majority of ventilating engineers may not agree with this attitude, nevertheless such a change is warranted by the experimental evidence available and by practical experience.

INDUSTRIAL WASTE DISPOSAL

INTRODUCTION

By W. L. Stevenson,* M. Am. Soc. C. E.

The conservation of water resources is of importance to the health and prosperity of the people of the United States. Life in modern cities is impossible without adequate public water supplies, and the protection and promotion of the public health demand that such water be pure and palatable.

Industry must have water for use in processes of manufacture, and for many industries such water must be clean. In agricultural areas clean streams are needed for watering stock, and the trend toward outdoor recreation is increasing the need for clean streams for that purpose in suitable localities.

Streams, however, are the natural drainage channels of the land and of necessity must receive the rain water which falls upon their catchment areas, carrying with it substances eroded from the surface of the earth and dissolved by the ground-water from beneath the surface.

Similarly, but artificially, the streams must also receive back again the water which having been used as public supplies in towns becomes sewage, and having been used in manufacturing becomes industrial waste, and being pumped or flowing by gravity from mines, oil wells, etc., carries substances from sub-surface strata. All these are hereinafter called waste waters.

The rule of law that each riparian owner is entitled to receive water from up-stream owners "unimpaired in quality" was undoubtedly just at the time it was declared and was practicable everywhere in this country when it was first settled. It may still be applied in the undeveloped and sparsely settled parts of the country, but elsewhere modern civilization, with sewered cities, industries, and the development of underground resources, has completely changed the primitive conditions which existed in the days of the pioneer.

Therefore, if real conservation of water resources is to be attained in order to make adequate provision for all the manifold and diverse uses of streams in the developed parts of the country, it will be necessary to adopt and carry out, on a nation-wide scale, a broad comprehensive plan for the sanitary conservation and the prudent utilization of the water resources.

Such a plan should be based on the fundamental principle that conservation is primarily intended to render the water resources increasingly useful for the well-being of the Nation, but it is not intended to return them to a state of pristine purity nor arbitrarily to estop the discharge of all unpurified waste waters to them.

Such a comprehensive plan, therefore, should include:

(*a*) An order of precedent of use of water, in which the first and highest use generally will be for sources of public water supplies for domestic and municipal purposes.

(*b*) An allocation of the use of river systems, streams, or even parts thereof, for whatever purpose best serves the general public interests and is not directly incompatible with the local interests.

* Chf. Engr., Pennsylvania Dept. of Health, Harrisburg, Pa.

(*c*) A recognition of the natural capacity of rivers to assimilate inoffensively and purify ultimately limited quantities of certain kinds of waste waters.

(*d*) An equitable and just assignment of this natural assimilating capacity among those parties who properly discharge waste waters to the rivers and also an equitable and just assignment of responsibility for purifying before use the water of the streams among other parties who divert the water for various proper purposes.

(*e*) An economical and practicable procedure to determine the assimilating capacity of streams for various kinds of industrial wastes and to find reasonable and practicable ways and means of treating industrial wastes to produce effluents capable of inoffensive assimilation.

In some States discretionary power is vested in the executive officer, board, or commission, which administers the statutes relative to sewerage, and the discharge of sewage and industrial wastes. This makes possible the adoption of a comprehensive plan such as that described. In the statutes of other States there are inflexible and positive prohibitions against any discharge of enumerated substances to streams, or against groups or classes of wastes deemed detrimental to certain uses of streams, and in such cases worth while results cannot be obtained where the prohibition is impracticable or merely idealistic. Also, anti-stream pollution statutes are generally of State-wide application and do not differentiate between the widely varying characteristics and needs of the different sections of the State.

The folly of this principle is being corrected in the matter of municipal development through the zoning of cities, whereby the variation of requirements for residential and industrial uses is recognized and defined. The principle of zoning is applicable to a comprehensive plan for the conservation of water resources.

As this is an introduction to an industrial waste symposium, only that part of the proposed comprehensive plan concerning the assimilating capacity and methods of treatment of waste waters will be considered herein.

Many scientific investigations have been made of the conditions of streams receiving sewage, so that definite knowledge is now available as to the amount of sewage which streams can inoffensively assimilate. Also, processes have been developed and established whereby sewage can be treated to any required degree. As regards sewage, therefore, the needed data are now at hand, and the problem is largely one of determining the required degree of treatment of the sewage, if any, the designing of structures, providing funds, constructing works, and then efficiently operating them.

Such, however, is not the case with industrial wastes. For many years, both technical and lay investigations have been made concerning the treatment of various industrial wastes. All over the country industrial waste treatment works have been installed—some entirely satisfactory and efficient, others, regardless of the expenditure of considerable funds, failures or gravely inefficient.

Ofttimes only the engineer who designed the works and the company that operates them know any of the details of either the successes or the failures. Such data are not generally available to the Engineering Profession, nor to industry as a whole.

It is certainly uneconomical for any one company engaged in a certain industry to expend its own funds in research and experimental installation in order to find out how to treat an industrial waste which is or may be a common problem to many other companies engaged in the same industry, except in special cases or for the profitable recovery of by-products.

For the solution of such problems in any State a more practicable and economical procedure is for the State agency which administers the statutes having to do with discharge of industrial wastes to enter into co-operative agreements with the various groups of industries, whereby funds are provided to be expended by a committee of competent technical experts in investigations to determine:

(1) The polluting strength and characteristics of the ingredients of the industrial waste.
(2) The assimilating capacity of streams for the industrial waste, untreated and treated to various degrees.
(3) Reasonable and practicable processes of treatment to provide a progressively increasing quality of effluent so as to meet the varying requirements of different streams.
(4) Cost data of construction and operation.

There are technical problems which are common to several industries and questions to be answered of common interest to different industries, such as the basic principles underlying standards of cleanliness of streams used for various purposes. To solve these technical problems and answer these questions there should be co-operation between the industrial waste committees of the various States.

Certain industries operate in many States and in such cases economy of funds and enlargement of scope of work may be attained by providing for coordinating or even unifying investigations of industrial waste disposal through a National committee made up of representatives of the State officials, the technical experts, and the executives of the industry in those States where such co-operative agreements may be put into effect. Such a project is not a theory. It has been inaugurated.

In Pennsylvania, technical committees have been created and are at work on the unsolved problems of disposal of tannery wastes and on pulp and paper mill wastes.

In Ohio, committees have been created for the study of the waste disposal problems confronting the canning, dairy, acid, iron, and paper industries.

In Wisconsin, pea-canning and pulp and paper committees are in existence and, in Michigan, a tannery committee has been organized.

The American Paper and Pulp Association has created the "National Stream Purification Committee for the Pulp and Paper Industry", consisting of representatives of the industry and of five State officials.

Therefore, it appears possible to build on the existing foundations a superstructure which will be a sane, practical, comprehensive plan for the sanitary conservation and prudent utilization of the water resources of the United States.

TREATMENT OF WASTES FROM OIL REFINERIES

By Robert Spurr Weston,* M. Am. Soc. C. E.

The treatment of wastes from oil refineries is different from that of most industrial waste liquids. This is because oil-refining processes differ so greatly from those the wastes of which the engineer is usually called upon to treat.

An outline of typical refinery practice has been presented† by the writer and will not be repeated here. It is sufficient to state that in an ordinary refinery much water is used for cooling; various petroleum products are treated with chemicals and washed with water; and, at times, there are leakages from condensers and from the multitude of tanks and pipes containing the oil and oily products. All these waste liquids reach the refinery sewer, together with many results of bad or experimental processes and many operators' mistakes.

So much for the waste liquids. There are also waste semi-solids and solids. Refinery practice varies widely. In some refineries the crude oil is only "topped", that is, the gasoline is distilled, the residue being used for fuel. In others, the whole range of products from petroleum ether to coke, is made. The heavier products, petroleum residues, waxes, and coke, are sometimes denser than water.

As time goes on, one may expect that the waste liquids from oil refineries will become more and more complex, because the petroleum industry is still in its infancy. Thus far, oil refining has existed largely for the separation and sale of the various groups of elements in crude oil. In the future, it is certain that, in addition, as many products will be made from petroleum as are now made from coal-tar. When this day comes, one may expect more complications in the treatment of refinery wastes.

Refinery sewers are usually on the combined system, and the sewer inlets from refinery yards (seldom paved) carry much dirty storm water in addition to the usual leakage of ground-water and the refinery wastes themselves.

Most refineries have a separator into which the refinery sewer discharges. Usually this is a simple basin with skimming-boards and swinging, floating arms by which the oil is decanted from the surface of the separator and pumped back to the refinery to be passed through the process again. In many refineries the basin is divided into several compartments to facilitate the skimming of oil.

From one point of view, separators for liquid wastes alone may be considered as subsiding basins upside down. They receive oil and water and separate them by gravity. Unfortunately, the operation is not so simple as this conception. In many of the processes, and in tanks and pumps, emulsions are formed which are difficult to destroy. Also, treatment with various

* Cons. Engr. (Weston & Sampson), Boston, Mass.

† *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 383.

chemicals causes the formation of oily products with densities about the same as that of water, or greater. In many refineries, only the easily recoverable oils are skimmed off, the remainder being wasted. All these add to the difficulty of separation. After a time the oil discharged with the waste water inevitably separates, usually as a film on the surface of the body of water into which it is discharged.

The coke and heavier residues present a more difficult problem than the oils. Many of these residues are hot and fluid when discharged, but become plastic solids when mixed with the cooler wastes in sewer and separator, where they subside as pasty masses difficult to remove.

The design of the separator is usually simple, shallow basins with either vertical or sloping sides being customary. In the best practice, the wastes are passed through fore-basins where the larger part of the oil is readily skimmed off and the mass of settleable solids collected. These fore-basins greatly reduce the volume of water accidently skimmed off with the oil and minimize the labor of removing the heavier solid matter from the system of basins.

Probably because refineries have been located on large bodies of water where the discharge of waste therefrom has not been particularly objectionable, few have done more than to build simple separators. This has been done more to save oil than to protect the water receiving the effluent. A few other refineries have been compelled to go further.

In the manufacture of lubricating oils, wastes which are emulsions of oil and water are quite prevalent. As is well known, the permanence of oily emulsions is more or less dependent on chemical reaction, and although it is probably possible to separate and treat these preliminary wastes by adjusting the reaction and separating the oil by centrifugal machines, the practice is not general.

The coke residues are removed from separators either by hand or by hand and bucket hoist. There seems to be much opportunity for improvement in this regard, and apparently there is no reason why automatically cleaned tanks of the type used so successfully for sewage should not be adapted to oil refinery wastes.

Thus far, the chief factors in the purification of refinery wastes are gravity and time, and regarding the latter, there is no standardized practice. There are large refineries with small separators and *vice versa,* and it is rarely ever known what periods of detention are necessary or desirable.

The separator of one refinery was observed by the writer's firm for a year. The brackish water (30 to 50% sea water) used for condensing was returned through the sewer and separator, with its content of oily matter. The separator had a capacity of about 4 hours' flow, and the effluent from the basin generally contained from 5 to 19 parts per million of oily matter (ether soluble). There were, however, two days on which the content of oil rose to 42 and 78 parts per million, respectively. The variations are shown on Fig. 1. The average quantity of oil found was 12 parts per million. The body of water into which this effluent discharged had an average oil content of 3.1 parts per million. This refinery was in a large city, and the

presence of oil in the water receiving the effluent was due only in part to the discharges from the refinery and in part to the discharges from ships and from the sewers of the city, where much oil was used for fuel.

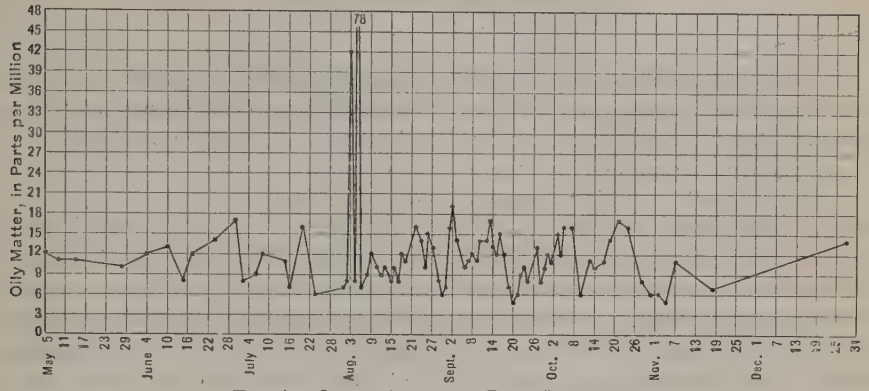

FIG. 1.—OIL IN SKIMMING POOL EFFLUENT.

Two other separators that were tested, produced effluents having the characteristics given in Table 1.

TABLE 1.

	PARTS PER MILLION.	
	Separator *A*.	Separator *B*.
Total solids	17 540	17 200
Loss on ignition	3 850	3 815
Turbidity	95	300
Oils (ether soluble)	40	40
Acidity, as H_2SO_4	.....	421
Alkalinity, as $CaCO_3$	110	.....

The conclusion from Table 1 is that at present the art of treating oil-refinery waste is rather rudimentary, and although methods are effective to a certain degree there are many improvements which suggest themselves.

A satisfactory treatment works should discharge an effluent practically free from settleable solids and one containing less than 20 parts per million of oily matters (ether soluble).

DISPOSAL OF DRAINAGE FROM COAL MINES

By Andrew B. Crichton,* Esq.

In the past the disposal of drainage from coal mines has been a simple and inexpensive proposition. As coal properties have been opened and the workings driven, water is always developed, which is either pumped or flows by gravity from the mines into the nearest waterway.

Practically all coal-mine drainage contains sulfuric acid, which soon impregnates the fresh-water streams into which it flows to such an extent that they are unfit for either industrial or domestic use. The natural alkalinity of fresh-water streams will neutralize large quantities of mine water, but as it requires 80 to 100 gal. of fresh water to neutralize 1 gal. of average mine water, it will be seen that dilution is not long effective, in the mining regions. Some of the principal rivers and many of their important tributaries are acid for long distances during their flow through the coal regions.

The stream-pollution problem from mine drainage is by no means new, and in the mining regions has long been the cause of great inconvenience and expense both to the mining companies and the public. Until quite recently it has been strictly a mining community problem. As the mining companies usually controlled the communities, if a water supply were destroyed by mine drainage no attempt to treat the water was made if other unpolluted supplies could be found. In many instances large sums have been spent in building treatment plants, which because of unsatisfactory results have later been abandoned and unpolluted water brought long distances at great expense.

The largest industries and public utilities have suffered most from stream pollution from mine drainage, because of their large and growing needs for pure water. Nearly one hundred water companies in Pennsylvania have similar problems, which are daily becoming more serious.

For years the mining industry has been considered paramount, but one is forced to admit that although coal is necessary, water is necessary for human existence; that one is dependent on the other, and that both are vital to the welfare and prosperity of the Nation. The development of the coal industry has gradually progressed during most of the past century, but has not nearly reached its maximum. Whatever ills have come with it have likewise been long in developing, so that good judgment and patient investigation, rather than drastic legislation, should govern in handling this problem.

Importance of the Coal Industry

The Nation could not long survive without the coal industry. It is the principal source of power and serves mankind in so many and varied capacities that one can hardly recount its blessings. The value of its gas and chemical products to civilization has never been properly appraised or appreciated. With the decline of oil resources the country will become even more dependent

* Min. Engr., Johnstown, Pa.

on the coal industry, and nothing should be done that will needlessly add to the cost of producing coal, or that will in any way affect its usefulness to mankind.

Coal is produced in twenty-eight States and is fairly well distributed. The capacity of the developed mines is said to be 750 000 000 tons annually. The United States produces about one-half the world's supply of coal and the value of this annual product is more than $1 500 000 000 at the mines. Including freight charges and other transportation costs, the ultimate cost to the consumers would be more than $4 500 000 000. Proposed National legislation prohibiting the discharge of acid mine drainage into the streams might easily add $200 000 000 to the annual coal bill, with doubtful results or without materially improving the fresh-water supplies.

Additional Legislation not Advisable

Until some satisfactory method has been found to treat or take care of mine drainage no additional legislation is needed. It has been said by many that this is a National issue, that any legislation requiring the disposal or treatment of mine drainage that will add to the cost of producing coal, should bear equally upon the whole industry. The operators of one State or district should not have any advantage over another as a result of legislation, but National legislation will not bear equally upon all districts, because the problem is not the same everywhere.

The problem is most acute in Western Pennsylvania, Northern West Virginia, and Ohio, and under any plan the cost of disposal will be greater in those districts than elsewhere. Mine drainage from Northern West Virginia flows through Pennsylvania, so that Pennsylvania legislation without any control of West Virginia mine drainage would be ineffective and would add an additional burden to the coal operators of Pennsylvania. Any apparent disregard of the rights of others or the protection of water supplies by the mining industry may in a measure be attributed to the principle laid down by the Pennsylvania Supreme Court in the now famous Sanderson case.

Court Decisions Affecting Mining

In 1886 Sanderson bought a property in the City of Scranton through which flowed Meadow Brook, a pure, unpolluted stream. He built a dam and developed a water supply for his own use. About the same time the Pennsylvania Coal Company opened a coal mine which soon produced acid mine drainage, destroying the use of the brook water. Sanderson brought suit for damages resulting from loss of the stream. The case was twice tried in the Courts of Lackawanna County, Pennsylvania, and was twice before the Supreme Court of Pennsylvania. The first Supreme Court decision affirmed the lower Court's award of damages to Sanderson; Justice Paxson filed a strong dissenting opinion, which was sustained in the second Supreme Court decision.

The Court took the position that if Sanderson could collect damages, every riparian owner thus affected could do likewise, and if they could collect damages they could also enjoin the pollution of streams by mine

drainage, which would practically stop all mining operations, except by consent of the lower riparian owners; that trifling inconvenience to particular persons must sometimes give way to the necessities of a great community, especially where the leading industrial interest of the State is involved. The Court further stated in its opinion that the Coal Company was making the natural and ordinary use of its property, and that Sanderson, with others, was then securing an abundant supply of pure water from other sources, but that it would not say that a case "may not arise in which a stream, from such pollution, may not become a nuisance, and that the public interests as involved in the general health and well being of the community may not require the abatement of that nuisance".

Pollution a Problem of Long Standing

Since about 1885 one water supply after another has been abandoned in Pennsylvania, due to mine drainage pollution, until there are few available supplies not polluted or subject to pollution. The protection of water supplies, to meet the constantly increasing demands for domestic and industrial needs, is, therefore, imperative.

In 1905 and shortly prior thereto the Pennsylvania Railroad Company was put to considerable trouble and expense by a water shortage. Old sources of supply had become polluted, and attempted treatment was unsatisfactory, resulting in engine failures and serious delays in operation. Millions of dollars were appropriated to secure an adequate supply for the Company's present and future needs. It was then not possible to secure supplies reasonably convenient to points of consumption which were not being polluted nor subject to pollution from mine drainage.

Development of Indian Creek Supply

The Mountain Water Supply Company was organized in 1905 and appropriated the waters of Indian Creek to supply the Pennsylvania Railroad System in Southwestern Pennsylvania, as far west as Pittsburgh. A large storage dam was built about 4 miles from the mouth of Indian Creek. The drainage area above this point is 110 sq. miles, of which 55 sq. miles are underlaid with the lower productive coal measures. At the time there were numerous small "country bank" openings for local supply for the farmers in the valley, but no commercial development of the coal lands. Several years later the Indian Creek Valley Railroad Company constructed a standard gauge track from Indian Creek, a point on the Baltimore and Ohio Railroad, up the valley to its headquarters, following which development of the lumber and coal resources was begun, but there was no material development until about 1917.

In addition to supplying the Railroad Company, the Water Company furnished water to several municipalities in Western Pennsylvania, supplying about 75 000 people. Active coal development began on a large scale, and it was apparent that this important water supply would be quickly destroyed for the purpose intended, unless something were done to keep the acid mine drainage out of the stream above the dam. During this time both the coal and water interests conducted studies and experiments in an effort to find

some satisfactory method of treating acid mine drainage that would permit the mining of the coal without the destruction of the water supply, but without success. The Water Company finally appealed to the Courts for an injunction to restrain the coal companies from discharging acid mine drainage into Indian Creek above the dam.

Indian Creek Pollution Suit

This case is known as the "Indian Creek Pollution Suit". The Fayette County Court decided there was no public use of the water and that preventing the mining companies from discharging water into Indian Creek would deprive them of the use of their property. The Court refused to grant an injunction restraining the mining companies from discharging mine water into this stream. The Pennsylvania Supreme Court reversed the lower Court, declaring that it was not a question of property rights, but that it was a nuisance to pollute the stream, and that the mining companies should not, after a certain period, discharge the mine water into Indian Creek or its tributaries above the dam of the Water Company. This opinion, which was concurred in by the United States Supreme Court, states:

"It is controlled by one fact and a single equitable principle: the fact that the stream has been polluted, and the principle that this creates an enjoinable nuisance, if the public uses the water".

The difference between the Sanderson and the Indian Creek decisions is that Sanderson, an individual who had access to another good supply of water, was not permitted to stand in the way of Pennsylvania's greatest industry, whereas in the Indian Creek case the public, also represented by the Commonwealth, is fighting to preserve one of the last available pure water supplies of the State, and the present decision merely carries out one of the principles enunciated in the Sanderson decision. As a result, there has been considerable discussion as to what constitutes mine drainage, or mine water. The water companies sought an injunction to restrain the mining companies from discharging acid mine waters into Indian Creek. It was admitted by both sides that eventually this mine drainage would destroy this water supply for the purpose for which it was then and is now being used. Some of the leading chemists, and water-works and mining experts of the United States were witnesses in the case, and there was no disagreement as to the fact that continued pollution by mine drainage would eventually utterly destroy this stream and render it unfit for any use.

There was much testimony introduced regarding the treatment or disposal of mine water, without material disagreement regarding it. Nearly every one in discussing "treatment" refers to neutralization by the introduction of lime. A prominent chemist, in a paper prepared especially for the purpose of fixing accurate and understandable definitions, repeatedly mentions "purifying" mine water by introducing lime. There is much confusion as to what is meant by treatment. The Conservation League wants a water that will not kill fish or vegetation; the Army engineers apparently want an alkaline water that will not affect the metal parts on the locks and dams,

or interfere with shipping; the water companies, for the domestic and industrial user, want a water fit for human consumption and industrial use; and every one would like the iron oxide kept out of the stream beds.

Treatment of Mine Water

The neutralization of acid mine water by the introduction of lime does not make the water fit for either domestic or industrial use. This matter was clearly before the Court, and was undoubtedly the reason for the decree that the mine waters must be kept out of the stream. The meaning of that decree is surely that the water supply is to be preserved in condition for use, and the only safe way to do that is to eliminate the mine water.

Of the total rainfall, it is estimated that only 25% penetrates into the ground, and only a small proportion of these percolating waters reach great depth. The sandstones and shales overlying the coal seams become great reservoirs, storing vast quantities of water. Immediately under the coal seam is usually found a stratum of impervious fire-clay through which these percolating waters do not penetrate. It is at these levels that surface springs are found, and through which the ground-waters find their way back into the streams. In the coal regions, the surface springs are an important guide in prospecting for coal. Prior to coal mining, these percolating waters, although penetrating the coal seams and carrying varying amounts of dissolved solids, do not become acid.

It requires the combined action of air and water to dissolve the iron pyrites, found in the coal seams, to form sulfuric acid. This acid combines with other elements in the water, usually calcium, magnesium, and iron, and forms sulfates, so that waters not showing free acid, but containing magnesium and calcium sulfates, are often highly corrosive and are hard and unfit for either domestic or industrial use. There is quite general agreement that when a water supply contains 4 grains of sulfates per U. S. gallon, it requires softening. When the pollution exceeds 12 grains, treatment is no longer effective because the large quantity of soda ash required so heavily charges the waters with solids as to cause foaming in boilers and renders it undesirable for domestic use. It will be seen, therefore, that if the waters require treatment with the small percentage of coal mined, with continued mining it will be only a comparatively short time until treatment by any known method is no longer effective.

On exposure to air the iron constituents become less soluble and are precipitated, causing the yellow deposit in the beds of the streams so familiar to every one in the mining regions. After the rocks are coated with this iron deposit, the acid in the stream has no further access to whatever neutralizing elements the rocks may contain, and the only further change in the acid content of the stream waters is from the natural alkalinity of fresh-water tributaries, the process of dilution.

In the course of mining, as the coal is removed, the inferior coal, carbonaceous shale, iron pyrites, and other refuse material, as far as possible, is stored in the mine. As mining proceeds, water is developed from the coal and the

overlying strata and flows promiscuously through the mines, coming in contact with this refuse material containing the acid-forming elements, and reaches the surface as acid mine drainage. In upward of 300 mines examined, only 4 or 5 have been found in which the drainage was not acid. In one mine it was due to dilution from surface waters encountered in shaft-sinking, and, in others, to the percolating waters coming in contact with limestone. Large quantities of this refuse material are also hauled from the mines and stored in great piles around the mine openings, and there is less chance of control of the acid from these dumps than that from the mines. Any contemplated plans for disposal or the treatment of mine drainage seem to have overlooked this prolific source of pollution.

Quantity of Mine Drainage

To determine the quantity of mine water to be expected from the mining of coal, 250 to 300 mines have been examined. It was realized that probably no two mines in any region are operating under exactly similar conditions, but average conditions could be expected in entire fields of about the same size operating the same measures. It was realized that the daily or annual production of coal has slight, if any, relation to the quantity of water to be expected, although that method has been so often referred to in the anthracite region, and in recent Government reports. The area of coal exhausted was considered to be the most reliable basis for an estimate, although it, too, has many factors affecting the results. Some of these factors are the thickness and nature of the overlying strata; the thickness of the seams and methods of mining, particularly regarding the drawing of pillars—whether pillars are drawn near the crop or in extremely shallow cover; the protection given to streams; and the pitch of the measures.

An acre of coal exhausted in the bottom of a coal basin might affect a large surface-drainage area. This accounts for unusually high yields per acre in some small mines. In fairly deep mining, say, 250 ft. or more, the maximum yield of mine drainage should not be expected to exceed 25% of the rainfall, the estimated penetration. However, with the drawing of pillars, serious surface breaks occur where the coal has as much as 600 ft. of cover. In such cases undoubtedly a much larger percentage of the rainfall reaches the mines, reducing proportionally the surface run-off. This increased quantity of mine drainage during wet-weather periods does not reduce the acid content of mine waters, but the waters reaching higher levels in the mine come in contact with new sources of pollution and usually contain more acid.

Effect of Mine Development on Yield of Drainage Area

In the mines examined, the area of coal exhausted and the mine-drainage flows were measured, showing in one extreme a yield of 10 000 gal. of mine water per acre per day, although the average of all mines was about 1 100 gal. per acre per day. Average mining conditions show yields of 2 000 to 2 500 gal. per acre per day where less than 100 acres are exhausted. With increased mining the rate per acre naturally declines, until an average of about 1 000 gal. per acre per day is reached.

Under average conditions the flow of mine drainage is relatively constant, and does not vary directly with rainfall. In a coal field in Central Pennsylvania where 4 300 acres of coal were exhausted, and where the cover on the coal averaged 250 to 300 ft., records of rainfall and mine drainage were kept over a period of a year. The average rainfall was 3 300 gal. per acre per day, whereas the average mine drainage was about 900 gal. per acre per day, or 27% of precipitation. The surface drainage area was much larger than the worked-out coal area, but the coal area was compact, and these figures fairly represent the percentage of percolation. The difference between the average and the minimum mine flows was only 17 per cent. Another coal operation in Pennsylvania (average cover on coal about 300 ft.; area exhausted, 2 200 acres; over 60% of which pillars have been drawn) the average rainfall was 3 000 gal. per acre per day and the mine drainage was 1 300 gal. per acre per day, showing a percolation of 43 per cent. This field is on the east side of a coal basin where additional territory than that actually mined is drained. The difference between the average and minimum monthly flow was about 14 per cent.

A drainage area of 36 sq. miles practically all underlaid with coal, of which one-half is mined, on a certain day in October, 1920, yielded 23 600 000 gal. of water, of which 10 800 000 gal., or 46%, was mine drainage. The yield of the drainage area was 1 025 gal., and of the mines, 937 gal. per acre per day. A drainage area of 62 sq. miles, 52 sq. miles containing coal, of which 12 sq. miles are exhausted, yields 41 200 000 gal., of which 7 600 000 gal. are mine drainage. This shows a yield of 1 039 gal. per acre in the total drainage area, whereas in that part of the territory developed by mining, the mine drainage yield was 989 gal. per acre exhausted per day.

If the exhaustion of less than 10% of the total coal reserves has already produced mine drainage sufficient to destroy such a large part of the water supply resources, it is apparent that continued coal mining will soon destroy the few remaining fresh-water supplies. During the summer of 1926, in the Pittsburgh District, the railroad companies were compelled to haul water for their own use and for the use of coal operations on their lines.

Quality of Mine Water

The quality of mine drainage is quite as important as the quantity. Table 2 gives typical analyses of mine waters, in grains per U. S. gallon, by Mr. E. C. Trax.

Some Pittsburgh seam mines in the Greensburg District of Pennsylvania show total apparent acidity, in grains per gallon, as follows:

Mine.	Grains per gallon.
Keystone Shaft	98.42
Sewickley	61.74
Greensburg Nos. 2 and 3	121.68
Seaboard Shaft	137.68
Claridge	169.40
Salem	91.20
Crow's Nest	123.96

Neutralization

In treating acid mine water the custom is to neutralize it with lime, converting it into hard water, and then to add soda ash to soften it. Most waters that have been treated with any degree of success have contained a very low percentage of sulfates, as compared with mine drainage. The writer does not know of any successful attempt to treat mine drainage of the quality encountered in the Pennsylvania coal fields. After the decree of the Court in the Indian Creek case was made effective, three of the mining companies built plants to neutralize the mine water by the introduction of hydrated lime, as a compliance with the decree, but this attempted method is very expensive and is not satisfactory.

In Table 4 is given the analyses of mine water before and after treatment with hydrated lime at the plant of the Melcroft Coal Company, made for that Company by Mr. J. O. Handy, Chemist.

TABLE 4.—Analyses of Mine Water Before and After Treatment with Hydrated Lime.

(Acidity and Alkalinity Expressed in Parts per Million as $CaCO_3$.)

	Raw.	Treated.
Total acidity	940	.....
Alkalinity	.....	5
Sulfate (SO_4)	1 600	1 500
Iron (Fe)	250	2
Aluminum	5	1
Calcium	200	630
Magnesium	78	43
Silica	40	8

From Table 4 it will be apparent that there is little change in the total sulfates before and after treatment, and that the water is still unfit for use. Besides, the Melcroft water is not what would be considered a bad mine water, or nearly as high in acidity as the average mine drainage of Western Pennsylvania. The companies are now building a tunnel to carry the mine drainage to a point below the dam before discharging it into the stream. This may be a compliance with the Court's decree in the Indian Creek case, but it does not solve the problem—the disposal of mine drainage.

The cost of neutralizing mine water has been variously estimated by different chemists at 15 to 25 cents per 1 000 gal. This depends on the cost of lime, the cost of gathering the water to one central plant, the capacity of the plant, the labor, and the handling of the sludge which alone is an exceedingly difficult and expensive, if not impossible, proposition. The cost of constructing a plant for lime treatment would be about $100 per 1 000 gal. daily capacity, thus making a 1 000 000-gal. plant cost $100 000.

Quantity of Drainage and Cost

A recent estimate of the acreage worked out in the bituminous mines of Pennsylvania, based on the total tonnage exhausted, would indicate a total production of mine drainage of 750 000 000 gal. daily. The cost of lime treatment plants for this enormous quantity of water would be $75 000 000. The annual cost of treatment, at 15 cents per 1 000 gal., would be $41 062 500, and at 25 cents per 1 000 gal., $68 437 500. It is estimated that the mine drainage reaching the streams from anthracite mines is 700 000 000 gal., daily, so that these estimates for the entire State of Pennsylvania would be about doubled.

It must be understood that the cost mentioned is for neutralization only, and that even after this treatment, which is the one most often referred to, the water is still unfit for either domestic or industrial use. To soften the water would cost more than double the estimate for neutralization, and even with that the value of the product, or the final result, would be doubtful. It will be seen that, with an average annual production of 160 000 000 tons in the bituminous fields of Pennsylvania, the cost will be from 26 to 43 cents per ton for neutralization, and from 50 to 90 cents per ton for softening.

Difficulty of Handling Sludge

In the bituminous fields of Pennsylvania alone there would be more than 4 000 tons daily, or 1 460 000 tons yearly, of sludge to handle. Even if dried and piled outside, it would be likely to reach the stream beds with every rain storm, and would eventually fill them. This iron oxide may be used for purifying gas and in the manufacture of paint, but it has a very limited market, and with such quantities as would then be available it would be without value. To mining men it would be nothing but slimy yellow mud, too thick to pump and too thin to shovel. In the writer's opinion, the disposal of this sludge presents almost as expensive and difficult a problem as mine drainage itself.

There have been other methods of treatment suggested, but none has proved to be satisfactory, from one cause or another. By the use of barium salts it has been found that calcium sulfates can be removed from water, but the cost is prohibitive, and as barium is poisonous the Department of Health would not permit its use. The electrolytic process has been suggested as a possible solution for the removal of sulfuric acid and its compounds from water, but the cost would be excessive, and the handling of sludge would still present its difficulties.

Satisfactory Treatment Yet to Be Found

As far as known, there is no satisfactory method of treatment of acid mine water in quantities such as are now being produced by the mines of the United States. Acid wastes are being treated in small quantities by lime, and as a result extravagant claims are being made as to what could be done with coal mine drainage. It is apparent that these claimants do not realize either the bad quality or the enormous quantities of mine drainage that would have to be handled. Increasing the alkalinity of the stream by the introduction of lime in the mine water would greatly increase the assimilating power of the stream, but in most cases there is so much mine water that dilution would not be effective, even after the high cost of lime treatment. With these tremendous costs in Pennsylvania alone, the cost of treatment for the coal industry throughout the Nation would be staggering, and never could be justified.

In addition to the acid drainage from coal refuse dumps, there are millions of gallons flowing daily from old abandoned mines, most of which would have to be handled in some satisfactory manner before treatment of the remainder would render results worth while. In many places the sealing of abandoned mines would be helpful, by preventing the flow of mine water; perhaps shutting off the air would prevent the formation of sulfuric acid, and thus more nearly restore original conditions, but this likewise would be difficult and expensive, and the question arises as to who is now responsible?

Legislation has been introduced in Congress which, if passed, would make it unlawful within the limits prescribed by the Secretary of War to discharge any free acid into navigable waters or their tributaries. It places in the hands of the Chief of Engineers, U. S. Army, the power to require neutralization of acid water or wastes, and provides a fine for each offense, of $500 to $2 500, or imprisonment of not less than thirty days, or more than one year.

The State and individuals have spent thousands of dollars in attempts to solve this problem, but without success, so that the time has surely come for wise Governmental action—not the hasty passage of drastic laws as now proposed, that would so greatly embarrass the mining and manufacturing industries, but a sane public policy that will tend to preserve the water supplies at as little cost to the community as possible.

One thing seems certain, that is, that coal cannot be mined without destroying the water in the mining regions. Therefore, the only sure and practical method of conserving the water supply is to stop mining coal in the few little developed areas yet remaining. This cannot well be done as between individuals, and the Government or the State is justified in purchasing, if necessary, under some plan to be devised, coal lands necessary to the protection of the few remaining water supplies in Western Pennsylvania and elsewhere. That the State of Pennsylvania recognizes the importance of this problem is evidenced by its participation with the water companies in the Indian Creek case.

The leaders in the coal industry are beginning to realize the seriousness of this situation, and that the water supplies must be preserved. There would be no objection to spending a few cents per ton of output if, in doing so, the problem could be satisfactorily solved. Some coal operators of Western Pennsylvania are suggesting that a supply of water be obtained from Lake Erie when mine drainage pollution becomes excessive. Further drains on Lake Erie would not likely be permitted, even if such a plan were feasible. However, this scheme is no further afield, and would not cost as much as the proposal that all mine drainage be treated. Any solution must be economically sound, and the writer is certain that it would cost less in Pennsylvania and elsewhere to preserve the present unpolluted streams and to stop mining in some little developed areas, in order to protect the water supplies for the present and future.

The policy of the Pennsylvania Department of Health, to protect all unpolluted streams; to stop further pollution of all streams that can be restored; and to use those now destroyed for carrying sewage, industrial wastes, and mine drainage, is the first real step toward a solution of this problem. It is commendable, and undoubtedly will result in much good at the least possible cost to the community.

PULP AND PAPER MILL WASTES

By G. K. Spence,* Esq.

The first paper mill in America was established in 1690 at Germantown, near Philadelphia, Pa., by William Rittenhouse. Since then the manufacture of pulp and paper has expanded until at present (1926) it constitutes one of the major industries of the United States.

Paper in various forms has come into use for so many purposes that it is now an essential necessity of domestic and industrial life, and it was so considered during the World War.

There are 844 paper mills and 310 pulp mills in the United States, located in 34 of the 48 States. New York State leads with 244 pulp and paper mills; Wisconsin is next with 115; followed by Massachusetts with 112; Pennsylvania with 87; Maine with 75; Michigan with 71; Ohio with 58; New Jersey with 44; Connecticut with 43; New Hampshire with 41; Illinois and Indiana each with 31; and so on down to four States with one mill each.

More than 8 000 000 tons of pulp, paper, and paper-board are annually made in this country, which output is valued at more than $900 000 000. The prosperity of the United States is, therefore, directly affected by the stability of the industry.

Paper is made from different pulps in various proportions, selected according to the grade of paper desired. Of the paper manufactured in the United States 90% is made from wood pulp, the remainder being made from rag, straw, jute, hemp, and other fiber-producing materials.

Rag Pulp

The rags are first sorted by hand, cut and dusted by machinery, and then passed to the cooking boilers where they are cooked under pressure with either a solution of caustic soda or caustic lime. After cooking, the liquor containing the soluble substances is washed from the pulp, requiring about 65 000 gal. of wash water per ton of rags treated. The washed pulp is then bleached with a solution of calcium hypochlorite and again washed in order to remove the last trace of bleach preparatory to using the pulp for the manufacture of paper.

Wood Pulp

There are two classes of wood pulp, namely, mechanical wood pulp and chemical wood pulp.

Mechanical Wood Pulp.—This pulp contains all the intercellular substance, the wood being ground to a pulpy mass by being pressed against a revolving stone in contact with water. This is the cheapest grade of wood pulp made, and, as the intercellular matter has not been removed, it deteriorates very

* Chf. Chemist, Castanea Paper Co., Clarion Mills, Johnsonburg, Pa.

rapidly. It is for this reason that newspapers, which are made mostly from mechanical wood pulp, cannot be preserved for any length of time.

The pulp from the grinders is run into a vat, taken up by a wire-covered revolving cylinder, and transferred to an endless felt, which, in turn, transfers it to a wooden roll on which it accumulates until the desired thickness is reached. It is then cut off and folded into laps for shipment or use in the beaters.

Chemical Wood Pulp.—There are three processes used for the manufacture of chemical wood pulp, namely, sulfite, soda, and sulfate.

The wood is prepared in practically the same manner for treatment by any one of the processes. It comes to the preparing room in 4 or 5-ft. lengths and from 6 to 10 in. in diameter. If the bark has not been removed, the wood is passed through revolving cylindrical drum barkers. By tumbling around in these drums in contact with water, the sticks by rubbing against each other are stripped of the bark which is washed through slots in the side of the drum. Some drum barkers are of the batch type; others are continuous, that is, the wood is fed in at one end and the barked sticks removed at the other. Sticks too large for the chipper are split to the desired size.

From the preparing room the sticks are passed to the chipper, which is a revolving cast-iron disk with projecting steel knives set so that the size of the chip can be regulated. The wood is fed through a slanting trough and moves forward by its own weight until it comes in contact with the projecting knives on the revolving disk. The size of chips in soda pulp mills varies from $\frac{3}{8}$ to $\frac{3}{4}$ in, whereas those in sulfite and sulfate pulp mills are from $\frac{3}{4}$ in. to $1\frac{1}{4}$ in. In chipping the wood, fine pieces, or sawdust, is produced, which is screened from the chips of the desired size.

The Sulfite Process

This process has reference to the method of manufacturing pulp through the isolation of the intercellular matter by means of bi-sulfite liquor. This liquor is made by burning sulfur and absorbing the sulfurous acid gas either in milk of lime or in towers filled with limestone over which water is sprayed. The resultant cooking liquor is calcium bi-sulfite when high calcium lime is used, or bi-sulfite of calcium and magnesium when Dolomitic lime is used, an excess of sulfurous acid being produced in each case. The intercellular matter is removed by cooking the chips in this liquor, under pressure, in large vessels termed digesters. The cooking liquor forms soluble calcium salts of ligno-sulfonic acid, and the lignin and other intercellular matter is removed from the fiber by washing and bleaching.

The Soda Process

The soda process has reference to the method of manufacturing pulp through isolation of intercellular matter by means of a solution of caustic soda. The caustic soda solution is prepared by causticizing sodium carbonate with caustic lime. The intercellular matter is removed by cooking the chips in this liquor, under pressure, in digesters similar to the sulfite digester, except that they are not lined, the lining being necessary in sulfite digesters due to

the acid action. In the soda process the cooking liquor forms soluble salts of the organic acids present in the wood, such as sodium acetate, sodium formate, sodium resinate, etc., and thus the intercellular matter is removed from the fiber by washing and bleaching.

The Sulfate Process

This process is very similar to the soda process in action, the cooking liquor being made up of a mixture of caustic soda and sodium sulfide. The sodium sulfide is prepared by smelting sodium sulfate in contact with carbonaceous matter which reduces the sulfate to sulfide. The caustic soda is prepared by causticizing sodium carbonate with caustic lime as in the soda process. The cooking takes place under pressure in digesters similar to those used in the soda process. The chemical action, although practically the same as in the soda process, is not as severe, due to the fact that there is a smaller excess of caustic soda present, and, as the cooking takes place in a reducing atmosphere, there is less tendency to over-cook or form oxycellulose. When cooking for strength, as is necessary in Kraft stock, the sulfate process is used.

In soda and sulfate pulp mills there are elaborate systems for the recovery of the soda used in cooking the wood. In both processes the stock from the digesters is washed with as little water as possible. The liquor from the stock is concentrated by passing it through multiple-effect evaporators after which the concentrated liquor is passed to rotary incinerators.

In the soda process the liquor is burned in the incinerators to a black ash containing 80% sodium carbonate and 20% carbon, which ash is later leached free from soda. The carbonate liquor is passed from the leachers to the alkali room, where it is re-causticized with fresh lime to be re-used in cooking more wood, 90% of the original soda used being recovered.

In the sulfate process the liquor is not burned as completely in the rotary, being discharged as a sticky mass into the smelters where fresh sodium sulfate is added to make up for loss in recovery. The carbonaceous matter present reduces the sulfate to sulfide, the mass being discharged from the smelter in the molten state, the excess carbon having been completely consumed in the operation.

Straw, hemp, jute, etc., are cooked in somewhat the same manner as rag stock, either caustic soda or caustic lime being used. As considerably less chemicals are used in cooking, it has not been considered economical to recover them.

Reclaimed Paper Stock

More than 2 000 000 tons of old papers and magazines are reclaimed annually. They are cut, soaked in a solution of sodium carbonate in order to free the ink, defibered, washed, and bleached. This reclaimed paper stock is mixed with other pulps in making certain grades of paper.

Paper is made by mixing the different pulps, according to the quality desired, in vessels termed beaters. At this point, china clay, talc, or some other form of filler is added to load the sheet and improve its finish; sizing material

is added to make it more water- and ink-resistant; and the proper coloring matter is added either to tint the sheet or to dye it to the desired color.

After preparation in the beater the paper stock is passed through the Jordans or refining engines where the fibers are cut to the proper size for the desired formation, and thence to the paper machine.

The paper machine consists of a moving endless wire with a lateral shake, on which the suspended stock flows, and forms into a sheet, the excess water passing through the wire. The sheet is then carried through the press rolls by means of a felt and thence over the cylindrical steam-heated dryers, where the remainder of the moisture is removed. At the end of the paper machine, the sheet is passed through highly polished steel rolls termed calanders, where the desired finish is imparted, after which it is either cut into sheets, or slit and wound on reels into rolls, of the desired size.

Pulp and paper mill wastes could, if not properly handled, enter the stream from the following sources.

1.—Bark from the wood-preparing room. This varies from 12 to 24% of the weight of the wood, depending on the kind used.

2.—Sawdust from the chipper room where the wood is reduced to the proper size for cooking. This does not amount to more than 1% of the weight of the wood chipped.

3.—Dust from preparation of the rag stock, which represents about 3% of the weight of the rags treated.

4.—Washings from the cooked stock in rag, straw, jute, and hemp pulp mills, as well as soda and sulfite wood pulp mills. These washings contain the soluble salts of the intercellular substances removed from the fibers. As the yield from rag stock is about 85% of the weight of the prepared rags, that from hemp and jute, 60%, and that from straw, soda, sulfite, and sulfate pulp processes, 40%, the washings will contain, respectively, 15%, 40%, and 60% of the weight of the raw materials treated, in addition to the excess chemicals used, and entrained short fibers representing about 1% of the total fiber production.

5.—Wash water from the brown stock thickeners in mechanical wood, sulfite, soda, and sulfate pulp mills, the water containing finely divided unbleached fibers. The loss of fiber at this point is from 4 to 5% of the total production in mechanical wood pulp mills, and from 2 to 3% in chemical wood pulp mills.

6.—Wash water from the white stock thickeners of rag, soda, and sulfite pulp mills, which contains finely divided bleached fiber. The loss of fiber at this point is from 2 to 3 per cent.

7.—Occasional small quantities of entrained spent liquor from the evaporator in soda and sulfate pulp mills. From a stream-pollution standpoint this waste is negligible.

8.—Black carbon residue left after leaching sodium carbonate from the black ash in soda pulp mills. This amounts to about 15% of the weight of the total pulp production.

9.—Lime sludge (calcium carbonate) containing a small percentage of calcium and sodium hydrates from the alkali room of soda and sulfate pulp mills. The weight of this sludge amounts to about 50% of the total pulp production of the mill.

10.—Lime sludge containing a small percentage of calcium hypochlorite, discharged from the bleach-dissolving department of rag, sulfite, and soda pulp mills. This discharge is proportionately small and can be considered negligible.

11.—Wash water, containing finely divided fibers from the beaters, where the stock is washed and prepared for the paper machines. The loss of fiber at this point is about 1% of the total production.

12.—Excess white water from the paper machines which contains finely divided fibers, clay, and colored water from the pigments and dyes used to color the paper, about 45% of the clay used and 5% of the fiber produced passes away with this white water.

13.—Wash water from the reclaimed paper stock, containing finely divided fiber, clay, and carbon from the removed ink. The waste materials in this water amounts to about 25% of the weight of the old papers treated.

Effects Upon the Receiving Body of Water

Finely divided particles of bark and sawdust from the wood-preparing room and chipper, as well as black ash residue from the soda pulp mills and entrained fibers from the various steps in the manufacture of pulp and paper, will not have any deleterious effect on the sanitary conditions of the stream. However, they will have a tendency to increase the turbidity, and render the stream less pleasing to the sight. In addition, there is a possibility of these materials affecting aquatic life by entering the gills of fish and, through settling on the bed of the stream, affecting the spawning. On the other hand, fish have been known to thrive at the mouth of small streams copiously charged with such effluent.

Spent liquor from sulfite mills, on account of its dark color, will have a tendency to impart a brown coloration to the stream. In addition, the liquor is charged with sulfur dioxide which, being a de-oxidizing agent, will reduce the dissolved oxygen content of the stream.

Spent liquor from soda and sulfate pulp mills will slightly increase the alkalinity content of the stream, but has no deleterious effect, either from the standpoint of sanitation or aquatic life. It will, however, impart a brown coloration and frothy appearance to the stream, making it appear more harmful than it really is.

Lime sludge when discharged into the stream will increase the turbidity. Being composed of lime salts, the hardness of the water will be increased, decreasing its fitness for boiler purposes. It will not affect aquatic life, and will improve the sanitary condition of the water. This discharge has been known to improve greatly the waters in some localities where they are subjected to acid discharges from manufacturing plants.

Clay discharges will increase the turbidity of the stream, but otherwise are entirely inactive. After a rain storm many times the quantity of clay

that could possibly be discharged from paper mills is naturally washed into the streams by the surface water. This waste material, therefore, should not be considered from a stream-polluting standpoint.

The lime sludge from the bleach-dissolving department which contains a small percentage of calcium hypochlorite will increase the turbidity, but has no deleterious effect. However, the presence of free chlorine will improve the sanitary condition of the water.

Assimilating Power of Streams

Although, to the writer's knowledge, no concrete study has been made relative to the amount of pulp and paper mill effluent a stream of a given flow can inoffensively assimilate, it is known from observations that the streams are very effective in this capacity.

When reviewing the points at which waste materials might enter the stream from pulp and paper mills, the worst possible conditions were cited, that is, a mill operating entirely for production without any reference to economy of operation or removal of waste materials from the effluent, as was true before the days of industrial research chemistry.

The pulp and paper companies of the United States, through their research departments, have spent millions in developing uses for, and devising means of, disposal of waste materials from the mills. In addition, the Technical Association of the Pulp and Paper Industry has done considerable work toward eliminating stream pollution, and, at the same time, curtailing waste in the industry.

There are three phases to be considered in discussing waste in pulp and paper mill effluent: First, the improvement of the condition of the stream; second, the re-use of the materials removed; and, third, clarifying the waste waters to such a degree that they can be re-used in the mill and thus conserve the use of fresh water. This last phase is very important for mills dependent on small streams for water supply, which streams are very low during the summer.

Owing to the extensive investigations made by the pulp and paper manufacturers, many of the problems relative to waste in the industry have been solved, and the others are rapidly approaching a satisfactory solution.

Known Methods for Elimination of Waste and Improvement of Streams

Bark from the wood-preparing room is pressed to remove excess moisture and burned in Dutch ovens for its fuel value.

Sawdust from the chipper room is burned either in Dutch ovens or rotary incinerators for its fuel value.

Dust from the rag department has found a market with manufacturers of roofing paper and other similar products.

Improvements have been made in the methods of washing brown stock in soda pulp mills, so that at present the quantity of colored water entering the stream from this source has been reduced to the minimum. If the cycle washing system or continuous filters are used, no washings enter the stream, the drain line being locked.

Waste water from brown and white stock thickeners in rag, mechanical wood, sulfite, soda, and sulfate pulp mills is being passed to efficient save-alls where as much as 98% of the suspended fiber is being removed before passing the water to the stream, or re-using it in the system.

At present, lime sludge from soda and sulfate pulp mills is passed to filters, where the excess water is removed, and thence to rotary dryers, or incinerators, where the lime is either dried, prepared and marketed as agricultural lime and whiting, or re-burned and used again to causticize more soda.

Wash water from the beaters and excess white water from the paper machines is at present being passed to efficient save-alls where as much as 98% of the suspended fibers and 92% of the suspended clay is removed before passing the water to the stream or re-using it in the system.

Unsolved Problems—Waste Sulfite Liquor

Although more money has been spent and more research work conducted to find methods for the disposal of waste sulfite liquor than on any other pulp or paper mill waste, it is still considered one of the unsolved problems. Considerable progress has been made toward reaching a practical solution. Some companies have been able to dispose of some of the waste sulfite liquor for core binder, road binder, tan extract, linoleum cement, and a few other uses, which only consume a very limited quantity of the supply to be had, should all the sulfite pulp companies re-claim this liquor.

It has been contended that the liquor can be evaporated and burned in boiler plants for its fuel value, and this has been tried in several mills; but as the heat value of the organic solids is about 8 000 B.t.u. per lb., and it costs about $5.50 per ton to evaporate it to the point at which it can be burned, this outlet does not appear to be very promising. Some coal companies have found it profitable to briquette hard coal dust by means of waste sulfite liquor and are using the liquor from two mills. When all coal companies reach this same conclusion, they will be in a position to use all the waste liquor at present entering the streams from sulfite pulp mills. This appears to be the not far distant solution to this problem of waste sulfite liquor disposal.

Spent Liquor from Soda and Sulfate Pulp Mill Evaporators

There are times when a small quantity of spent liquor will pass the vacuum pump of the evaporators in soda and sulfate pulp mills. Evaporator manufacturers have improved their product to such an extent that the liquor entering the stream from this point has been reduced to the minimum; when it does occur it only imparts a frothy appearance to the surface of the stream without any deleterious effect.

Carbon Residue from Soda Pulp Mills

At present, some of the black ash residue from soda pulp mills is being prepared and marketed under the names of Filchar, Nuchar, "Superchar", and other trade names, some of it being activated and used as a decolorizing agent. A limited quantity is used as an adulterant for lamp black, and some has been used for the case-hardening of steel.

The outlet for these various purposes is limited, and the disposal of the greater bulk of this waste is still an unsolved problem. However, a furnace has recently been designed and experiments are being conducted for completely burning the carbon in reclaiming the sodium carbonate, thus utilizing its fuel value in the steam boiler plant. If successful, this will be the future method for the recovery of sodium carbonate in soda pulp mills, and will eliminate waste carbon from the mill effluent.

Lime Sludge from Bleach-Dissolving Plants

There has been no satisfactory means for the disposal of lime sludge from bleach-dissolving plants; but as most mills have resorted to the use of liquid chlorine, this discharge is very small, and as it contains a small quantity of calcium hypochlorite, it will act as a germicide.

Pigments and Dyes in Paper Machine Waste Water

There is no known practical method by which the color can be removed from waste water from paper machines when dyes or pigments have been used to produce a high colored sheet. The quantity of such water, however, is small and has no deleterious effect on the stream.

Wash Water from Reclaimed Paper Stock

Numerous experiments have been conducted and considerable money has been expended in endeavoring to dispose of the waste materials washed from de-inked paper stock. It is very difficult to handle this waste material with any form of filter, and as it has so little value, due to the ink carbon content, when reclaimed, the problem of economically handling it is as yet unsolved; but paper manufacturers are optimistic regarding a satisfactory solution in the near future.

Pulp and paper manufacturers are doing everything consistent with operating conditions to improve the waters of the streams. Committees have been formed in some of the States, consisting of State engineers and technical representatives of the various pulp and paper companies, so that they can cooperate in reaching an early solution of the problems. In addition, the President of the American Paper and Pulp Makers' Association has appointed a National committee to deal with these problems.

STUDIES ON TANNERY WASTE DISPOSAL

By Wilhelm Howalt,* M. Am. Soc. C. E., and Edwin S. Cavett,† Esq.

Synopsis

This paper presents the results obtained in a two-year investigation of the disposal of tannery wastes, conducted by the Tannery Waste Disposal Committee of Pennsylvania, which is presided over by the Chief Engineer of the Department of Health of Pennsylvania, and is composed of representative engineers and chemists from the tanning interests of that State. The writers served as Resident Engineer and Assistant Resident Engineer, respectively, of the Committee.

The wastes used throughout the investigation were produced by a medium-sized sole leather tannery at which the vegetable tanning process was used. The study is presented in this paper in four main parts, as follows:

Part I.—Laboratory study of the individual wastes, including chemical analysis of each.

Part II.—Laboratory study of the wastes to find methods of treating by mixing in various combinations, by chemical treatment, etc., to produce reduction of color, of suspended solids, of oxygen demand, etc. From the results obtained a number of treatments were developed and selected for full-scale experimentation.

Part III.—Experimental plant: The experimental plant located at Instanter, Pa., was equipped to operate at full scale. The selected treatments were experimented with in this plant, studies being made by analysis of the various effluents and sludges. All operating data, such as volumes of wastes, effluents and sludges produced, chemical consumption, etc., were collected.

Part IV.—The manner in which the various full-scale treatments affected the receiving body of water was determined by analyzing the river water at certain places for a distance of 12 miles below the tannery. The results are presented in tabular form.

Conclusions are drawn concerning the facts presented and their relation to the general problem of tannery waste disposal.

Introduction

The pollution of streams by industrial wastes has been recognized for many years as an impending problem to the use of water supplies for domestic and municipal purposes. Many industries produce putrescible and deleterious wastes. Some of the more important producers of such wastes are: Coal mines, oil refineries, gas-works, water-gas and coal-gas, chemical works, coke ovens, creameries, tanneries, distilleries and breweries, canneries, municipal sewage, pulp and paper mills, and tin-plate, tubing, and galvanizing works. Many of these industries lately have appreciated the fact that the treatment of industrial wastes, regardless of whether marketable or useful products can

* Asst. Chf. Engr., Elk Tanning Co., Ridgway, Pa.
† Chemical Engr., A. C. Lawrence Leather Co., Peabody, Mass.

be recovered from them, is a just charge against their processes. This more reasonable attitude has resulted both from economic conditions and from increasing power given the State and municipal authorities regarding stream pollution.

The importance of stream pollution is emphasized by the fact that almost every State has such a problem and that legislative and constructive measures for its prevention have been steadily increasing.* Practically every State and many municipalities have some law dealing with the pollution of the waters within their jurisdictions.†

In Pennsylvania this subject comes within the jurisdiction of the Health Department and the Sanitary Water Board. In general, this State forbids the discharge into streams of wastes deleterious or detrimental to public health.† Discharge of sewage is forbidden except under permit. Discharge of wastes detrimental to fish is prohibited unless all practicable means are used to prevent pollution. The tanneries are included in these rulings, compliance with which means either the withholding of the wastes or effecting some treatment thereof. Obviously, treatment is the only way open to the tanneries because it would be practically impossible for them to withhold the wastes entirely.

The importance is further emphasized by the magnitude of the tanning industry. The value of all leather tanned in the United States is, roughly, $500 000 000 per year. Probably 50 000 men are employed in the tanneries as wage earners. The hides and skins from the following animals are tanned annually into leather in this country:

Cattle	25 000 000
Calves	15 000 000
Goats	40 000 000
Sheep	33 000 000
Other animals	7 000 000

The Census of Manufacturers of 1921 ranks leather and its finished products—boots, shoes, etc.—as fifth in importance, and the relative position of States producing leather, according to the value of the product, is as follows:

(1) Pennsylvania.
(2) Massachusetts.
(3) New York.
(4) Wisconsin.
(5) New Jersey.
(6) Illinois.
(7) Michigan.
(8) Delaware.
(9) Ohio.
(10) Virginia.
(11) North Carolina.
(12) West Virginia.
(13) California.
(14) Tennessee.

Just what position, on the list of industrial wastes, tannery waste would occupy is a matter of conjecture, although the general public usually considers it the source of obnoxious odors and unsightly, colored, and poisonous liquids, and, being governed thereby, would probably rate it among the worst.

* U. S. Public Health Report, January 15, 1926.
† 69th Cong., H. R., Doc. No. 417.

The problem of tannery waste disposal has never been adequately solved to the satisfaction of interested parties, although the literature contains many references to tannery waste disposal.* Most of them, however, are descriptions of specific treatments and disposal plants and do not contain many data.† No account has been found of an investigation which would presume to set forth any general principles governing the treatment of these wastes.

Realizing the importance of studying the problem from the viewpoint of the industry as a whole, rather than from that of the individual tannery, a committee was formed of engineers and chemists representing the tanning interests of Pennsylvania and having for its Chairman the Chief Engineer of the Department of Health of that State. This Committee, known as the Tannery Waste Disposal Committee of Pennsylvania, has functioned uninterruptedly since 1924. The work was financed by the tanning interests of the State and by the State of Pennsylvania, the money to be expended for laboratory studies, construction, and operation of a full-scale treatment plant, and for river studies. It is the final intention of this Committee to publish a report covering various progressive steps of treatment in order that there may be available an answer for every tannery working under its particular conditions both as to size, process, surroundings, and size and nature of the receiving body of water. It is the object of this paper to describe the results to date.

The investigation was conducted in the following sequence:

1.—A study was made of the characteristics of the individual wastes.
2.—Experiments were performed to find methods of treatment for the wastes.
3.—Full-scale operations were carried out on selected methods of treatment.
4.—Effect of these treatments was determined on the receiving body of water.

The individual wastes were studied by means of chemical analysis. Information of this kind served several purposes. It provided a means of classifying the wastes as alkaline, or acid, as to color, and as to process, such as beam house, tan yard, and scrub house. It also provided a means of establishing an order of degree of putrescibility. In practically all cases, these classifications had a direct bearing on the planning and the undertaking of the laboratory investigations for methods of treatment. For these laboratory investigations the wastes were mixed in a carefully planned sequence of combinations and studied as to rates of settling, color reduction, solids reduction, etc. This particular end of the investigation has not been thoroughly and exhaustively completed as yet, but for the type of full-scale operation available and for the degree of treatment desired at this time, a sufficient number of methods have been developed.

Several selected treatments, which, from the laboratory viewpoint, seemed promising, were chosen by the Committee as worthy of trial on full scale. These treatments were carefully studied in all respects from the practical and

* Bibliography of Tannery Waste Treatment, by P. A. Esten, *Journal*, Am. Leather Chemists Assoc., October, 1911.

† *Public Health Bulletin No. 100*, November, 1919.

economical standpoint as well as from the degree of success and efficiency obtained. Finally, the effect of the effluents on the stream, after treatment and after they had been discharged to the stream, were studied by analyses of the receiving body of water, sampled at five carefully selected stations along the 12 miles of stream immediately below the point of discharge.

The laboratory investigation and the routine analyses of the river water, and treatment plant samples were made in the main laboratory of the Elk Tanning Company, Ridgway, Pa. The treatment plant was at the Instanter Tannery of the same Company, at Instanter, Pa., and the river water samples were taken over a course of 12 miles on the East Branch of the Clarion River, between the Towns of Instanter and Johnsonburg, Pa. There were several excellent reasons for selecting this tannery and this location:

First.—The Instanter Tannery is a typical example of a sole leather tannery working an average number of hides and producing an average volume of wastes. These facts were confirmed by a survey of all the tanneries practicable. A questionnaire was sent to all the tanneries in Pennsylvania. The authorities of Ohio and West Virginia, having signified their intention of co-operating with the Tannery Committee in Pennsylvania, were also supplied with questionnaires for distribution in their respective States. These questionnaires asked for specific information regarding the pounds of hides worked and the volumes of waste produced per day from the various operations of the tanning process. Fifty-one tanneries, in ten States, returned answers. Tanneries in other States sent replies by reason of the fact that several members of the Committee represented companies having tanneries in these States which were likewise supplied with the questionnaires. The 51 tanneries were distributed as follows: 24 in Pennsylvania; 10 in West Virginia; 8 in Ohio; 2 in New York; 2 in Wisconsin; 1 in Maryland; 1 in Michigan; 1 in Kentucky; 1 in Tennessee; and 1 in Virginia. Of the 51 reported, 45 manufacture sole and belting leather. There was great variation in the amount of waste produced, which, based on 100 lb. of hide, ranged from 230 to 1 790 gal. per day, due to scarcity or abundance of water supply. The Instanter Tannery, with 617 gal. per day per 100 lb. of hide, is a good average.

Second.—The tannery is situated just at the confluence of two small streams, neither of which receives any pollution from sewage or industrial waste. Likewise, below this point of confluence, and for 12 miles down stream, there is no incoming sewage or industrial waste, the tannery being the only user of the river within this distance.

Third.—It was allowable for the tannery to pollute the river at will within the 12-mile distance in order to experiment with the various degrees of treatment.

Fourth.—The convenience and almost necessity of having the laboratory so near the whole field of action made the location at Instanter unusually favorable to the investigation.

Thus, an ideal situation obtains for making a direct study of the receiving body of water to determine the effect of dilution, temperature, aeration, and the various other factors influencing the wastes in their course down the river.

Origin and Description of Individual Wastes

Instanter Tannery is a sole leather tannery, and uses the vegetable process, which is the most common of all in use at present for tanning heavy leather. The finishing processes for such leathers are somewhat different in various tanneries, but, as a rule, the wastes produced are few and are negligible as compared with the whole volume of the other wastes. At Instanter the bulk of the wastes studied were produced from three departments of the tannery, namely, the beam house, the tan yard, and the scrub house. The individual wastes produced from these three places and their volumes per day are, as follows:

Wastes from:	Gallons per day.	
Beam House:		
Soaks	9 600	
Limes	2 900	
Hot water	2 900	
Unhairing machine	3 100	
Wash wheel	25 800	
Fleshing machine	7 200	
Float box	4 700	
Green stock pools	43 600	
Brown hair wash	14 300	
White hair wash	1 200	
Total		115 300
Tan Yard:		
Spent tan liquor	7 800	
Total		7 800
Scrub House:		
Acid bleach	1 700	
Soda bleach	1 700	
Acid water	1 700	
Total		5 100
Floor Wash:		
Floor wash from all departments		1 800
Grand total		130 000

The wastes as produced from the three departments can be classified as continuous, or those discharging continuously during the day, and as intermittent, or those released at a certain time once each day.

The three principal departments of the average tannery of this kind are the beam house, the tan yard, and the finishing department, of which the scrub house is a part. The beam-house operations prepare the hide for tanning; the hides are tanned in the tan yard; and the leather is finished in the finishing department. The description of the tanning process at Instanter, therefore, naturally starts with the beam-house operations.

Beam House

Soaking.—Heavy, green, salted cow and steer hides are first placed in vats containing water which is discharged twice a week. They hang in these vats for one day, after which they are moved forward into another vat. The water is discharged once a week. The hides are moved in this manner every day during the 3 to 5 days comprising the soaking period. As the hides move forward from vat to vat, they become cleaner and softer, so that generally the last soak waters can be used longer than the first. This accounts for the fact that the first soak is renewed twice a week and the others only once a week. A stream of clean water runs into the vats day and night. Thus, the waste soak waters will contain the dirt, dung, blood, and considerable quantities of hair and sodium chloride as major impurities, and are usually a dark, dirty, olive green color. They will vary in strength from day to day, making it possible to discharge four different strengths. During the normal operations, three vats are discharged daily, amounting approximately to 9 600 gal. per day.

Liming.—The hides, having been thoroughly cleaned and softened in the soak vats, are reeled into vats containing a super-saturated solution of calcium hydroxide, to which a small percentage of sodium sulfide has been added. In the lime solution the hair is loosened by the dissolution of the outside layer of the hide—the epidermis—and the cementing substances in the hair follicles. The process requires usually from 4 to 6 days, depending on the kind of hides. The lime solutions are used from 1 to 3 weeks, being strengthened daily with fresh lime. When the lime solution has been in use so long that it will no longer give the proper action, it is discharged as a waste liquor. At Instanter, the supernatant lime liquor is discharged to the sewer, and the lime sludge, which accumulates in the bottom of the vats, is shoveled out and hauled away. It is not washed into the discharge sewers. The principal impurities of the lime liquors are dirt, hair, and dissolved organic matter of a putrescible nature. It has a typical milk-of-lime appearance with a slight bluish color and contains much lime in suspension. There are six different kinds, or strengths, of limes resulting from the fact that the hides dirty the first limes more than the later ones and for other reasons having no bearing on the problem at hand. This waste amounts to about 2 900 gal. per day.

Hot Water.—The last lime solution, called the hot-water solution, differs from those preceding it in that it is not strengthened after it is once made up and that it is maintained at a temperature of about 90° Fahr. This solution is never used longer than three days, when it is discharged and made up new. It has the general appearance of the lime wastes and is discharged in the same manner. It amounts to about 2 900 gal. per day.

Unhairing Machine, Brown Hair Wash, White Hair Wash.—When the hides are removed from the hot water, the hair has been loosened and can easily be removed. This operation is performed on the unhairing machine by a heavy, revolving, roller knife sweeping down over the hide and brushing the hair off. A small quantity of water trickles over the knife during the time it is in operation and washes the hair into a trough below, down which it floats into a vat where it is automatically removed. This hair is the brown hair,

which is then collected and washed in a stream of clean, running water, the overflow from which unites with that from the aforementioned vat to form the combined unhairing machine and brown hair wash wastes. The white hair, having been removed by hand previous to the unhairing operation, is washed separately, and furnishes the white hair waste. The unhairing machine, brown hair wash, and white hair wash produce daily wastes amounting to 3 100, 14 300, and 1 200 gal., respectively. The appearance of all three wastes is much the same, having a slight turbidity due to lime and containing some fine hair which has escaped the screens.

Wash Wheel.—The hides having been unhaired and fleshed still contain much lime. To remove this lime the hides are placed in large wheel drums and drummed while a stream of clean water is flushed on them. The pounding and tumbling in the wheel works the lime out and the water carries it away. The wash-wheel waste is quite large in volume, amounting to about 25 800 gal., and contains mainly lime and small pieces of flesh. It is slightly turbid and has the appearance of milky water.

Fleshing Machine.—After the hides have been unhaired and drummed, the flesh, more or less of which is always present on the back of the hide, is removed by a machine similar to that used for unhairing. The fleshings drop down behind the machine and are floated in water into a vat from which the water passes to the sewer. This wash water carries with it small pieces of flesh and a considerable amount of fine particles of fleshings and fat in suspension. This is highly putrescible waste, has a cream-colored appearance, and averages about 7 200 gal. per day.

Float Box.—The float box is nothing more than a long vat with a stream of clear water running in at one end and overflowing at the other. Its purpose is to keep the unhaired, fleshed, and washed hides in a water-soaked condition from the time they leave the fleshing machine until they are ready to be trimmed and hung in the clear-water pools. The float-box water contains very little lime and a small amount of suspended matter composed principally of small pieces of hide substance. It has the appearance of clear water with light-colored particles suspended in it, and amounts to about 4 700 gal. per day.

Green Stock Pools.—Into green stock, or clear-water, pools the now thoroughly washed and cleaned hides are placed to await the tanning process. Clean water is run into these vats continuously, and the waste water contains very few impurities and shows practically no discoloration or suspended matter. It has a slight turbidity and amounts to about 43 600 gal. per day, or one-third the total daily waste from the tannery.

This process concludes the beam-house operations, which furnish the bulk of the daily wastes from the tannery.

Tan Yard

Rockers.—The hides are taken from the green stock pools and placed in the oldest and weakest tanning liquor in the system. The tanning liquors are composed chiefly of infusions of chestnut wood, quebracho wood, and hemlock bark. This liquor, containing only about 0.5% of tannin, is known as the "tail rocker". The name, "rocker", is attributed to the fact that the

frames upon which the hides are suspended in the vats are rocked slowly up and down. After remaining in the tail rocker one day, the tail-rocker liquor is drained off, as waste or spent tan liquor, and is run to the sewer. This waste is highly colored and represents the worst single waste from the tannery as to color, solids, oxygen demand, etc. It amounts to about 7 800 gal. per day, has a reddish, chocolate brown color, and is slightly acid in character. The hides are then passed from the rockers to vats called "layers", containing heavy tanning liquor in which the tanning is completed. No liquor from the layers finds its way to the waste. The only waste produced in the tan yard is that from the tail rocker.

Finishing

Scrub House.—In this department the leather from the layers is bleached and impregnated with oils, concentrated tanning liquor, sugar, salts, etc., depending on the character of leather desired. Except for the bleach, none of the other operations furnishes waste. The bleach liquors are made up daily and discharged to the sewer at the end of the working day. The bleaching proper takes place in a solution of sodium carbonate, after which the leather is given a dip in a weak sulfuric-acid solution to neutralize the excess sodium carbonate, and, finally, a dip in water. The three wastes are designated soda bleach, acid bleach, and acid-water bleach, each furnishing 1 700 gal. per day.

Part I.—Chemical Analysis of Individual Wastes

The object of carefully analyzing the individual wastes was to bring out the differences existing between them so that they might be classified physically and chemically according to their several attributes. It was found that the volumes of the wastes varied somewhat from day to day, due mainly to the use of different quantities of water in the processes, but that the actual constituent parts of the wastes remained fairly constant. In some instances, therefore, more than one analysis was made of a given waste to note this effect. A study of these analyses threw considerable light on the subject of treating the wastes, and on the accurate planning of the preliminary laboratory work. These analyses are shown in Table 5.

The hide substance was calculated from the total nitrogen, assuming that the nitrogenous matter represented that of hide matter and that it equalled 17.8% thereof. Only three of the wastes were acid, namely, the spent tan liquor, the acid bleach, and the acid-water bleach. Combined, these three weak acid wastes amounted to only approximately 11 000 gal., which was 8.5% of the whole volume of waste and would have little influence toward neutralizing the combined volume of the other wastes, due to their high alkalinity. The remainder of the wastes, except the soda bleach, originated in the beam house and were alkaline, due to the lime used there; that is, all the wastes discharging from the beam house following the limes were contaminated, so to speak, with the lime carried over by the hides from the lime vats. Approximately 50% of the alkalinity of the soaks, however, was due to free ammonia, whereas the alkalinity of the soda bleach was due to sodium carbonate.

Referring to Table 5, the wastes listed as intermittent represent by far the worst. They are all vat wastes, or those which result when the solutions in

the vats, having been used over and over, no longer function properly and are discharged. In general, the characteristics of the intermittent wastes were that they contained the most total solids, suspended solids, and color, had the greatest oxygen demand, and were responsible for most of the variation in volume from day to day.

All the continuous wastes were alkaline; and as they originated from a washing operation were neither as putrid nor as concentrated as the intermittent wastes. This fact is interesting, because it means that at some tanneries on large streams these wastes can be disposed of without treatment. On the other hand, where it is necessary to treat all the wastes, these would serve well for dilution purposes. In this investigation, however, all the wastes were used in the experimentation, as obviously no such investigation would be complete unless all were included in the study.

*Intermittent wastes.

Referring to the determination of 5-day bio-chemical oxygen demand given in the last column of Table 5, an interesting arrangement of the wastes is obtained when using this determination for the standard. This arrangement is shown in Table 6.

Two sets of samples of the wastes, shown in Table 6, were collected on two different days. In the first column of each set is given the 5-day oxygen demand at 20° cent., in parts per million. The number in the column, "Order", refers to the order of intensity, No. 1 having the highest oxygen demand, No. 2 the next highest, etc. The figures in the column, "Quantity Units, in Pounds

of Oxygen", are obtained by reducing the parts per million results to a pound basis. These figures represent the pounds of oxygen required in five days by each waste for stabilization. If they are divided by 0.167 in each instance, the pounds are converted into people; that is, the average person produces enough waste material in a day of 24 hours to create a 5-day oxygen demand of 0.167 lb. at 20° cent.* These figures are given under the column, "People". The other column gives the "Percentage Quantity Units".

It is interesting to note that the spent tan liquor, although only representing 6% of the entire waste by volume, accounted for almost 50% of the total oxygen demand; also, that the combined wastes per day represented the sewage from a town of about 4 200 people; that is, for a tannery of 300 hides per day, 1 hide produces waste with an oxygen demand equivalent to that of the sewage of 14 people.

Another point of interest is the wash-wheel waste. It has a relatively low oxygen demand, eighth in order of intensity, but when converted to quantity units assumes a position second only to the spent tan liquor, representing about 14% of the total oxygen demand of the wastes. This is by reason of its relatively large volume of 14 300 gal., or 11% of the total daily wastes from the tannery.

The statement made previously that the intermittent wastes were by far the worst is very strikingly brought out by the figures of Table 6. In both sets of samples the intermittent wastes represent slightly more than 75% of the total oxygen demand, whereas their combined volume is less than 30% of the total daily waste from the tannery.

The principal points of importance learned from the preliminary investigation of the wastes are:

(1) The majority of the wastes were found to be alkaline; only the acid bleach, acid-water bleach, and the spent tan liquor proved to be acid.

(2) In many cases the continuous wastes probably could be disposed of without treatment, or could be used as a diluent in treating the other wastes.

(3) With the exception of the soda bleach, all the alkalinity found was due to lime.

(4) The spent tan liquor and the three bleach liquors contained most of the coloring matter of the wastes.

(5) The intermittent wastes constituted about 75% of the total oxygen demand of the wastes.

(6) The continuous wastes representing more than two-thirds of the total volume of all the wastes accounted for only 25% of the total oxygen demand.

(7) Based on quantity units, the spent tan liquor required about 45% of the total oxygen demand.

Part II.—Laboratory Studies

The object of the laboratory tests was to develop methods of treatment by making a thorough study of all the possible mixtures of the various wastes. In order to make such an investigation it is first necessary to learn the proper-

* "Treatment of Packing-House, Tannery, and Corn Products Wastes," *Industrial and Engineering Chemistry*, October, 1926.

ties of the individual wastes and then to study systematically their behavior when mixed each with the other, then each with two others, etc., until all possible combinations have been tried. The sterilizing, deodorizing, stabilizing, decolorizing, etc., of tannery waste is not a difficult problem as such, but to do all this by merely mixing the wastes in combinations which produce chemical reactions, precipitation, sedimentation, etc., at low cost, throws an entirely different light on the problem. To date more than one hundred such combinations have been investigated.

A limitation defining the proportion of each constituent in the mixtures made it necessary to consider in these laboratory investigations the importance of always mixing the wastes in the same proportions in which they are discharged. Not only a change in the proportion of one or more constituents in a mixture, but also in practice, the time of day of discharge of a given waste, or its variation in amount, strength, and character from day to day, might influence the success of a treatment.

In the preliminary study of the various mixtures, practically the only objectives were rapidity and adequateness of sedimentation, solids removed, and color removed. Whenever an outstanding mixture, with regard to these qualities was obtained, it was studied in greater detail. In other words, unless a mixture proved to be above the average, it was listed as a matter of record as negative information.

The equipment used in the laboratory for the study of sedimentation, color, and general physical characteristics were either 1 000 or 500-cu. cm., graduated glass cylinders. They were of uniform bore and colorless, and a practice was made from the start to use cylinders of the same size throughout a given experiment; that is, the contents in a 500-cu. cm. cylinder were never compared with the contents of a 1 000-cu. cm. cylinder.

Sampling

Throughout these experiments the wastes were always sampled in the same manner, and only fresh samples were used. The soaks, limes, and hot waters were sampled by plunging up the vats just prior to their discharge to the sewer. The unhairing-machine wastes were sampled by taking a quantity from the trough and removing the excess hair. The wash-wheel waste was sampled by placing a bucket beneath the wheel so as to catch a small quantity of the wash water during the whole time the wheel was running, care being taken to prevent the bucket from overflowing. The fleshing-machine waste was sampled in the same manner as the unhairing-machine waste, but large pieces of flesh were removed. The float-box waste was sampled by merely dipping out a pailful. The green stock pools were sampled in the same manner as the float box. The brown hair wash was sampled by placing a bucket near the overflow so as to catch a small portion of the waste over a period of several hours, care being taken not to overflow the bucket. The white hair wash sample was taken from the wash water contained in the white hair washing vat, first plunging up the water and withdrawing a quantity. The soda, acid, and acid-water bleaches were sampled by plunging up the vats just prior to their discharge, and a sample taken from each. The spent tan liquor was sampled by making a

composite sample of the six rocker vats discharged each day. It was not practicable to obtain a sample of the various floor washes which varied so much in quantity and character, and because of their relatively small volume they were neglected.

Treatment of Intermittent Wastes

It has already been stated that the intermittent wastes represent by far the worst group from the tannery. Considerable time, therefore, was spent in experimenting with these seven wastes in whole, in part, and with chemical treatment. The particular result looked for in these treatments was rapidity of settling the settleable solids, and the reduction of color, oxygen demand, and suspended solids.

Experiment No. 14 (Fig. 2) was performed several times in order to note the main reactions between the individual wastes. Unless there was a tendency to settle or a decided change in the two constituents, the mixture was termed "no reaction". Experiments Nos. 2 and 3 (Fig. 3), 4 and 5 (Fig. 4), 7 and 8 (Fig. 5), 11 (Fig. 6), and 12 (Fig. 7), are examples of many such experiments using several combinations of wastes, permitting them to settle, and then combining the resulting supernatants. The object of these experiments was to find ways and means, without chemical treatment, to effect good settlement and to produce light-colored and clear effluents. Experiment No. 1 (Fig. 8), shows the general characteristics of the whole mixture of intermittent wastes.

After a considerable number of experiments had been performed similar to those described, it became evident that to produce a really worth-while effluent and not to complicate a treatment with too many refinements, the number of separate treatments of any of the wastes or combinations thereof should be kept as low as possible. Treatment of a large number of small units materially introduces operating difficulties which are hard to overcome. Also, the cost attending the handling of any treatment consisting of a group of small units usually is prohibitive. From a practical standpoint a mixture of all the wastes in one batch would offer the simplest means for treatment in most cases, and even if additional agents, such as acids, alkalis, coagulants, etc., were required, the ease and simplicity of operation would probably be a deciding factor in its favor.

One of the most difficult problems was to produce a mixture which would settle readily. Several plans were developed which gave encouraging results, but the disadvantage was that several separate units had to be treated individually in order to produce the desired effect. As stated, it became apparent that a paramount requisite was simplicity; that mixing all these wastes together seemed the most promising method for further study. As such, however, as was shown by Experiment No. 1 (Fig. 8), and reproduced many times thereafter, the mixture of the intermittent wastes was alkaline, and there was little or no tendency toward sedimentation. A number of experiments having to do with the treatment of all the intermittent wastes mixed together, therefore, were carried out, using the chemical agents, lime, sulfuric acid, sulfur dioxide, aluminum sulfate, ferrous sulfate, etc. Three typical examples of this study are shown by Experiments Nos. 9 (Fig. 9), 26(*a*) (Fig. 10), and 42 (Fig. 11).

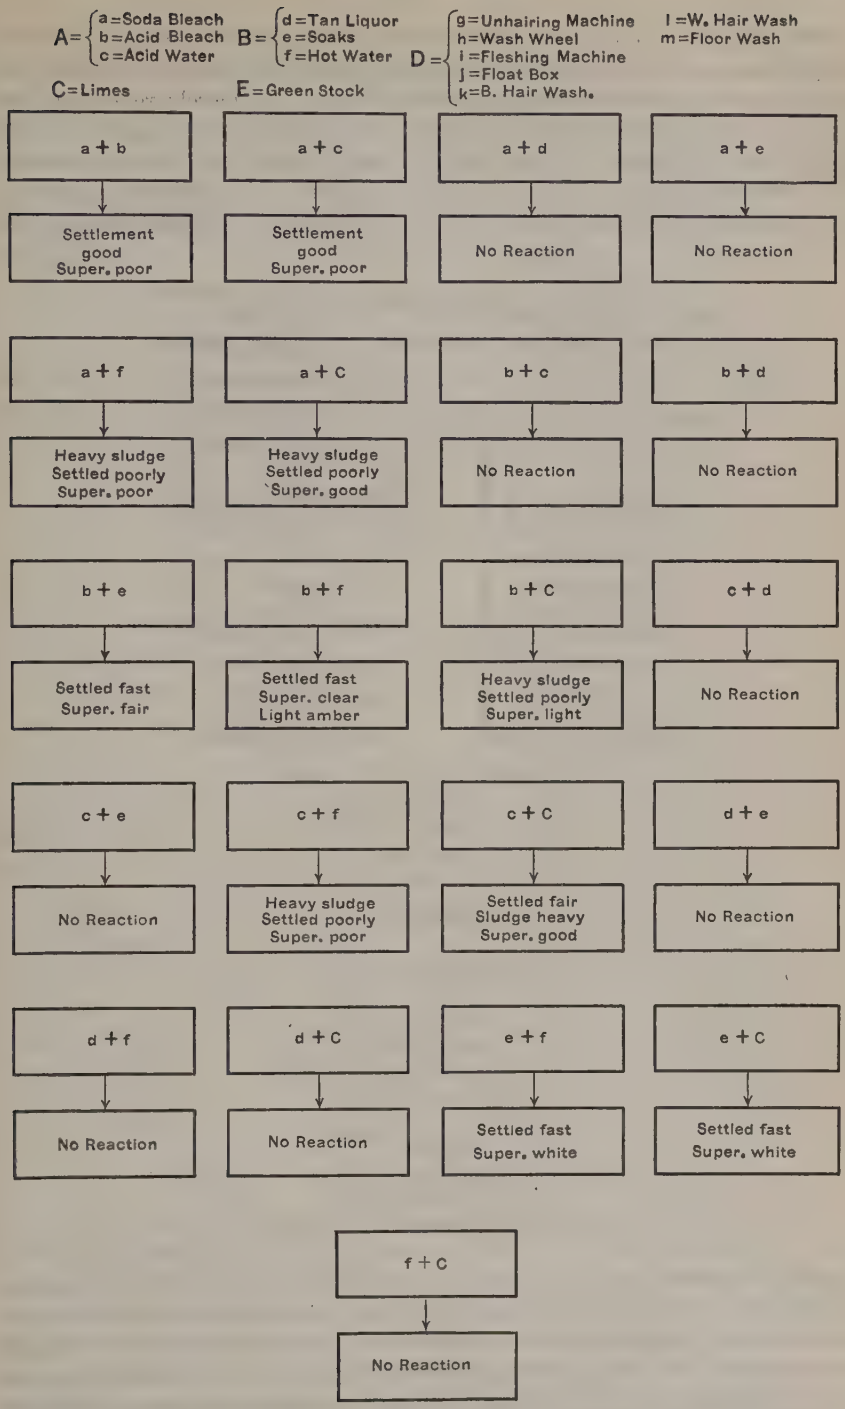

FIG. 2.—EXPERIMENT NO. 14 TO NOTE MAIN REACTIONS BETWEEN INDIVIDUAL WASTES.

The treatment of the intermittent wastes with sulfuric acid was selected as the most promising from all standpoints, because it represents probably the simplest and the most dependable thus far found. By merely regulating the pH of the mixture to between 5.0 and 6.0, the settleable solids readily settled out in about 3 hours to about 20% of the volume, and the supernatant liquor contained practically no suspended matter. This simple regulation, requiring little acid, had in its favor the advantage of producing with un-

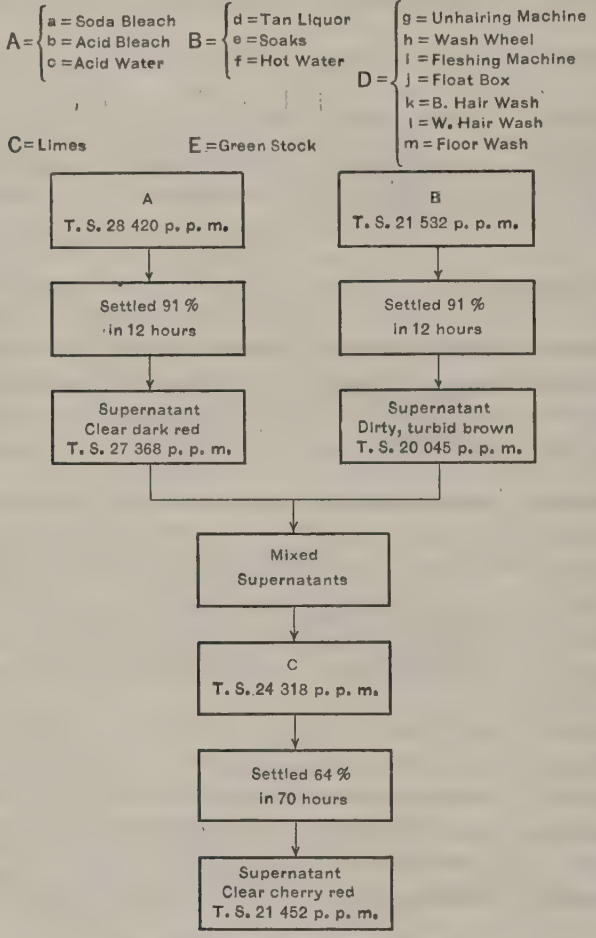

FIG. 3.—EXPERIMENTS NOS. 2 AND 3.

wavering regularity the same kind of effluent from day to day. Variations in amount, strength, and character had little influence on the mixture, for, regardless, the suspended matter never failed to settle readily when this pH was attained. The average data obtained from twenty-two separate mixtures of the intermittent wastes, treated with sulfuric acid, are given in Table 7.

TABLE 7.—Analysis of Intermittent Wastes Before and After Treatment with Sulfuric Acid.

* Average of three samples.

There are probably many cases where this kind of treatment of the most foul wastes would suffice. In such, it would be assumed that the continuous wastes were of such a nature, or the receiving body of such magnitude, that they could be disposed of without treatment.

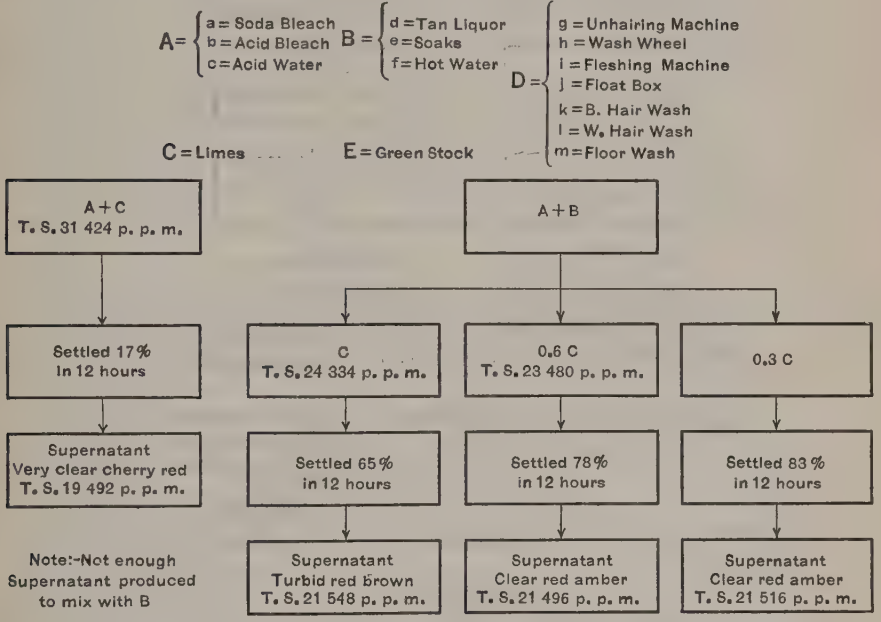

Fig. 4.—Experiments Nos. 4 and 5.

Fig. 5.—Experiments Nos. 7 and 8.

Treatment of Intermittent and Continuous Wastes

In this section of the paper the writers consider not only the intermittent wastes, but, in addition, the continuous wastes, except the green stock. Many experiments were carried out with these wastes in much the same manner as that followed in the preceding section. They were studied first, by mixing them in small units, permitting sedimentation, and eventually combining the supernatants until the final effluents represented all the wastes; then, less complicated methods were tried; and, finally, the number of separate mixtures

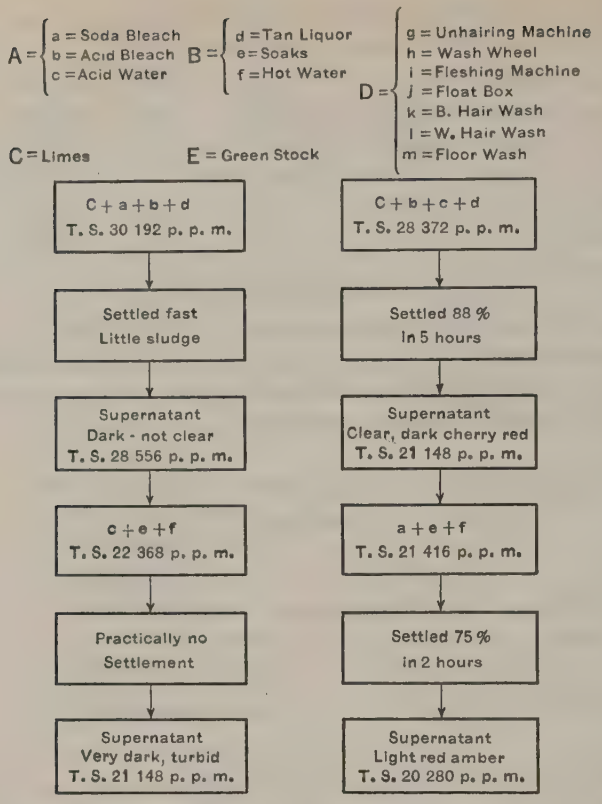

FIG. 6.—EXPERIMENT NO. 11. FIG. 7.—EXPERIMENT NO. 12.

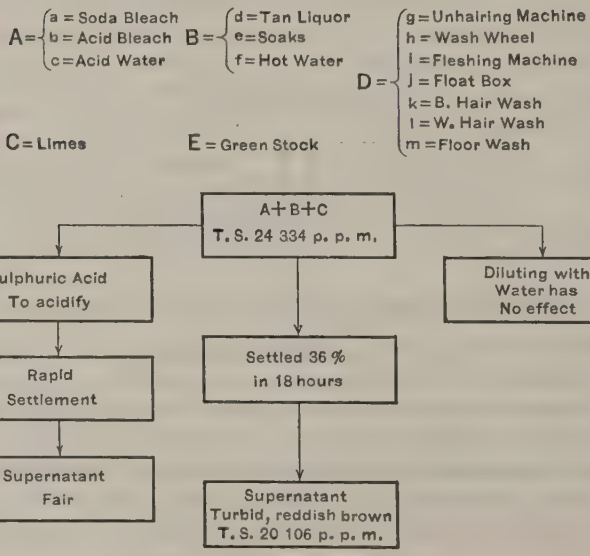

FIG. 8.—EXPERIMENT NO. 1.

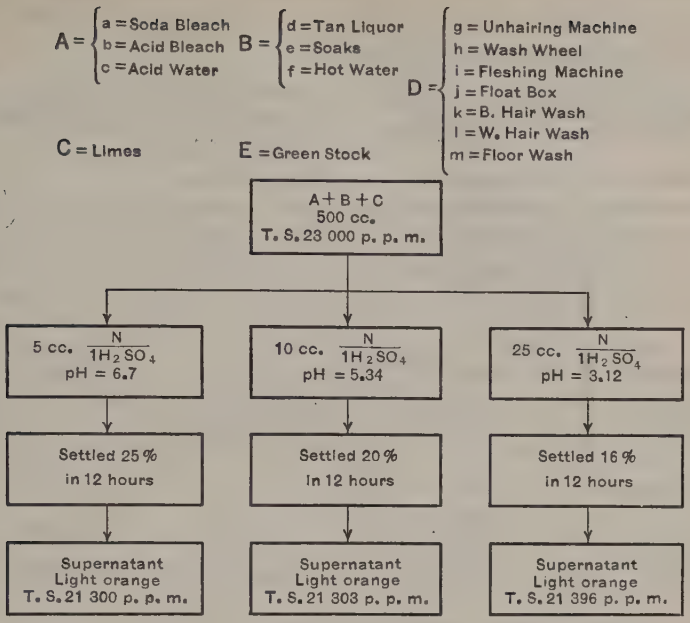

FIG. 9.—EXPERIMENT NO. 9.

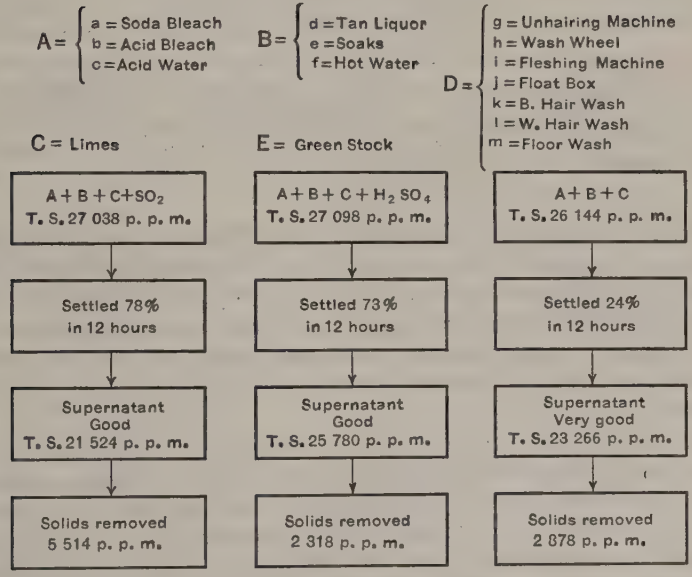

FIG. 10.—EXPERIMENT NO. 26(*a*).

was reduced to one. At first, it was attempted to produce results by natural inter-reaction of the wastes; later, studies were made with the addition of the various chemical agents already mentioned.

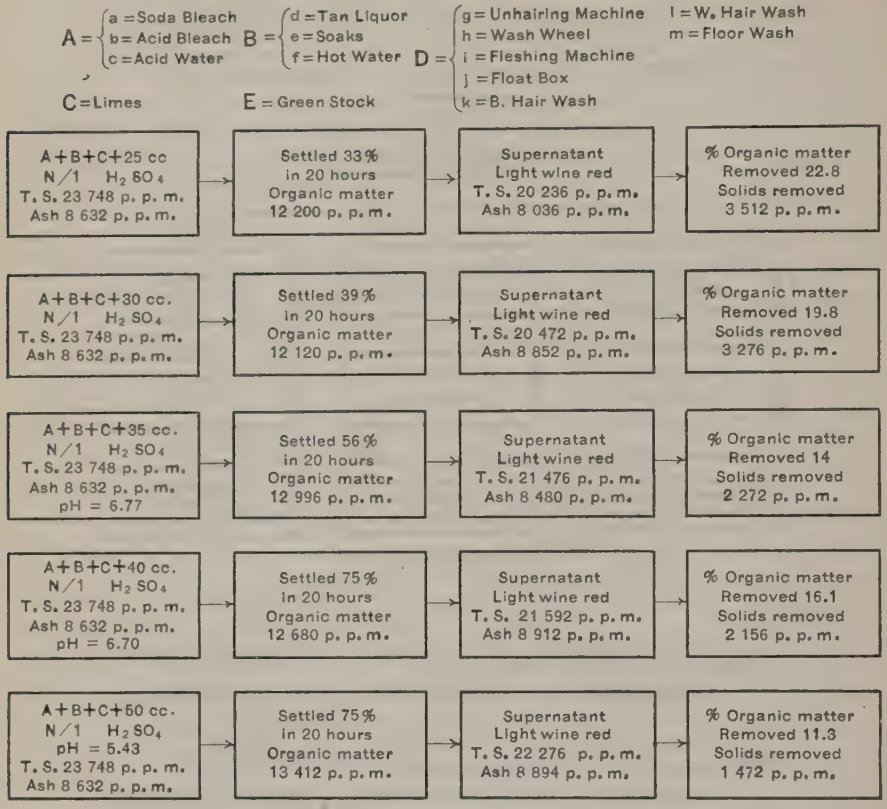

FIG. 11.—EXPERIMENT NO. 42.

Examples of experiments describing some of the most promising methods of treatment are shown by Experiments Nos. 31 (*a*) and (*b*) (Fig. 12), 32 (*a*) and (*b*) (Fig. 13), 33 and 34 (Fig. 14), 55 (Fig. 15), and 79 (Fig. 16). Several experiments were conducted, treating all the wastes as one single group. This mixture responds to the treatments with alum, lime, acid, etc., and produces a fair effluent. It does not, however, show as good results as some of the other treatments.

In addition to the kind and type of experiments just described, others have been performed dealing with certain special points which seemed supplementary. For instance, in certain tanneries the intermittent wastes might not form as alkaline a conglomerate as at Instanter. In such an event the omission of the soda bleach in the first treatment would lessen the alkalinity and, in some cases, to such an extent as not to require an acid treatment. Again, several experiments were based on the theory that a reaction of the tannin on lime would remove a large amount of solids in the form of an

insoluble calcium tannate. This proved to be the case, but was only practicable when the lime and spent tan were diluted at least once with fairly clean waste, such as the green stock. Treated in this manner the settlement was good and the effluent was fairly clear. A still better procedure included the soda bleach with the lime and tan liquor. When the supernatant from this mixture was added to the remaining wastes, together with alum and sulfuric acid, a very good effluent was produced.

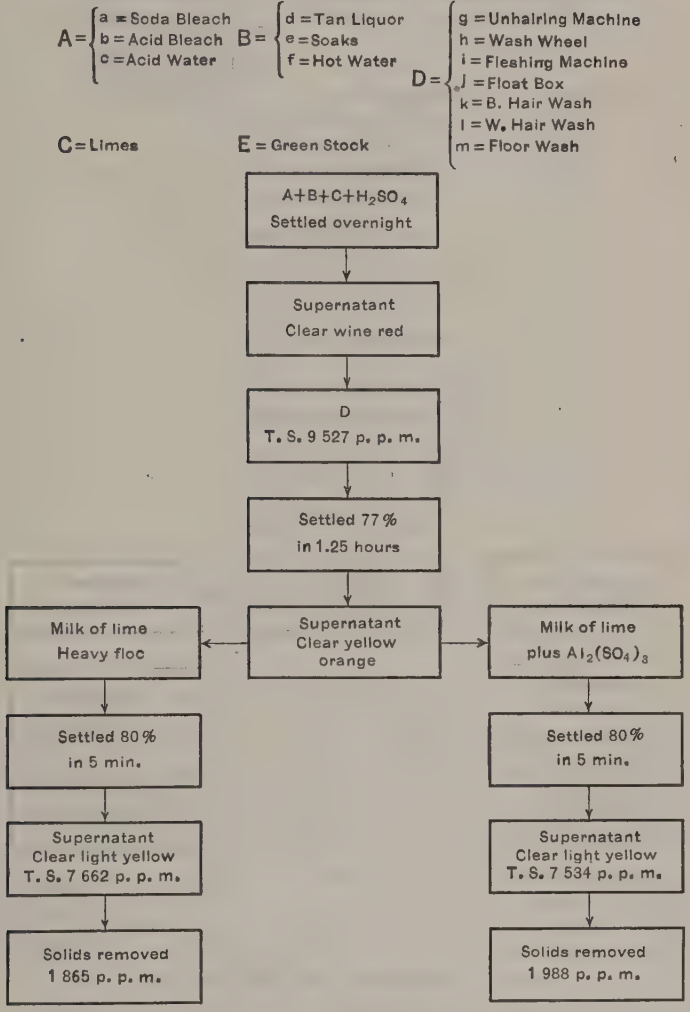

FIG. 12.—EXPERIMENTS NOS. 31(*a*) AND (*b*).

Several experiments involving the use of lime sludge as a precipitant did not show favorable results.

An experiment permitting the lime and tan liquor to re-act several hours before mixing with the other intermittent waste, did not show favorable

results; that is, there was nothing in the way of improvement to sanction the separate treatment of the tan liquor.

Separate treatment of the bleaches, separate settling of a mixture of the lime and spent tan liquor, and the resulting supernatants mixed with the other wastes, gave very good results.

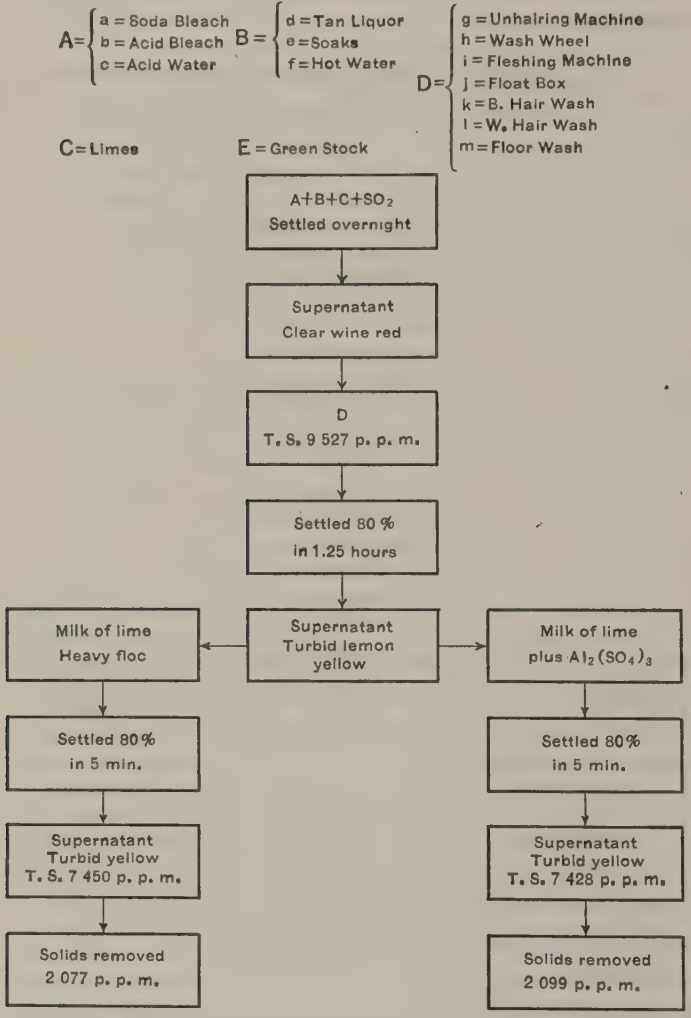

FIG. 13.—EXPERIMENTS NOS. 32(*a*) AND (*b*).

Experiment No. 55 (Fig. 15), which is typical of a number of such experiments performed, describes a very good and dependable method of treatment. In this type of treatment the intermittent wastes were mixed together, and the pH of the mixture regulated to about 5.5 by the addition of sulfuric acid. This mixture was then permitted to settle quietly over night as would have been done in actual operation. The next day the supernatant liquid was added to

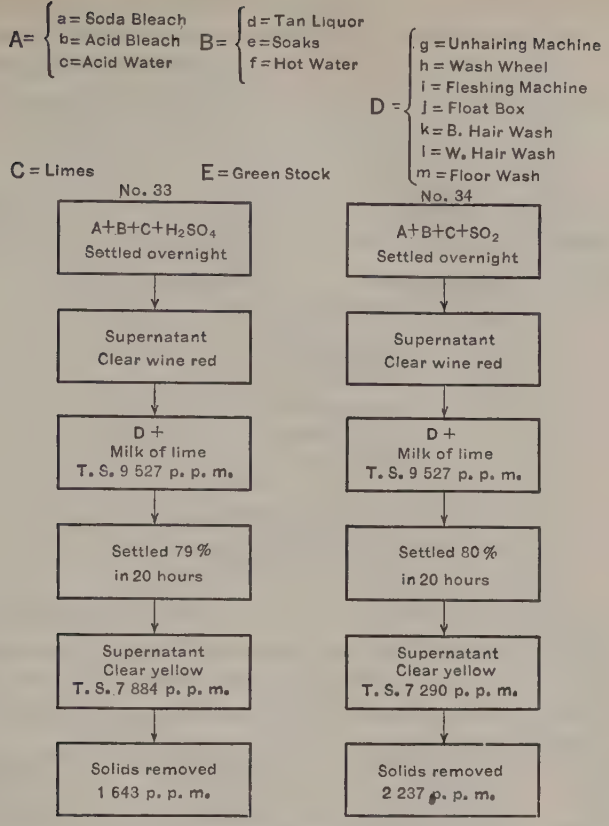

FIG. 14.—EXPERIMENTS NOS. 33 AND 34.

the continuous wastes, except the green stock, together with 20 grains per gal. of aluminum sulfate, and the whole mixed thoroughly. The mixture was then permitted to settle quietly. This particular treatment has been repeated in the laboratory with about twenty-five different samples of the wastes and has been found to give very uniform results. In Table 8 are shown the important determinations made on the final supernatant, which represents the effluent that would be discharged from the tannery after treatment.

TABLE 8.—AVERAGE ANALYSIS OF FINAL SUPERNATANTS, EXPERIMENT NO. 55 (FIG. 15).

	Total solids, in parts per million.	Suspended solids, in parts per million.	5-day oxygen demand, 20° cent., in parts per million.	Color.
Final supernatant.....	9 335	176	854	1 203
Percentage reduction..	31.1	93.6	57.1	60

Experiment No. 79 (Fig. 16) represents another very good method of treatment, which would probably be useful in tanneries producing larger quantities of spent tan liquor in proportion than that at Instanter. The final effluent of this treatment compares very favorably with that of Experiment No. 55 (Fig. 15).

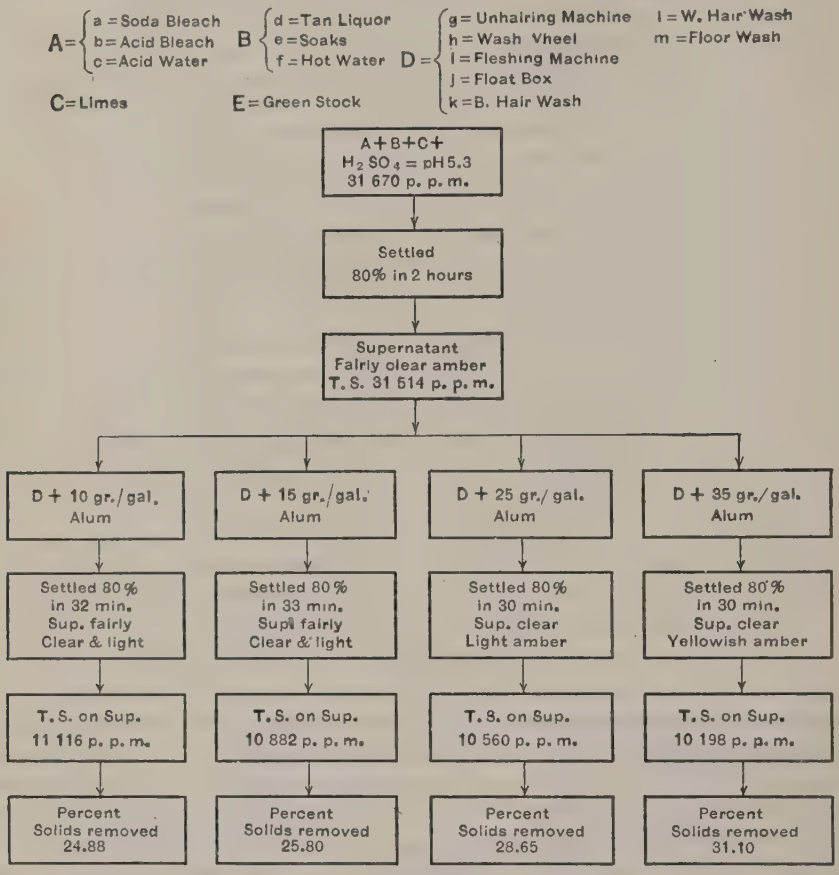

FIG. 15.—EXPERIMENT NO. 55.

It is important to note that in treating all the wastes there was strong evidence in favor of the "two-treatment" process. By two treatments is meant separate treatment of the foulest wastes, and then the effluent from this treatment mixed with and treated together with the remaining wastes. Many modifications of the treatments could be arranged, but the basic facts underlying them would be materially the same. The two-treatment process requires a little more equipment, but this is more than offset by the increased efficiency obtained. It is continuous, does not require skilled labor to operate it, and is reliable and inexpensive.

To summarize briefly the laboratory investigations on both the intermittent wastes alone, and then on the intermittent wastes plus the continuous wastes, the following points were noted:

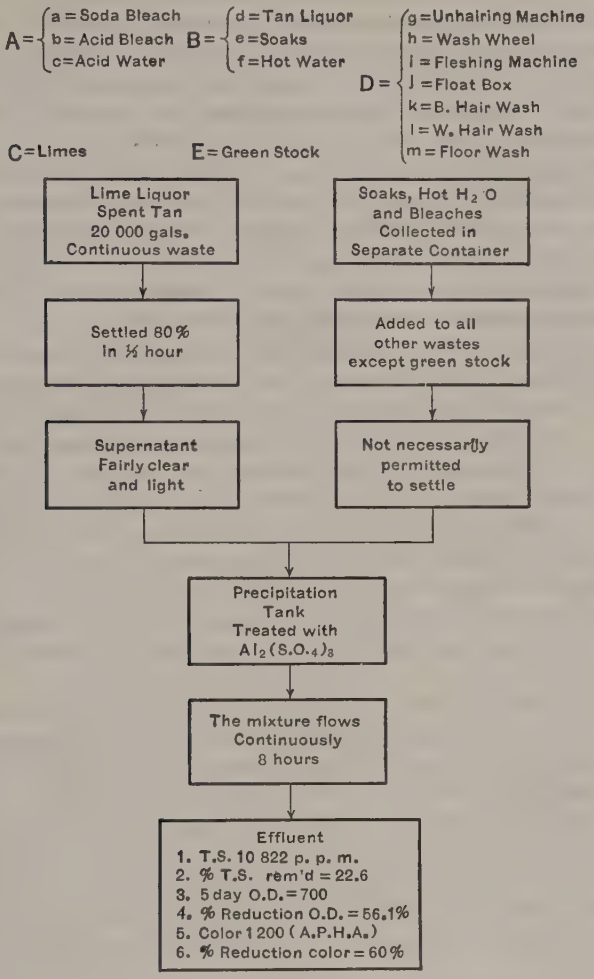

FIG. 16.—EXPERIMENT NO. 79.

(1) Several mixtures were obtained which gave good results and which did not require chemical treatment.

(2) Chemical treatment, or regulation of the pH of the mixture of intermittent wastes, produced the best improvement.

(3) In treating all the wastes from the tannery it appeared that two treatments were necessary to insure good and uniform results.

Selected Treatments

The most promising of the foregoing experiments were selected for full-scale experimentation and will be described in more detail later. Each of

the treatments selected represents, in the writers' opinions, the best method developed for that particular degree of treatment, based on the laboratory results. The object of the investigation was to solve eventually the problem in enough ways and by enough degrees of treatments to meet practically all the conditions for large and small tanneries located on large and small streams, having plenty or no surrounding land, and operating in expensive or inexpensive environments. The method of procedure in carrying out the investigation, therefore, was to study the waste treatments in degrees. For instance, for some tanneries on large streams, the direct discharge of their wastes without treatment might be possible. If not, a slight degree of treatment might suffice. This slight degree possibly could be merely the mixing of the combined wastes per day and discharging them, sludge and all, over a selected period of time. A still further degree of treatment would be to mix the combined wastes and allow the solids to settle, discharging only the supernatant liquid. Other refinements, such as chemical treatment, or separate treatment of certain individual wastes, would represent still further degrees of treatment. It should be borne in mind, however, that the methods of treatments referred to have to do only with a preliminary treatment to remove solids and color, etc. Such a preliminary treatment is necessary to prepare the effluent for further degrees of treatment such as aeration, spraying, filtering through sand, etc. These latter problems will be attacked in their order at the proper time, as naturally an investigation of this kind would not be complete without them.

After carefully considering all the various experiments in the laboratory, the following were selected as the most promising to be tried on full scale. They will be referred to henceforth as tests and the description of the experimental plant in which the three tests were operated full scale will be given under Part III.

Test No. I.—Mix (but not with the aid of air) the intermittent waste—limes, soaks, hot waters, bleaches, and spent tan liquor. Discharge the mixture to the stream at an even rate and over a period of 8 hours. Agitate (not by air) during the whole time of discharge. The remainder of the wastes, namely, the continuous wastes, should be discharged in the normal and regular manner.

The object of this test was to discharge everything from the tannery into the river, sludge and all, in order to show the effect of merely mixing the wastes together and discharging them over a period of time rather than releasing them vat by vat.

Test No. IV.—Thoroughly mix the intermittent wastes—limes, soaks, hot waters, bleaches, and spent tan liquor—by plunging up with compressed air. Regulate the pH to about 5.5 by the addition of sulfuric acid. Allow to settle over night. Draw off the supernatant liquid at an even rate and over a period of 8 hours, and discharge directly to the stream; all other wastes to be discharged without treatment. Deposit sludge on sludge beds.

Test No. VII.—Same as Test No. IV up to the point of discharge. Draw off the supernatant liquid and flow by gravity into a precipitation or sedimentation tank at an even rate and over a period of 8 hours. At the same time pump the continuous wastes into the sedimentation tank at an even rate and

over a period of 8 hours. Treat at the entrance of the sedimentation tank with either:* (*a*) Aluminum sulfate; (*b*) milk of lime; or (*c*) aluminum sulfate and milk of lime.

Discharge the effluent from the sedimentation tank to the stream at an even rate and over a period of 8 hours. Sludge to be deposited on sludge beds.

Tests Nos. II, III, and V, not listed here, were modifications of Tests Nos. I, IV, and VII; however, laboratory information, together with the results obtained from selected tests, provide sufficient indication of their behavior on full-scale treatment. For instance, Test No. II is the same as Test No. I, except in the manner of mixing; Test No. II to be mixed by air. Test No. III is the same as Tests Nos. IV or V, except that it is not given an acid treatment. Laboratory results have shown that as such it is impractical. Test No. VI is the same as Test No. VII, except in the manner of mixing.

Part III.—Experimental Plant

The experimental plant at the Instanter Tannery had capacity and flexibility enough to handle daily the total wastes from that tannery. The plant comprised sumps, tanks, pumps, engines, and the other necessary equipment for daily continuous operation.

Sumps.—There were two sumps. One, 6 by 10 by 14 ft. deep, was used as an intercepting sump located between the beam house and the main tannery concrete sump. It was so situated that the limes, soaks, and hot water could be separately selected if so desired and retained in this sump. A centrifugal pump was used to deliver the contents from this sump to the mixing sump, which was 32 ft. square and about 6 ft. deep. In this sump, commonly referred to as the 32-ft. sump, those wastes to be treated were delivered by gravity and by pumps and were stored during the day. This sump was equipped with an air-mixing device and a centrifugal pump.

Reaction Tanks.—These were four reaction tanks, each 16 ft. in diameter by 10 ft. deep. They were equipped with air-mixing devices, swivel-jointed draw-off pipes, traps for sludge removal, and other appurtenances.

Sludge Bed.—The sludge bed was not constructed to hold all the sludge produced, only a part of each batch having been so placed, the remainder either having been run to the creek or held in a lagoon provided for the purpose. The bed was 30 ft. square, was built up of rough gravel, limestone, and cinders, and was well-drained.

Sedimentation Tank—The sedimentation tank was nothing more or less than a long narrow tank coiled up. Its dimensions, straightened out, would be 4 ft. wide, about 100 ft. long, and 16 ft. deep. It was constructed as a round wooden tank so arranged with two concentric inner tanks as partitions to provide a spiral path of movement for the wastes which entered in the center and moved in the spiral path until the periphery of the outer tank was reached, at which point they were drawn off. The round tank was 24 ft. in diameter and 16 ft. deep, and the two inner tanks were 8 ft. and 16 ft. in diameter, the space between the 8-ft. and the 16-ft. tanks having been partitioned off. A 2-ft.

* Part (*a*) is the recommended method. Part (*b*), or Part (*c*), is to be resorted to only to improve on Part (*a*), if such is possible.

opening in the side of the 8-ft. tank and extending to the bottom, just ahead of the partition mentioned, permitted the wastes to move from the 8-ft. tank into the space between it and the 16-ft. tank. They then proceeded around in this 4-ft. channel until the partition was reached. At this point, a 4-ft. opening in the side of the 16-ft. tank, and extending to the bottom, permitted the wastes to enter the space between the 16-ft. tank and the outer or 24-ft. tank. A partition between the 24-ft. tank and the 16-ft. tank forced the wastes around the outer channel to the draw-off point located just in front of the partition mentioned. The tank was provided with traps for sludge removal and other appurtenances.

Alum Feed and Mixing Chamber.—The aluminum sulfate solution was mixed in barrels. It was so situated as to feed into the mixing chamber, a 3-ft. square box provided with baffles, at the point where the wastes received the alum dose. The baffles served to mix the alum with the wastes.

Operating conditions were necessarily maintained as uniformly as possible in order that the results of the tests would be comparable. The plant was operated, therefore, only when the same kind of wastes were produced, or when the variation from day to day was the least. At the Instanter Tannery this was possible every day, except Saturdays, Sundays, and Mondays. On these days certain intermittent wastes were not produced, but on Tuesdays, Wednesdays, Thursdays, and Fridays, the total amount of the wastes was produced. Other regulations were to limit the time of discharge to some certain period and to maintain an even rate of discharge during this period. These regulations served primarily to aid in comparing the results noted on the receiving body of water. In all the tests, therefore, the same kind of wastes were used, the period of discharge was the same, the rate of discharge over the period was even, and the whole amount of a given waste was used as produced, rather than a proportionate part thereof.

Test No. I

Test No. I, as previously described, was first operated for 5 days in November, 1925, and again for 5 days in July, 1926. Only the intermittent wastes were mixed together, the continuous wastes being discharged in the regular and normal manner. Everything was maintained the same in the two runs, except the method of agitation of the mixture of intermittent wastes during the draw-off, or discharge. In the 1925 test, air was used during the entire 8 hours, whereas in the 1926 test the agitation was accomplished by plunging by hand. The object of the two tests was to obtain the effect on the stream, of discharging the wastes as is, sludge and all. The reason for the different methods of agitating the mixture during the time of discharge was to determine the effect of the air on the mixture.

Operation.—The limes, soaks, and hot waters were pumped daily from the intercepting sump into the 32-ft. sump. Then, the three bleach liquors, namely, soda, acid, and acid water, and, lastly, the spent tan liquor, were delivered to this sump by 4:00 P. M. each day. These wastes, comprising the intermittent wastes, were mixed and pumped to the reaction tanks, leaving the 32-ft. sump empty and ready to accumulate the next day's wastes. The

following day this mixture, while being agitated in the reaction tanks, was withdrawn and discharged at an even rate and over a period of 8 hours.

In the 1925 test an average of 32 000 gal. of the intermittent waste mixture were handled per day and in the 1926 test, 39 856 gal. were produced. The analyses of the mixtures used in the two tests are shown in Table 9.

TABLE 9.—Average Analysis of Mixtures of Intermittent Wastes.

	November, 1925.*		July, 1926.†
	Start of run-off, in parts per million.	End of run-off, in parts per million.	Composite taken over period of discharge, in parts per million.
Specific gravity, 20° cent.	.....	.....	1.0166
Total solids	22 244	22 186	20 552
Soluble solids	19 518	18 612	16 666
Suspended solids	2 726	3 574	3 885
Volatile solids	11 773	9 896	10 461
Fixed solids	10 471	12 290	10 091
Color	8 400	8 600	9 800
pH	6.65	6.70	5.62
5-day oxygen demand, 20° cent.	3 315	1 551	3 876
Alkalinity, CaO	.....	.....	3 388

* Air used for agitation.

† No air used for agitation.

Each analysis in Table 9 is the average of five analyses. The important facts brought out by the analyses of the 1925 test, which were later confirmed by laboratory experimentation, were the decrease of 50% in the 5-day oxygen demand and the increase in color and in suspended solids in the wastes at the end of the run-off period. These differences were due to the aeration effect while agitating the mixture with air.

Test No. IV

Operation.—Test No. IV, as previously described, was conducted during June, July, August, and part of September, 1926. The intermittent wastes were held daily, mixed in the 32-ft. sump, and delivered to the reaction tanks in the same manner as in Test No. I. Here, they were treated with concentrated sulfuric acid until a pH of about 5.5 was reached. The pH was determined colorimetrically. The acid was added by hand from carboys. Usually the correct pH was obtained on the second trial, the whole acid-adding operation requiring less than 30 min. After the acid treatment a sample of the contents of the tanks was preserved in liter-graduated cylinders and permitted to stand quietly over night. In this manner the sludge content could be gauged very precisely the next morning and the quantity of supernatant liquid to be discharged that day could easily be determined. The mixture in the tank was permitted to settle quietly over night. The next morning the supernatant was started discharging at an even rate and for 8 hours thereafter. Composite samples for analysis were taken of the mixture before the acid treatment and of the effluent during the discharge. Whenever the sludge accumulated to the extent that it interfered with the efficiency of the tanks,

it was drawn off, a proportionate part being placed on the sludge beds. The continuous wastes were discharged directly to the creek without treatment in the normal and regular manner.

The average quantity of the daily intermittent waste mixture, based on 16 days' operation, was 37 937 gal., having an average specific gravity of 1.0135 at 20° cent. The average effluent produced per day from this mixture was 27 546 gal., having a specific gravity of 1.0141 at 20° cent. The difference, or 10 391 gal. per day, was retained as sludge, having an average moisture content of 96.78 per cent. In other words, 27.40% by volume of the total daily intermittent waste mixture was retained as sludge. The average sulfuric acid, 66° Baumé, used per day was 206 lb. Table 10 shows the average results of the sixteen analyses of this mixture before treatment and of the effluent as discharged.

* Increase.

Test No. VII

Just as Test No. VII, as described, was to be started, circumstances over which the Committee had no control caused the Instanter Tannery to cease operations. On September 8, 1926, the Committee was officially notified that hides would cease to be worked in at that tannery on September 11. Efforts were immediately concentrated on Test No. VII, although it was realized that it would probably be impossible to make a thorough study of this test in so short a time. It was possible, however, to obtain a complete and normal daily waste discharge for 9 days, which has indicated, in a general way at least, the character of this test.

Operation.—Test No. VII included the treatment of all the wastes except the green stock. The intermittent wastes were treated in the same manner as in Test No. IV. The effluent from the intermittent wastes contained in the reaction tanks was discharged into the main trough leading to the sedimentation tank. The continuous wastes were also pumped into this trough. This mixture was discharged into the sedimentation tank at the rate of about

12 000 gal. per hour. Before the mixture entered the sedimentation tank, however, it was passed through a small mixing box at which point a solution of aluminum sulfate was added. The nominal retention period in the sedimentation tank averaged about 2 hours. The effluent was discharged to the creek at the same rate the wastes entered the tank, namely, about 12 000 gal. per hour. The average length of discharge was 8 hours during the working period of the tannery. The contents of the sedimentation tank were permitted to stand quietly during the night. It was found necessary to remove the sludge accumulated in this tank twice during the 14 days it was in operation. The averages of the data collected during 9 days are given in Table 11.

TABLE 11.

Total wastes handled per day.	Quantity.
Continuous and intermittent:	
1. Total, in gallons per day	102 193
Intermittent wastes:	
1. Total in gallons per day	40 406
2. Effluent, in gallons per day	32 700
3. Sludge, " " "	7 706
4. Acid added, in pounds per day	218
Continuous wastes:	
1. Total, in gallons per day	61 787
Combined continuous wastes and effluent from intermittent waste:	
1. Total, in gallons per day	94 487
2. Effluent, in gallons per day	94 487
3. Sludge, " " "	2 980
4. Aluminum sulfate, in pounds per day	250
5. Aluminum sulfate, in grains per gallon	18
Sludge produced:	
1. Sludge from intermittent wastes, in gallons per day	7 706
2. Sludge from sedimentation tank, in gallons per day	2 980
3. Total sludge produced, in gallons per day	10 686

The amount of sludge produced daily in the sedimentation tank was 3.15% by volume based on the daily volume treated in this tank. The moisture content was 97.42 per cent. Considering the total daily volume of wastes, except the green stock, there was an average of 10 686 gal. of sludge produced per day, or 10.45% by volume.

The average results of the nine sets of samples taken during the operation of Test No. VII are presented in Table 12.

In Table 12 the column, "Combined Mixture—No Treatment", is the analysis of the mixture, as produced, of all the intermittent and continuous wastes except the green stock; the column, "Before Alum Treatment", is the analysis of the mixture consisting of the effluent from the intermittent wastes after the acid treatment and the continuous wastes; and the column, "Effluent Discharged to Creek", is the analysis of the effluent from the sedimentation tank. This effluent is produced by treating with aluminum sulfate the mixture, the analysis of which is given in the column, "Before Alum Treatment", and, subsequently, permitting sedimentation to take place in the tank.

The usual preliminary adjustment and regulation of the functioning of the sedimentation tank could not be accomplished before starting this test, owing to the limited time available. Consequently, several alterations, glaringly in need, could not be made. A more efficient method of removing the

sludge would have provided a somewhat longer retention period. Lack of sufficient ground space on which to store the sludge forced the sedimentation tank to operate beyond its point of efficiency, due to sludge piling up inside. This fact partly explains the relatively large amount of suspended solids noted in the effluent. There is no doubt that this tank can be operated much more efficiently when it is properly adjusted.

TABLE 12.—Average Analysis of Waste Mixtures.

	Combined Mixture.* No Treatment.		Before Alum Treatment.		Effluent Discharged to Creek.		Total amount retained as sludge, percentage.	Amount retained as sludge from sedimentation tank, percentage.	Reduction, percentage.

* Laboratory mixture.

The point of draw-off, being only 10 in. wide, caused the effluent to be accelerated in that region, resulting in considerable stirring up of the sludge. This trouble can be eliminated by simply making the draw-off trough the width of the channel of the tank. These, and other mechanical features, can easily be adjusted. Color and suspended matter showed 72% and 70% reduction, respectively. The 48.60% reduction in 5-day oxygen demand is also notable because it must be remembered that no special treatment for oxidation, such as aeration, biological filtration, and the like, was made. This reduction in oxygen demand is due primarily to the removal of solids in suspension and in solution. Attention is called to the fact that of the 56.15% removal of solids, 45% was accomplished in the sedimentation tank. This, of course, was by reason of the relatively much larger volume treated in this tank and does not minimize in the least the efficiency of the acid treatment of the intermittent wastes because the efficacy of both treatments has already been ably demonstrated by these tests. The removal of approximately five-sevenths of the total suspended matter and two-thirds of the total oxygen demand was accomplished in the sedimentation tank.

The success of this test is evident from the actual facts noted. The production of a suitable effluent has consumed practically the entire attention of the investigation to date (1926). A detailed study of the sludge problem will be taken up as soon as the experimental plant has been transferred to another

tannery. Although the abandonment of Instanter Tannery cut short further experiments, the information derived from the tests is valuable.

Summary of Full-Scale Operations

1.—Test No. I, which amounts to mixing certain wastes, and prolonging their discharge, undoubtedly could be used to advantage by some tanneries.

2.—The use of air for mixing produced a 50% reduction in the oxygen demand of the untreated intermittent wastes.

3.—Test No. IV proved to be a dependable method of producing sedimentation of the intermittent waste mixture at little cost and little labor.

4.—Test No. VII, although not operated long enough to prove its ultimate efficiency, clearly indicated an effective treatment.

Part IV.—River Studies

River studies were made to determine the effect of the various treatments described in the preceding section, on the East Branch of the Clarion River, immediately below the point of discharge of the wastes, and for a distance down stream of about 12 miles. The river studies were carried on only during the summers of 1925 and 1926. Most of the river work of the summer of 1925 consisted in determining its condition during the regular and normal daily operations of the tannery. The river investigation during the summer of 1926 consisted only of the study of Tests Nos. I, IV, and VII.

The samples of the river water obtained for analysis were taken from carefully selected stations located at definite points along the river over the 12-mile stretch.

Station 1 was immediately below the point of discharge of the tannery waste, but far enough down stream to insure thorough mixing of the water and waste.

Station 2 was 1½ miles below Station 1, and just above the junction of Straight Creek with the Clarion.

Station 3 was 3 miles below Station 1 and 1½ miles below Station 2, just above the junction of Swamp Creek with the Clarion.

Station 4 was 5.6 miles below Station 1 and 2.6 miles below Station 3, about ½ mile above the junction of Crooked Creek with the Clarion.

Station 5 was about 12 miles below Station 1 and 6 miles below Station 4.

The river was accurately gauged at each station so that the discharge, area, and velocity could be determined whenever desired. The time of flow between stations was also determined a number of times.

During the sampling of the river no sludge or other extraneous matter likely to mask the effect of the treated wastes was permitted to discharge into it. Samples of the river water were collected at each station during 24-hour periods—one sample taken each hour during the period. The dissolved oxygen, temperature, pH, and turbidity were determined in the field, and the total solids, soluble solids, suspended solids, color, oxygen demand, etc., in

the laboratory, all results being calculated to standard discharge conditions. The standard drought flow discharges for the sampling stations are as follows:

Station 1	5.0	sec-ft.
" 2	5.0	" "
" 3	7.9	" "
" 4	10.2	" "
" 5	13.9	" "

Although figures are submitted in this paper, the writers feel that final conclusions cannot be given at this time (1926). It is known that a number of foreign factors have upset, to some extent, the results, and before these factors and their influence have been fully analyzed, definite statements cannot be made.

Preliminary Stream Study, Summer, 1925

In the normal and regular daily operation of the tannery the wastes are discharged, sludge and all. The practice is to remove the plug in the vats and permit the wastes to discharge directly to the creek. Most of the heavy lime sludge deposited in the bottom of the lime vats is shoveled out in a pile, but does not find its way to the stream. The continuous wastes are pumped to the stream directly. The only waste from the Instanter Tannery which does not regularly discharge into the creek is the spent tan liquor. This waste is pumped up into earthen lagoons, situated above the tannery, in which the liquor is permitted to settle and otherwise to trickle over and filter through the sides, and down the hill. In this manner considerable oxidation occurs before the waste finally reaches the river.

The average analysis of the 24-hourly samples by stations is given in Table 13. The column, "1", is the analysis of the water at Station 1, and is comparable in all respects with the analyses of the other stations given in the table, except that in this case the spent tan liquor was discharged directly to the creek, whereas in the others it was pumped into the lagoons at the tannery. Only one station was sampled with the tan liquor discharged direct, because the officials of a large paper plant at Johnsonburg, 12 miles below, seriously objected to its presence in the water.

Temperature, in degrees centigrade	10.06	11.24	13.43	12.35	17.3	17.3	20.3

The analyses of Instanter Creek, Seven-Mile Run, and Straight Creek are given in Table 14 to show the character of the water of these tributaries. Instanter Creek and Seven-Mile Run are the two little creeks which come together just below the tannery, to form the East Branch of the Clarion River. Station 1, as stated, was just below the junction of these two creeks. The samples obtained for analysis from these creeks were taken immediately above the tannery on Seven-Mile Run, and just above the junction point on Instanter Creek. Straight Creek flows into the Clarion at Straight, Pa., 1½ miles below Station 1. A practice was made throughout the investigation of analyzing the waters of these creeks frequently in order to detect outside sources of pollution.

As in this test everything produced as waste at the tannery is discharged to the river, except the lime sludge, it should constitute the worst condition. Consequently, the removal of any suspended matter from the river should lessen the load on the stream to a noticeable degree. In Test No. IV, in which the intermittent wastes were treated with sulfuric acid, permitted to settle, and only the supernatant liquid permitted to flow to the creek, the retention of the settled material should be noticeable by a general improvement in the condition of the river.

Test No. IV, Summer, 1926

The stations were sampled once each in June, July, and August, during the operation of Test No. IV. The average analysis for each station, of the three times sampled, is given in Table 15.

There is an improvement noted in these analyses over those made for Test No. I. The condition noted farther down stream, however, is not as

good as was expected. It is difficult to ascertain at present just how much influence the wood distillation plant, situated on Straight Creek, several hundred feet from its mouth, had on the results below Station 2. All the samples below this point contained a strong odor of wood creosote, and Straight Creek showed a much higher oxygen demand than was noted before. The wood distillates are composed of a large proportion of unsaturated compounds and have a very high oxygen consumed value. The slight yellow color imparted to the water from the wood oils and tars seems to predominate for great distances, only dilution tending to diminish it.

TABLE 15.—Average Analysis by Stations, Test No. IV.

	Stations.				
	1.	2.	3.	4.	5.
Total solids, in parts per million	378	448	259	242	561
Soluble solids, in parts per million	331	414	220	206	527
Suspended solids, in parts per million	47	34	39	36.1	34
Dissolved oxygen, in parts per million	4.71	4.74	5.44	5.91	7.26
Percentage of saturation, dissolved oxygen	48.42	50.66	56.93	65.91	77.94
5-day oxygen demand, 20° cent	33.07	17.30	18.22	7.65	5.60
Color	269	262	247	277	198
Turbidity	43.7	52.6	24.4	18.05	26.2
pH	6.06	6.59	6.76	6.77	6.73
Temperature, in degrees centigrade	17.08	18.23	17.18	18.85	17.03

The dissolved oxygen and the percentage saturation of dissolved oxygen increased steadily with distance from the tannery. The turbidity, color, and oxygen demand decreased steadily. Most of the improvement seemed to have been accomplished in the first three miles below the tannery. From that point the change was very gradual.

The analysis was not the only means of detecting the improvement in the river condition. The removal of the sludge, of course, disposed of considerable suspended solids, the effect of which was very marked at Station 1. Throughout this test the water was clear enough to see the bottom plainly. At no time during the summer of 1925 and during the operation of Test No. I in July, 1926, was this possible. The quantity of small fish in evidence near Station 1 during this test was considerably greater than before, and the jet black appearance of the river bed seemed to have been washed to a more natural color. Thus, not only by analysis, but also by observation, was an improvement noticed at Station 1.

Test No. VII, September, 1926

The effluent from the tannery during this test hardly discolored the water at Station 1. The color at this station at the time of sampling was 33, barely noticeable in an ordinary household tumbler. This represented more than a 50% reduction in the color at this station.

The average analyses of the stations made during Test No. VII are given in Table 16.

TABLE 16.—AVERAGE ANALYSIS BY STATIONS, TEST NO. VII

* These figures are out of line when comparing the test results by stations.
† These figures are out of line when comparing the results of tests at each station.

In Table 17, Tests Nos. IV and VII show a decided reduction at each station in oxygen demand, assuming that Test No. I represents the worst condition. Paralleling this reduction throughout is the increase in the percentage saturation of dissolved oxygen. The color likewise shows improvement. It may be, however, that the colors noted in the lower stations are normal, that is, that the colors in the upper stations are not very persistent and are easily and quickly diffused or lost. The average color of the waters at Station 4 and at Station 5 at the time of sampling was about 25 and 12, respectively.

It is practically impossible to make conclusive statements about the river work. The importance, however, of the river studies cannot be over-estimated. The results thus far obtained demonstrate that it was possible to observe and show by analyses that Test No. IV was an improvement on Test No. I, and that Test No. VII was an improvement on Test No. IV. The fact that it was possible to bring out these differences in the water is a most important feature. It is hoped by future work to be able to calculate, or to forecast, the effect of any concentration and volume of tannery waste on any river.

General Summary

1.—Chemical analysis of the individual wastes revealed the fact that the intermittent wastes contributed about 75% of the total putrescence. Their volume was only 28% by volume of the total daily wastes.

2.—The laboratory experiments indicated that chemical treatment was necessary for dependable results.

3.—Several different types of treatment were developed in the laboratory.

4.—Two full-scale tests accomplished satisfactory removal of suspended matter in the wastes treated, one treating the intermittent wastes only, and the other treating all the wastes, except the green stock.

5.—The river studies proved to be important. The analyses of the river water showed that about 50% of the improvement is accomplished in the first 3 miles of the 12-mile stretch immediately below the tannery.

DISCUSSION

EDMUND B. BESSELIEVRE,* M. AM. SOC. C. E. (by letter).—Broad-minded and far-sighted ideals have been the background of the Department of Health of the State of Pennsylvania for a long time. The Keystone State, perhaps the first, and by far the foremost, State of the Union to recognize and accept the doctrine of co-operation between State and industry, has progressed far in regard to the allocation of streams to their most economic uses, the recognition of the basic rights of industry, and the discrimination between selfish interests and those necessary to the State's welfare. As have other States, Pennsylvania has some citizens who believe that their pleasure or convenience is paramount to any other consideration. It makes a good argument to claim that fish are killed because of stream pollution. However, is it right to stifle or penalize an industry which produces millions of dollars of revenue and employs thousands of people, for the sake of providing a few fishermen the right to pursue a sporting proclivity? No! The State of Pennsylvania (and here much of the credit is due to W. L. Stevenson, M. Am. Soc. C. E.) has been wise enough to form a Board to have jurisdiction over its intra-state waters. This Board, in turn, has promulgated wise rules that fully weigh the inherent rights of the individual as to industry and health.

Co-operation with industry, in assisting industrial groups to solve problems of pollution peculiar to that industry, has been another feature of Pennsylvania foresightedness which has been followed elsewhere. It is a basic fact, known to those who are closely identified with stream pollution, that industry is prone to balk at stringent requirements arbitrarily made and enforced. Waste treatment at its best is an expense, and an industrial plant owner cannot be blamed for holding off the fatal day as long as possible. Therefore, an inclination to assist by working with the industry and devising a sensible program of experiment is bound to be received with satisfaction. The only fault the writer can see in this policy is that it may lead to procrastination; that is, an industry, if faced with an expensive treatment, could continue its experimental work indefinitely and thus stall eventual compliance with the law. That is not true in the co-operative measures thus far undertaken, because the larger industrial groups have sensed the inherent justice of discontinuing pollution, and are genuinely ready to find a reasonable way of compliance. Much good can be accomplished by this industrial group work, as the financial burden entailed on any one member is small, and at the same time sufficient funds can be obtained to enable really worth-while work to be carried on. It should be encouraged, provided satisfactory and economical methods of treatment for the waste in question are not already known.

The third, and by no means the least important, co-operative measure developed in Pennsylvania has been the fostering of joint action with adjoining States over interstate waters. Obviously, no relief can be obtained on a stream which divides two States, without concerted action by both States involved. The co-operative arrangements among the States of Pennsylvania,

* San. Engr. and Mgr., Eastern Territory, San. Eng. Div., The Dorr Company, Inc., New York, N. Y.

Ohio, West Virginia, and New Jersey, and the work that has been done on the rivers which separate these States, is the best answer to the value of this phase of clear-sighted public health work. It is hoped that nothing will be allowed to interrupt or halt this good work so essential to the welfare of all.

Setting a standard of treatment or degree of purification is one of the best ways to get action, provided the standard is logical and practicable. Oil refinery wastes, as discussed by Mr. Weston, have not been given the extensive study that other wastes have received, and the efforts have been to extract as much of the oil and tar as possible by gravitational means. This simple treatment has sufficed in many cases, mainly because the volume of the diluting water receiving the wastes has been great. There are cases, however, where greater results must be produced, and sufficient work has been done on wastes from large refineries to show that Nature can be assisted at moderate cost.

Precipitation of tars and coagulation and flotation of lighter oils may be accomplished chemically, electrically, and mechanically. With proper sedimentation basins provided with mechanical skimming devices and means for collecting the deposited sludge, this process can be made continuous and will occupy little space. Assumptions, however, are dangerous in industrial waste practice, and tests should be made in each case to determine the best and most economical method to adopt.

Mr. Crichton is correct in his premise that treating coal mine wastes with lime or other chemicals is simply shifting the burden from the shoulders of the mine operator to the shoulders of the public through its water filtration plant. The question arises as to the relative economy of neutralizing acidity at one place, and reducing the increased hardness at another place, as against carrying out all the treatment at one place. The cost of treatment or neutralization mentioned, 15 to 25 cents per 1 000, is not excessive as compared to the cost of treatment of other wastes; but, although a few cents per 1 000 gal. may seem small, when multiplied by thousands of thousands the bills pile up swiftly.

At this point, it is proper to call attention to the fallacy of considering industrial waste treatment problems on the basis of cost of treatment of a small volume tested without ascertaining the true cost of the total volume to be handled in a given case. It does not seem expensive to throw a little chemical, perhaps a few grains, into a beaker of waste to achieve a result; but multiply those few grains by the number of gallons required to be treated, and the small pinch of chemical becomes a carload or a ton of the material. Investigations should be carried out with this clearly in mind, because frequently different methods may be required if one proves to be impracticable from a cost standpoint. Also, at this point, the relative initial cost of the plant, as compared to operating expense from the viewpoint of the chemical bill, must be visualized. If ground area is available, and experiment shows that a larger plant will require less chemical, and the interest charge on the investment for the larger plant is less than the cost of chemical for the smaller one, then the larger plant is the most economical.

Referring to the Melcroft problem, the writer was consulted on this, and the investigations showed that the wastes could be neutralized at about 16

cents per 1 000 gal., but that the hardness of the water was increased. This fact was reported to the Melcroft Company as was duly proper.

Paper mill wastes, discussed by Mr. Spence, are one of the few industrial wastes that offer a hope for economical recovery of usable material. To attack industrial waste problems in general from the standpoint of showing a profitable recovery of some ingredient is wrong in principle and is misleading. Very few wastes are entirely free from potentially valuable constituents, but the cost of reclaiming these substances is very often "a delusion and a snare", and new raw material may frequently be purchased at less than the cost of reclamation. Expensive plants have been built to recover waste materials and after operating for short periods at great cost close down. Industrial waste treatment should be attacked from the viewpoint of producing the desired result and of letting any recovered product be used as a partial stand-off of the cost of treatment. Do not spend the savings before they are made, but be happily surprised if a slight return comes from the operation.

A great deal of work has been done in the treatment of paper mill wastes, and it has been demonstrated to the satisfaction of some very large companies that sufficient pulp can be recovered not only to warrant the original expense of the plant, but to amortize the entire cost in a period of from one to three years. Recoveries of 95% and more of the wasted pulp are common, and even in cases where the pulp is valued at 1 cent per lb., it has been found to be a paying investment. In those cases of high-grade papers where pulp is worth 6 to 7 cents per lb., or more, the writing off of the initial investment is a matter of months. Carefully designed and constructed save-alls are in operation in many mills and that the results are satisfactory to the owners is attested by the purchase of duplicate plants for other mills. Sometimes, it is necessary to add alum to produce efficient results, but as in some high-grade papers, alum is used in the normal process of manufacture, this does not destroy the value of the recovered pulp.

In deciding between two competitive devices, one of which produces a much higher recovery by using alum or some other coagulant and the other of which achieves a lesser recovery without the use of alum, there are two factors to weigh: First, if the higher recovery is necessary to satisfy health authorities, then the unit producing the lesser recovery is out of the question, despite its possible lower cost; and, second, if one unit is cheaper in first cost than another, but requires the use of alum to procure a high recovery, which cost must be capitalized and added to the first one, and the other unit does not, the relative recoveries must be considered and evaluated. If a unit does not produce the required result it is bound to be an unsatisfactory investment despite the apparent saving of a few dollars a year. Guaranteed results are what count, and statements of expected results that are not based on test, should be looked at askance.

Relative to the paper by Messrs. Howalt and Cavett, the treatment of tannery wastes may be properly subdivided into two classes rated according to the difficulty of achievement of the object, namely, (1) partial treatment; and (2) complete treatment. It has been the writer's experience that the

second of these objects is the one least often sought for, at all events, this is true at present. It may be that, owing to the size and the nature of the streams in Pennsylvania and the location of the tanneries, the necessity for complete treatment in that State exceeds any other demand, but elsewhere this is not so.

Tannery wastes are relatively easy to treat from a standpoint of eliminating or reducing the elements of nuisance—solids, hair, sludge banks, scum, and odor. At present, a large number of installations in various parts of the country are satisfactorily achieving the purpose for which the plants were installed.

It is a recognized fact that a great deal of the hair, fleshings, and small leather scraps, may be most economically and satisfactorily removed by mechanical fine screens. This feature has been adopted at some of the largest and leading tanneries in the United States. Removal of the coarser solids and the hair, by mechanical fine screens, eliminates not only several of the elements of unsightliness and trouble where tannery wastes are conveyed in sewers or streams, but also lightens, materially, the load on subsequent units of treatment, where required. Screenings are mechanically handled and placed in convenient receptacles for final removal.

Tannery wastes contain (as Messrs. Howalt and Cavett show) large quantities of solids. These are mostly organic and, therefore, highly putrescible, and their reduction is desired at the least cost. Sedimentation alone (3 to 4 hours' detention period) will usually remove 75% of these solids. The addition of chemicals will add to this percentage, so that, if necessary, a clear effluent may be procured.

Clarity, however, costs money and all phases of a problem should be investigated before it is declared necessary to produce a clear effluent. Color is frequently hard to remove, at least to the point of invisibility in the effluent. After all, why remove it to that extent if the dilution factor of a stream is so high as to dissipate color when the effluent is mixed with it? Nature provides a decolorizing agent in the stream and it should be used.

Sedimentation basins have been developed, which eliminate the difficulties of older types. Manual handling of sludge, dewatering to remove it, duplicate basins, and deterioration of effluent by accumulating sludge, all have been eliminated by the use of the modern, mechanically cleaned, sedimentation basins, which have been successfully used at a number of tannery waste treatment plants.

Sedimentation alone will not remove color or bacteria. If their removal is required, other methods of treatment will be necessary. The work being done by the Joint Committee of Tanners and State Health Officials will undoubtedly add much to the literature of this subject and will provide an answer to the particular problem to be solved in Pennsylvania. As to its application elsewhere, the use of whatever remedy is finally decided upon as a result of these tests should be tempered with good judgment and careful study in order to make sure that that which is best for the client is recommended. The best for the client means the most economical form of treatment from a standpoint of first cost and operation cost, that will meet the

requirements of the compelling authority. More than this is unequitable; less is prejudicial to health. Let the good work of experiment continue, but let engineers apply the results with good judgment.

GEORGE W. FULLER,* M. AM. SOC. C. E.—Mr. Crichton's paper deals with an important and many sided problem. He has presented well its several phases which involve conflicting interests of unusual magnitude and numerous technical details. The Sanderson case dealt with the matter individually, while in the Indian Creek case the decision is founded on the interests of the public. The Sanderson case, which has meant so much for forty years in Pennsylvania, was never accepted by the Courts of last resort in any other State, except Indiana, the decisions in other States being less favorable to nuisances created by basic industries.

Mr. Crichton has stated that the coal mining companies are now building a tunnel to discharge their mine drainage into Indian Creek below the impounding dam from which the Indian Creek water supply of the Pennsylvania Railroad and subsidiary companies is obtained. This means that the pollution problem will simply be transferred to the lower reaches of the stream. This is an expedient that has been followed before in the case of some of the reservoirs of Allegheny County, at Johnstown, and in the Altoona District. Such diversions, aside from postponing the ultimate solution of the pollution problem, introduce another problem as to the capacity of existing reservoirs. More waters must be stored to compensate for the diversion. The speaker has too great an appreciation of the difficulties involved in connection with mine drainage to believe that a simple permanent solution may be found along the line of legislation alone. They must be dealt with in a practical way along the line of a comprehensive program that will be fair to conflicting interests. Such a program is contemplated in the creation of the Sanitary Board, which has set up a classification of the different kinds of water-sheds in Pennsylvania.

In this connection the speaker recalls the handling of some large projects in Great Britain, particularly the development of a large water supply in the midland country in England north of the City of Sheffield, involving cities like Nottingham, Leicester, and others. In Great Britain the rights of lower riparian owners are satisfied by compensation in kind, which ordinarily is taken to mean the release of water at times of dry weather roughly equal to the ordinary dry-weather flow of the stream. In the Sheffield instance, it is said that little or no impounded water was released at times of extreme drought as a supply of water can be taken from the lower reaches of the river and softened, filtered, and delivered to the vicinity of the impounding reservoir for use of riparian owners below. The speaker does not suggest, of course, this particular arrangement for the project under discussion, but merely cites it as an example of the way in which, from the standpoint of public policy, attempts have been made to balance equities and conveniences elsewhere. Surely there will come some way by which sizable communities may procure satisfactory water supplies and yet let industries flourish.

* Cons. Engr. (Fuller & McClintock), New York, N. Y.

ALMON L. FALES,* M. AM. SOC. C. E. (by letter).—This paper shows that very valuable studies on tannery wastes disposal were made, under the direction of Messrs. Howalt and Cavett, for the Tannery Waste Disposal Committee of Pennsylvania. As the authors have pointed out, their investigations thus far have been confined to the so-called partial or preliminary treatments. They have studied the effects of discharging the continuous-flow wastes without treatment, and mixing together the more objectionable intermittent wastes followed by uniform discharge into the stream during eight hours without sedimentation, after sedimentation alone, and after sedimentation followed by chemical precipitation, the continuous-flow wastes being included in the last-named treatment. Investigations remain to be made of the sludge disposal problem and of methods for the complete treatment of the wastes.

In considering the effects of the discharge into a stream, of untreated wastes or of mixed wastes, including sludge produced by the interaction of different wastes, it must be borne in mind that organic solids, deposited in the bed of the stream, tend to rob the overlying water of the dissolved oxygen required to maintain the stream in an inoffensive condition. Organic matter deposited in a stream in cold weather, when there is little or no bacterial activity, unless flushed out by high stream flows, will undergo decomposition during the following summer, thus adding to the current oxygen demand load on the stream. The effects of such deposits may have influenced the results of the studies during the second summer when the settleable solids were being removed from the wastes.

A period of 8 hours each day for uniform discharge of wastes or effluents was presumably selected because the bulk of the wastes are produced during this period, and the operation could be confined to one shift. From the point of view of the condition of the stream, it is desirable to discharge the wastes uniformly with respect to the stream flow. If the stream flow is substantially the same during the 24 hours, it is desirable to distribute the load as uniformly as practicable throughout the day and night.

It is stated that the tannery selected for the studies is representative of the sole-leather tanneries operating with the vegetable tanning process in general use. Variations were found in the composition and strength of various wastes at different times during the day and on different days. Still greater differences may occur between the wastes from different tanneries. In view of the differences in the quality and quantity of wastes, variations in the character and volume of stream flow available for dilution, and other varying local conditions, an investigation should be made at each tannery to determine the extent and kind of treatment required to satisfy the local conditions. Studies such as those made by the authors are of great advantage in solving these problems.

It may be helpful to describe briefly some of the tannery wastes treatment investigations and experience of the writer and of the firm of which he is a member.

* Cons. Engr. (Metcalf & Eddy), Boston, Mass.

The writer was first introduced to tannery wastes about 1900 at Worcester, Mass., where the wastes from a large sole-leather and belting tannery are discharged into the city sewer system. The tannery wastes in combination with the acid-iron wastes from the wire mills and foundries caused the sewage to be colored black, blue, or brown, much of the time, and the color was not always entirely removed by the method of chemical precipitation with lime, then in use. In this connection, it should be emphasized that if sulfate of iron, or copperas, and lime are used for chemical precipitation of tannery wastes, it is important to maintain an excess of lime in the wastes to prevent the formation of tannate of iron, which is an ink. It is reported that in recent years the quantity of lime in the wastes discharged by the tannery at Worcester has increased, causing precipitation of large quantities of hydroxide of iron in the new Imhoff tanks, and greatly increasing the quantity of sludge.

At Gloversville, N. Y., the tannery wastes constitute such a large proportion of the sewage of the city, that for studying the sewage disposal problem, a testing station was run for about a year in 1908 and 1909 to determine how the tannery wastes would affect the different methods of sewage treatment. It was found that these wastes more than doubled the strength of the sewage, but did not render the methods of sewage treatment inapplicable. A very good effluent was produced by preliminary sedimentation, trickling filter treatment, secondary sedimentation, and intermittent sand filtration, and a treatment plant was built embodying these features. This plant has functioned well, but difficulties have been experienced in handling the sludge because of excessive quantities of lime, hair, and fleshings in the tannery wastes, which were expected to be removed by tanks at the tanneries prior to discharge into the sewers.

About 1900, a question arose as to whether the wastes from a tannery at Ballston Spa, N. Y., would be susceptible of treatment by bacterial methods. It was found that although certain individual wastes from the tannery were sterile, the combined wastes contained considerable numbers of bacteria which increased on incubation.

At the C. S. Harriman Tannery, in North Wilmington, Mass., where heavy leathers are manufactured, studies made in 1913 indicated that the combined wastes could be treated satisfactorily by sedimentation and intermittent sand filtration, and a plant built for such treatment has proved very satisfactory. The effluent is discharged into a small brook. The sludge formed in the sedimentation tanks is removed periodically and de-watered on small sand beds. The de-watered sludge is reported to be excellent material for application to grass land. The sludge, when pumped to the sludge beds, created a strong hydrogen sulfide odor which was very objectionable for several days. This trouble has been overcome by applying creolin or crude coal-tar disinfectant to the sedimentation tank the night before cleaning, after the tank has been put out of service.

The wastes from the tannery of the White-Son Company, in Walpole, Mass., manufacturers of fancy leathers, are quite different from the wastes produced by the heavy leather tannery in North Wilmington. Nevertheless,

similar treatment by sedimentation and intermittent sand filtration has been satisfactory. The effluent is discharged into a small mill pond. The sludge is drawn about once a month to one of the sand filter beds and the de-watered sludge is used for filling low land near-by. This sludge, which is largely spent ground sumac, has no value, but is unobjectionable in character.

At the tannery of the J. G. Curtis Leather Company, in Ludlow, Pa., a detailed investigation of the wastes disposal problem in 1916 and 1917 indicated that the most practical method of treatment was to bring the different wastes together for interaction and sedimentation, and a plant for this treatment was recommended, including pumping station, sedimentation tanks, and sludge beds, with provision for the construction of works for more complete treatment if and when such treatment should become necessary.

At the Buckman Tanning Company Factory, in Woburn, Mass., where heavy leathers are made and subsequently split for the manufacture of patent leather, earth basins were originally provided for the wastes, but without adequate means of sludge removal. The effluent from this plant seriously polluted the brook into which it was discharged and the plant itself created a serious odor nuisance. The hydrogen-sulfide gas given off turned all the white houses in the neighborhood black, due to the formation of lead sulfide. The sedimentation basins were rebuilt and provision was made for removal of the sludge, thus greatly reducing the odors. It was found that by treatment of the wastes with sulfate of alumina solution, using sulfuric acid for the control of the hydrogen-ion concentration, or pH value, a well clarified effluent could be obtained; and this treatment, although not entirely satisfactory, is being used pending the construction of a sewer which will connect the tannery with the Metropolitan Sewer System. One difficulty experienced in this treatment is that the reduction in alkalinity causes hydrogen sulfide to be released to a greater extent on agitation of the wastes, but the odor from this source is much less than that formerly produced by the earth basins.

At the tannery of Winslow Brothers and Smith Company, in Norwood, Mass., where sheep, goat, and calf skins are tanned, and wool is scoured, it was found advisable to separate the wastes into three classes: Rinse waters from the wool department; wool scouring wastes; and combined wastes from the tannery and wool scouring wastes degreasing plant. The effluents are discharged into a small brook emptying into the Neponset River, which is already polluted by paper mill wastes.

The rinse waters from the rinsing of wool after scouring, contain bits of wool, but comparatively little other organic matter. They are passed through plate screens having $\frac{3}{32}$-in. perforations and then discharged directly into the stream. The wool removed by the screens is returned to the wool department.

The wool scouring wastes are exceedingly turbid and strongly alkaline. They contain much suspended and dissolved organic matter including considerable grease—sometimes as much as 2 or 3 per cent. These wastes are discharged into tanks for sedimentation and cooling, the resulting sludge being pumped from time to time to the sludge beds. The settled wastes are pumped to "acid-cracking" tanks where they are acidified with sulfuric acid to precipi-

tate the grease. The grease separates partly as sludge at the bottom and partly as scum at the top, and the clarified "middle liquor" is drawn off to the channel carrying the wastes from the tannery. The grease sludge is drawn off to "magma" beds of sand, and, after draining and drying, is wrapped up in pieces of burlap to form "puddings" which are placed on metal plates in the steam boxes of hydraulic presses where the grease is melted and pressed out, leaving a fairly dry, thin cake which has been used to some extent for fertilizer by farmers in the vicinity. The expressed oil is separated from the water by flotation in tanks and refined by boiling with sulfuric acid, forming "acid wool degras" which is put on the market.

The combined wastes from the tannery and degreasing plant are pumped to sedimentation tanks. The resulting sludge is drawn to sludge beds every 2 to 4 weeks in warm weather and every 3 to 6 weeks in cold weather. The de-watered sludge is used in part for fertilizer by farmers in the vicinty and the remainder is hauled to waste land.

During periods of cold weather and high stream flow, the sedimentation tank effluent is discharged into the stream without further treatment. Sedimentation accomplishes the removal of about 50% of the suspended solids, but the effluent is still colored and extremely turbid, and contains much finely divided suspended and colloidal organic matter.

During periods of warm weather and low stream flow, the settled wastes are treated by chemical precipitation with sulfate of alumina, the hydrogen-ion concentration, or pH value, of the wastes being controlled by the addition of sulfuric acid to give the most efficient and most economical treatment. The wastes are usually very strongly alkaline. Whenever there is a deficiency in alkalinity, milk-of-lime is added to the wastes. The combined wastes vary greatly in strength and composition during the day, and it is necessary to equalize the quality of the wastes, as by passage through the sedimentation tanks, prior to chemical precipitation. The chemically treated wastes are passed through tanks and the resulting sludge is discharged periodically on to the sludge beds.

The chemical effluent is well clarified, but contains considerable dissolved organic matter and is quite putrescible. This effluent is further treated by intermittent filtration to the capacity of the available area of sand filter beds, and the remainder is treated by dilution in the brook with water drawn from a reservoir owned by the Company. During periods of extremely low flow, practically all the tank effluent is filtered. The filter-bed effluent is practically clear and colorless and non-putrescible.

Experimental investigations of the treatment of the settled wastes by the trickling filter and activated sludge processes were carried out on a working scale, and it was found that a satisfactory effluent could be produced by either process, if all the wool scouring wastes were degreased prior to discharge into the tannery wastes channel. It was found that the activated sludge process would entail a considerably smaller capital expenditure, but much larger annual expense for operation and maintenance. An experimental sand filter bed was operated in conjunction with the experimental trickling filter, and it was found that the trickling filter effluent could be applied to the sand bed

at a high rate and produce a highly purified effluent. By following the method of treatment previously described, it has not been necessary to build either trickling filters or an activated sludge plant.

It has been pointed out that local conditions will govern the extent of treatment required at different places. It is also true that the extent of treatment required at a given place will vary with varying conditions of temperature and stream flow at different seasons of the year. This fact is well illustrated by the regulation of the treatment of the wastes from the Winslow Brothers and Smith Company tannery according to the requirements of the stream.

To recapitulate, during the winter, when there is little or no bacterial activity in the stream, and, in the spring, when the stream flow is relatively high, only the strongest of the wool scouring wastes are degreased and the other wastes are treated only by mixing and sedimentation. As summer approaches and the stream flow decreases, all the wool scouring wastes are conducted to the degreasing plant and water is drawn from the water supply reservoir for dilution of the sedimentation tank effluent. If the water-shed and reservoir were large enough, no further treatment, of course, would be required; but it is necessary to conserve the water and provide a more complete treatment of the wastes. The next step is the starting of chemical precipitation of the sedimentation tank effluent and regulation of flow of reservoir water drawn for dilution. Subsequently, the filter beds are put in operation.

By such regulation of the treatment, it is possible with a minimum expenditure, to produce an effluent at all times, which will meet the stream requirements.

Robert Spurr Weston,* M. Am. Soc. C. E. (by letter).—Since preparing his paper, the writer's attention has been called to an interesting treatment of oil wastes.†

At the El Segundo Refinery of the Standard Oil Company of California, where 20 000 000 gal. of salt water are taken from the ocean daily and used for cooling and other purposes, good results are obtained by means of a series of tanks baffled in such a way that the mixture of water and oil is kept moving toward the surface of the tank, rather than toward the bottom, as is the practice in tanks designed for separating heavy suspended matter from water.

This plan apparently accelerates the movement of the oil to the surface. Mr. Geiger states that all traces of the oil are removed from the surface of the water. The analytical methods used, are not given.

G. K. Spence,‡ Esq. (by letter).—In discussing the paper, Mr. Besselievre states that paper mill wastes are among the few industrial wastes offering hope for economical recovery of usable materials. He also cites that in other

* Cons. Engr. (Weston & Sampson), Boston, Mass.

† Methods Used by Oil Company to Stop Pollution of Streams," by Charles W. Geiger, *Water Works Engineering*, Vol. 81, p. 90.

‡ Chf. Chemist, Castanea Paper Co., Clarion Mills, Johnsonburg, Pa.

industries recovery plants have been constructed at great costs and, after operating for a short time, have been compelled to shut down.

This same thing is true of the paper and pulp industry. The writer knows of a paper company in Pennsylvania that built a waste sulfite liquor recovery plant several years ago at a cost of $300 000, which was only operated for two months when it was compelled to shut down, the plant being a total loss. Other paper companies have expended enormous sums of money on this same problem, as well as on the utilization of the waste carbon from soda pulp mills and many other wastes which have brought no returns. However, as Mr. Besselievre states, there have been some wastes from the mills which have been reclaimed at a profit.

To the present, if all the money expended on solving these problems were compared with the profits made, the pulp and paper manufacturers would be very much on the wrong side of the ledger. The writer is, however, optimistic as to the future in regard to all wastes from pulp and paper mills being reclaimed at a profit, or at least a "break-even" proposition, but until such a time the manufacturers will continue to expend large sums of money on research and experimental installations necessary in solving these problems.

Paper No. 1688

PROBLEMS IN CONCRETE DAM CONSTRUCTION ON THE PACIFIC COAST*

By Arthur S. Bent,† Affiliate, Am. Soc. C. E.

With Discussion by Messrs. Arthur P. Davis, M. M. O'Shaughnessy, R. A. Hill, and Fred A. Noetzli.

The first thought that arises out of a long experience in the building of dams is that no two of them are exactly alike and no one plan of operation is the optimum for more than a single location. This is true in spite of the obvious fact that different contractors might have different plans for the same work. Thus, it is evident that the success of an operation is measured by the correctness of what might be called its diagnosis. In the case of one notable California dam, the plan of an unsuccessful bidder for handling the work was so radically different from the one actually used, as to indicate definitely that they were not equally good and could not possibly produce anything like the same results in costs or speed.

It follows, therefore, that the first step in estimating, and by far the most important, is a painstaking, thorough study of the site and all its conditions, and this is where the contractor's skill and vision are tested. If he is inexperienced in the building of dams he will probably learn much on his first job, but even with long experience he will be impressed with the truth of the opening statement that no two projects are alike. While remembering all the things that did not operate well on previous work and all the unexpected conditions that arose, he must not be bound by precedent. He must have the ability to discard every type of plant and method of attack he ever used if they do not seem to fit, and to devise those that will. Standing on the untouched site

* Presented at the meeting of the Construction Division, Seattle, Wash., July 15, 1926.
† Pres., Bent Bros., Inc., Los Angeles, Calif.

with the plans before him, he must have the vision to follow through step by step the processes ahead and see clearly and in detail the methods, organization, and equipment required for each one.

After a lifetime spent in construction work of various kinds the writer believes this is more difficult with a Western dam than with any other structure. Compared with a Class "A" building, for instance, a dam seems very simple—just a block of concrete between two walls; but it is a significant fact that many fortunes have been sunk on single dams, while on others very low bidders have made good profits.

This paper is an attempt to suggest, from a long experience, the fundamental elements that must be carefully and intelligently considered in advance to make a success of a concrete dam, and to outline some of the methods of meeting specific problems.

Estimates

In the preliminary estimate the first thing to consider is the owners with which one has to deal. Are they responsible and fair-minded? are their financial plans sound? are they likely to use up in other developments the funds that should go into the dam before it is completed? What are the character, reputation, and experience of the engineers? An unfair, hard, or inexperienced engineer can make any job a misfortune to the contractor and take all the joy out of it without adding to the safety or usefulness of the structure. If a contractor has reason to believe that he will be in the hands of such a man, he should not bid—it does not pay.

The site should be visited many times and a long and thorough study made of it. The writer's method is to have independent studies and plans of operation made by different members of his organization, these being later reconciled in the office, so that the plan finally adopted represents the consensus of its best judgment.

These site studies must include accurate knowledge of the topography, water run-off, high-water period, weather history, water supply for entire year, length of working season, and possible methods of river diversion. Thought must be given to the effect on the plant and work of the inevitable floods and the work so scheduled as to reduce this misfortune to a minimum. Here, again, the co-operation or otherwise of the engineer is important. On one project the engineer needlessly delayed the placing of the concrete in the foundation with the result that an unexpected flood filled the excavation and cost the contractor a loss of $20 000. The remoteness and inaccessibility of most dams is an important matter. None of the ordinary facilities for securing skilled labor, supplies, repairs, and spare parts is at hand. The job must be constantly supplied with all these facilities and must be completely self-contained at all times.

Excavation

The estimate must take into careful consideration the character and proportions of soil and rock and their disposal after excavation. This seems too obvious to be worthy of mention, but it is probably on this item that errors

of judgment are most common. Certainly, there is greater difference in methods and plant for handling the excavating than for the concreting. On one of the writer's jobs it was believed that bed-rock was nowhere more than 14 ft. below the stream bed, but in one section it was found at a depth of 52 ft. through large boulders and much water. This required a complete and costly re-adjustment of the entire excavating plant.

As a rule the estimated cost of excavating and wasting proves inadequate. The excavating constantly suffers all the disadvantages of the work. For instance, it is the reservoir for the poorest of the labor. Untried men are put in the excavating crew. If they prove extra good they are transferred to something else. Again, shooting of rock cannot be done in the most advantageous way because of the two dangers of injuring the plant and shaking the foundation. Also, other work is usually going on simultaneously and has the precedence, from which it happens that excavating frequently must be done at night, or in very restricted areas, each of which increases the cost.

Cleaning the bed-rock (which should be computed by the square foot) is slow and costly and, although computed only once, frequently must be done several times. Here, again, the engineer is an uncertain element. It must be done to his satisfaction, and this may mean removing loose stuff and hosing off, or it may mean much hand-picking and scrubbing with wire brushes, and jetting with compressed air and water.

Wasting should be definitely planned and carefully computed. It is a frequent cause of loss. The quantity may far exceed that anticipated and thus bring in an entirely new problem of disposal, which possibility should be clearly provided for in advance.

Altogether the excavation on dams generally costs much more than other excavation jobs that appear to be similar, and has proved to be abnormally difficult to estimate with accuracy.

Plant and Method

On these depend in the main the success of the work and final decision in regard to them is determined by many considerations. The time limit and transportation facilities affect the selection of plant almost as importantly as the type of dam and the topography. If there is no railroad, and the job is large and the time short, it will pay to build one. A railroad also should be provided usually if work is to be carried on through the winter. On a recent job, during which 400 000 cu. yd. of concrete were placed in 16 months, no trucks were used either at the dam or at the gravel pit which was 20 miles away. Where aggregates can be had near the work it sometimes proves economical to haul and store cement and equipment during the dry season. This would apply particularly to small dams in remote locations. The distances and quantities to be hauled should be accurately ascertained. On one of the writer's contracts a difference of $0.01 per ton on aggregates alone meant a saving of $10 000.

On high dams a hillside plant is desirable. This set-up takes full advantage of gravity, and reduces the flood hazard and the danger from falling rocks. However, when roads cannot reasonably be built to the top and there is room

for both concrete and excavation plants in the stream bed, a tower is better. In all cases the concrete delivery point should be well above the dam crest and chutes should be amply large.

Low long dams frequently are best handled by trestle plants with the mixers at one end.

In general, although it is easy to "over-plant" a small job, it is highly important that the equipment should be fully adequate, always bearing in mind that rate of progress cannot be determined by dividing daily capacity into the total time allowed by the contract. The plant will produce its maximum output only in the middle of the construction. This further suggests that costs are increased by the fact that the same plant must be maintained throughout, while at the start and finish the output is small because of limited working space.

On a fair-sized job it pays well to make a solid and thorough set-up, using plenty of concrete for foundations of derricks, mixers, compressors, etc. The extra cost is more than compensated by regularity and certainty of operation.

The plant which is to produce the aggregate should be of ample capacity. Delays for materials are disastrous not only to costs but to morale, and in spite of seemingly careful preparation this very often happens. The writer's practice is to provide for an output fully 50% beyond the needs and on rush jobs to double the estimated demand, yet he has never overdone it.

If the rock is to be quarried near the work the usual estimating cost of $1.50 per yd. should be about doubled, and the manufacture of sand should be avoided at almost any cost of haul.

The supply of compressed air, power, and light should be ample and reliable, and the last two should be electric wherever possible because of greater flexibility. A complete machine shop and a saw-mill are essentials.

Finally, the equipment should be not only adequate, but first-class throughout, and the supply of rails, pumps, tanks, pipe, cables, nails, clips, fittings, rope, wire, and small tools should always be kept well ahead of the needs.

Camp

Too much emphasis cannot be laid on the importance of this unit because the character of labor attracted to the work and its contentment and efficiency are largely the result of the living environment of the men. Quarters must be adequate, well lighted, heated, and ventilated. Sanitary regulations must be perfect, drinking water pure and palatable, the dining-room fly-proof, and the food first-class in quality and variety. There should be an ice plant, refrigerator, bakery, store for families, plenty of hot and cold showers, hospital with doctor and nurse in constant attendance, police and fire protection, post-office, telephone, schools, amusement hall, and recreation features. Different quarters should be provided for the different shifts as well as separate meal hours. As many as eighteen different meal hours may be required on rush jobs.

On one of the writer's projects the boarding-house plant cost $15 000. Incidentally, it was completely destroyed by fire early in the job. Notwithstanding the fact that the camp was on a side-line railway, with no road for auto-

mobiles, on the third day after the fire it was again in complete running order. Only two meals were served in the open and the construction work was never halted.

It is of prime importance that no reasonable detail be overlooked that will add to the comfort and well-being of the men.

A contented little city on his job is a matter of pride and satisfaction to a right-minded contractor. He should regard it not merely as a matter of enlightened self-interest, but as a fortunate opportunity to make life as good as possible for the group of men who, for a little while, come closely within his range of influence. He may never have that privilege again.

Organization

The superintendent must be selected with the utmost care and with particular reference to the work in hand. Splendid building superintendents can fail utterly on a dam. A rare combination of resourcefulness, speed, economy, executive ability, tact, good judgment, energy, and poise is required. He should also have technical training sufficient for the clear understanding of complicated plans, a first-hand intimate knowledge of all his equipment and machinery, and actual experience in rigging. He should of course neither drink nor gamble on the job, and his loyalty to his employer should outrun every personal consideration. An absolute desideratum, however, is the ability to plan every detail of the operation long in advance, without oversight or errors. He must never be caught unprepared by any detail of the work or by any emergency. His task is very similar to that of a military commander and his blunders may be as serious. Under the superintendent are carefully chosen heads of departments as follows: (1) Accounting and purchase; (2) commissary; (3) transportation; (4) excavation; (5) aggregates; (6) carpentering; (7) rigging; (8) mechanics; (9) electricity; (10) steel; (11) concrete; and (12) engineering.

Transportation

This has already been touched upon, but may be elaborated briefly as it is of great importance. A wrong guess on this feature at the outset may paralyze the work later. Provision must be made for handling materials rapidly and certainly and single pieces of equipment weighing as much as 75 tons. Motor trucks may be relied upon, but must be furnished with a first-class roadbed constantly maintained or they cannot give adequate and uninterrupted service. Almost any amount of money is well spent in securing reliable transportation.

Conditions must determine the best plan and these are never twice alike. On one of the writer's projects, everything had to be transported through a 5 by 7-ft. tunnel, 4 miles long. This compelled the cutting and re-welding of large mixer-drums and similar heavy units. Where the yardage is comparatively small and the country extremely rugged tramways can be used to advantage. On major projects such as the Exchequer and Hetch Hetchy Dams, standard gauge railways are indicated, and they should be operated as systematically as main-line roads.

Diversion of Water

In the diversion of water the constructor of dams faces one of his most serious problems. A mistake of judgment may cost him not only great damage to his plant and work, but the loss of a whole season's work. On one project it was stipulated in the contract that such a delay would damage the owner $500 000. Nobody prayed for rain on that job.

The problems involved in handling the water are many, for the bottom may be solid rock, or it may be quite pervious and the run-off may vary during the life of the job from a few to tens of thousands second-feet. Diversion is accomplished by tunnel, flume, wing-dams, or an open section through the dam, controlled by gates. Pumping must be expected and its cost is nearly always under-estimated. If the rock is fissured, pumping may become a heavy expense. When coffer-dams are used they should be placed far enough from the site to be safe from injury by blasting.

Demolition

Demolition is a trying part of the work and unless exceptional vigilance is exercised, and the morale of the crew carefully maintained, it will show loss and waste. The writer's system is to sell at once as much of the plant as possible, and on major projects a yard with railroad facilities is rented for the temporary storing and handling of equipment. All equipment, whether to be sold or retained, should be put in first-class order and painted without delay, and all loose parts should be marked to prevent confusion and loss.

The energetic handling of this feature may determine the entire outcome, as it is not uncommon to find on a heavily "planted" job that its profits must come out of salvage. This may be regarded as one of the results of unintelligent competition.

Dam building is at once one of the most interesting and precarious types of construction. In spite of experience and care there is constant hazard from conditions beyond control. On the great majority of the writer's jobs floods have repeatedly submerged the work. Temperatures range from snow to 115° Fahr. on single projects. In one case a mountain side above the dam slid down dumping 25 000 cu. yd. of rock on the concrete. In two days the contractor's steam shovel and narrow-gauge railway working double shift cleared it away, and this equipment had to be taken 200 ft. up the vertical face of the mountain. These things suggest the necessity for a liberal contingency item in the estimate for unforeseen and uncontrollable emergencies.

The interest in dam building lies in the fact that conditions are never the same and the ever-changing vicissitudes of the work call forth almost daily the utmost resources of the constructor. More than in any other type of structure, the final outcome depends on his foresight, energy, and courage. A big dam is always a splendid adventure in construction.

DISCUSSION

ARTHUR P. DAVIS,* PAST-PRESIDENT, AM. SOC. C. E.—The speaker agrees with the stated undesirability of manufacturing sand where it can be avoided. At the site of the Roosevelt Dam, for instance, no suitable sand was available in Nature and had to be manufactured from existing materials. The first attempt was with a pure hard limestone which was being used in the manufacture of the cement. In crushing this rock for sand it had a tendency to chip into long thin flakes and was deficient in fine particles. After some experiments with that, an attempt was made to mix it with other rock, and, finally, a mixture of half limestone and half sandstone was adopted, both of which were conveniently at hand and made an excellent combination which tested high and was satisfactory throughout the job.

Another experience was that of the contractor in the construction of the Shoshone Dam, Wyoming, where conditions were especially difficult on account of limited working space, a narrow gulch with high cliffs on each side forcing such operations some distance up stream where more space was available. No suitable sand was available in sufficient quantities, and the little that was at hand required washing and was very fine. The contractor tried to crush granite rock which was very hard, and this hardness made the operation extremely difficult. One machine after another was worn out and cut to pieces in use. It was almost impossible with that granite to get a sufficient proportion of fine material without discarding a great deal of coarse. Finally, by washing the fine sand and using this, to the extent available, with the granite, it was possible to make a passable sand still lacking somewhat in gradation.

Another experience was in the Klamath Valley, Oregon, where no rock was available except lava flows. After a great deal of experimenting, it was discarded and sand was shipped from Marysville, Calif. After these and other trials, the speaker is certainly in accord with the motto of the author, "don't do it".

M. M. O'SHAUGHNESSY,† M. AM. SOC. C. E. (by letter).—Having been identified with the construction of about twenty dams, the writer is sincerely interested in some of the viewpoints advanced by Mr. Bent.

All first-class engineering plans should include information about topography, water run-off, high-water period, weather history, water supply for the entire year, length of working season, and possible methods of river diversion. It should not be necessary for the contractor to waste any time in worrying over those subjects, as any one who is going to build a large dam must have employed engineers of sufficient standing and experience to procure precise information on all of them.

In the matter of excavation for foundations, careful consideration of surface examination may disclose, when the digging is done, that the bottom will

* Chf. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

† City Engr., San Francisco, Calif.

be quite different from that anticipated, and it is well always to provide a liberal estimate for such contingencies, which are bound to occur.

Experienced rock men can blast a foundation without serious damage to machinery, if the latter is properly placed. Except in the core trench and scab rock on the surface, the shooting should not be serious. Cleaning the bed-rock is an important element. A successful expedient in the foundation of the dam at Hetch Hetchy was the use of a sand blast to clean off the old scum from submerged granite rock, which was buried under 100 ft. of loose rock and gravel.

Mr. Bent is correct in stressing the necessity of a railway. A standard gauge railway, 68 miles long, was built to the dam at Hetch Hetchy. Six locomotives were found to be inadequate at the peak period of construction, and a seventh had to be rented to haul cement, over 4% grades, up to the dam.

The author's statement that hillside plants are desirable, does not always hold. It was found desirable for the dam at Hetch Hetchy to provide a mixing and hoisting plant near the foundation, up-stream portion of the dam, and there build a tower, 350 ft. in height, to handle all materials. The reason for this was that any amount of excellent broken fragmentary rock from the granite bluffs was found around the basin within 1 mile of the dam site. It was crushed ½ mile away from the dam, assembled in heaps, and hauled by a separate narrow-gauge railway down to the mixing plant. At first, it was thought that the contractors had made a mistake, and that a high-head plant with a quarry would have been more economical; but the high cost of powder from 1919 to 1923, and the high cost of labor, demonstrated that the contractor's plans, with a crushing plant in the valley and a mixing plant near the dam, were the most economical.

An interesting feature in connection with the dam was that the most attractive and accessible sand in the river bed near the dam and mixing plant was physically undesirable, because for thousands of years a grove of oak trees grew over it. The leaves and drippings from the oaks saturated the sand with tannic acid, which proved fatal to its setting qualities in concrete, and sand was brought from an excellent uncontaminated bed that contained more than 200 000 cu. yd., about 3 miles up stream from the dam.

Mr. Bent's camps are always orderly, sanitary, and well conducted, and all experienced contractors and engineers are now educated to the necessity and desirability of having first-class comfortable camps for the men.

Building contractors will surely fail in dam construction, because it is a business about which they know nothing. The writer knows two instances of builders attempting this kind of construction, with a consequent loss, in one case of more than $100 000 and in the other of more than $200 000. Builders are not trained for successful dam construction.

The most important suggestion Mr. Bent has made is in regard to the handling of water and saving the construction plant from destruction by floods. It was the writer's duty to compel a contractor to raise a proposed diversion dam more than 5 ft. higher than his contemplated plans in order to deflect a stream of 8 000 sec-ft. during flood periods into a diversion tunnel.

Raising the dam was the only thing that saved his plant from destruction and his pocket from a damage loss.

On the whole the author, as well as the Society, deserves credit for bringing the practical man's point of view into the construction of dams, thereby causing engineers to think over many of the problems the contractor has to study before successfully building them.

R. A. Hill,* M. Am. Soc. C. E. (by letter).—The author very aptly calls attention to the fact that no two dams are identical, and that they all usually require radical differences in construction methods. He emphasizes justly the necessity of a painstaking, thorough study of the site and all its conditions, and the further need for the contractor to be able to discard all precedent in his visualization of the processes involved from the excavation of the foundation to the final cleaning up of the work.

With rare exceptions, engineers responsible for the design of dams, spend a great deal of time in the compilation of data regarding the conditions which will affect the cost of construction. Generally there is furnished to bidders all available knowledge, such as the frequency and time of occurrence of floods. In some instances, such information is not available, and it is regrettable that in others the engineer does not realize his responsibility and gives extremely limited information to bidders. Yet, how many contractors make a careful study of the information which is furnished them?

Unfortunately, the basis of estimation set forth by the author is not followed by a large proportion of contractors. Not long ago bids were asked on one of the most unusual and difficult pieces of dam construction yet to be attempted. It was the boast of one entirely responsible contractor that he arrived at the site of the work at 10:00 A. M., investigated the possible sources of aggregate, and returned to a near-by town in time for lunch. Another contractor bidding on the same work assumed that his plant would cost a fixed sum per cubic yard, and at the time he submitted his bid he did not even know where he would locate his construction plant if he was awarded the contract. This contractor did not start to estimate his costs (which ran into millions of dollars) until two weeks before the opening date of the bids.

A short time ago a number of bids ranging from less than $10 000 000 to more than $15 000 000, were submitted on a tremendously large dam. It is generally known that a few of the bidders followed the ideal practice, set forth by the author, and spent several months analyzing all the factors affecting the cost of such a tremendous project. On the other hand, there were certain bidders who practically ignored some of the very important considerations. For example, one contractor expressed the opinion that transportation was the only item which required special study, and that the plant and methods of pouring several million cubic yards of concrete were of relatively slight importance. In his opinion, this was purely a manufacturing process and entirely straightforward, although a variation in cost of only 10 cents per cu. yd. would make a difference of $400 000 in his profits or losses.

These instances, unfortunately, are typical of the procedure followed by many who are deemed responsible contractors. Under press of other work,

* Cons. Engr. (Quinton, Code & Hill), Los Angeles, Calif.

contractors are prone to postpone the preparation of estimates, so that the limitation of time usually requires that detailed studies be omitted. Yet, it is common to hold engineers' estimates in scorn and to view contractors' bids with reverence. The writer does not wish to imply that he is a proponent of force account work, as it is his opinion, that, in so far as practicable, all construction of this character can be best handled by contract. He does wish to stress, however, the fact that the procedure outlined by the author is an ideal one and is not customarily followed, except by a minority of contractors.

In most cases, however, it would be advisable to segregate the hazardous and uncertain items of construction from those subject to no especial contingencies, rather than include all the work in a lump-sum contract by which the owner must pay for all contingencies which the contractor thinks might arise. This is particularly applicable in the case of foundation excavations within the limits of the stream channel, which, as it involves river control, is one of the major uncertainties. The amount and character of wet excavation are almost indeterminable in advance, in spite of the number of borings which may be made, except in a few cases where bed-rock is exposed for practically the entire width of the river channel. The borings can do little more than determine the depth to rock, and only by actual excavation is it possible to fix on the exact amount of excavation into rock that is desirable.

There is one important step in the preparation of bids, and in the execution of the work, which the author has not stressed. The time available for the construction of a dam is usually fixed by the contract, and, consequently, the entire work must be scheduled so as to be finished within the allotted period. To be sure, extensions are granted, but these are in themselves an expense to the contractor, due to the ever-present item of overhead.

A careful study of the climatic conditions, and the occurrence of floods in the river, immediately brings out the necessity of beginning certain operations at specific times. In the western part of the United States, it is generally possible to determine with reasonable accuracy the number of days during which work must be stopped due to adverse climatic conditions. It is also possible to determine the time at which floods may be expected and the probable magnitude and duration of such floods. The writer has recommended to contractors of his acquaintance the advisability of preparing a chart covering the entire period of operation, upon which should be shown a typical occurrence of storms and a typical number and grouping of floods in the river. Obviously, the actual conditions will not correspond with this typical weather chart and river hydrograph, but the total number of off days and their general occurrence will correspond quite closely to the actual conditions. With such a chart available, it is then possible to analyze each operation, such as river diversion, excavation in the river channel, cleaning of foundations, pouring of concrete up to river level, re-diverting the river, and closing temporary outlets. The time required for any of these operations is subject to considerable variation. The number of men and amount of equipment necessary to complete each operation in the time available are then matters of

calculation, which, while not absolute, at least materially reduce the element of uncertainty.

The author discusses the necessity of a superintendent who can foresee such contingencies and who can plan his work a long time in advance. It would seem that this procedure results in shifting the responsibility for the plan of execution from the contractor to his superintendent. A very careful scheduling of operations, from the inception to the completion of the work, might better be prepared by the contractor in conjunction with the superintendent. Such a schedule, covering the entire job, and prepared as the result of the co-ordination of the best thought of the contractor's organization, certainly is to be preferred to the limited foresight of one man directly engaged on the work.

The advisability of constructing a railroad to the dam site is a matter to be determined in each specific case. Some contractors so much prefer the use of railroads that they are inclined to disregard the possibility of truck transportation. Other contractors, particularly those whose early experience has been on highway work, or on work in the close vicinity of a city, are disposed to overlook the saving which can be effected by railroad operation. The reliability of motor-truck transportation is steadily increasing, as are the number of suitable highways, so that the construction of a railroad is becoming of less importance than heretofore.

The concrete plant should be regarded as a step in the flow of material from the source of supply to the completed work. Usually there are certain conflicting considerations. If a plant is placed so that it is easy of access it usually is difficult to distribute the materials from this plant. On the other hand, if the plant is so located that the delivery of mixed concrete is easiest, it becomes extremely complicated to get material to the plant. On account of the fact that there is a single product sent out from the plant, it is generally simpler to provide this single line of outflow than several lines of approach for materials which go to make up the product.

The writer agrees that for the construction of a dam in a narrow canyon it is generally advisable to bring in materials to a point above the crest of the dam, and then let them flow downward to the plant and from the mixer downward into the dam. If such a procedure can only be accomplished by hoisting all materials to a point well above the crest of the dam before they enter the plant, the advantage of this location immediately disappears.

The author favors distribution by a trestle for a long low dam, with the plant located at one end. A typical layout of this character was analyzed some time ago, and it was found that if the concrete plant were located at one end there was an average haul of 1 400 ft., with a maximum haul of almost 2 000 ft. By locating the plant on the bank of the river down stream from the dam, and by hoisting directly from the plant to the trestle, the average haul was reduced to less than 500 ft. and the maximum haul was reduced to about 1 200 ft. In either case, the material had to be lifted to the same height.

No hard and fast rule can be followed, and as much consideration must be given to the ease of access to the plant as to that of distribution of the

mixed concrete after it leaves the plant. Irrespective of the position in the line of flow of materials, the same tonnage must be handled. In other words, the shortest and easiest route from the source of supply to the finished structure should be followed, and the concrete plant should be placed along the line of flow wherever it will produce the smoothest operation.

A great many dams which have been built, or which are proposed for construction, are located in relatively inaccessible places, so that each job must be a self-contained unit. As the author states, the success of the work depends on maintaining a high morale, thereby reducing the labor turnover to a minimum. Not only is turnover expensive in itself, but the desired smoothness of operation can only come from the work of men familiar with their tasks. In order to create and maintain this desirable "elan", the environment in which the men live must be maintained at a high standard. For a great number of years, construction camps were, to say the least, undesirable places. Far-sighted contractors have brought about a change in this condition, and it is safe to say that the future will see even better and more complete facilities provided for the men. It is noteworthy that the camps on force account work are frequently of a lower standard than those provided by contractors.

Summarizing, the writer is of the opinion that far less study than should be, is given to the conditions surrounding the construction of a dam by any one risking his capital or his reputation. This, of course, does not apply to all contractors, but, unfortunately, it does apply to a great number of contractors, and likewise to a great number of engineers responsible for the execution of work of the magnitude of a dam. Most of the uncertainty and contingencies, which contractors provide for by arbitrarily adding 10, 15, or 20% to their cost estimates, could be eliminated by a detailed analysis of all conditions, and by careful scheduling of operations and co-ordination of the different steps involved in the construction of any large concrete dam.

Fred A. Noetzli,* M. Am. Soc. C. E. (by letter).—The problems encountered in dam construction are many and varied. No two dams are exactly alike, each site or type of dam involving new problems in one way or another. Usually, it is hard-earned experience that points the way for the proper planning and efficient execution of the work. Lack of experience in dam construction often leads contractors to under-estimate rather than over-estimate the difficulties and, therefore, the cost.

In some recent cases the estimate of the highest bidder was almost double that of the lowest bidder, which is hard to explain for relatively simple structures like concrete dams, especially when the contract is to be let on the basis of unit prices. Perhaps the low and "successful" bidder has the right explanation for this discrepancy after he is through with the job.

The author's organization has built more dams than probably any other construction firm on the Pacific Coast. His paper deserves most careful consideration by engineers as well as by contractors.

In dam construction, probably more than in any other type of building, a close co-operation between the constructors and the supervising engi-

* Cons. Hydr. Engr., Los Angeles, Calif.

neers is essential to the economic and structural success of the work. The engineering plans and specifications should be as complete as possible. Besides structural features, they should also include as much information as practicable on the peculiarities of the rock formation, especially as to what extent blasting will be permitted; and on the stream flow and methods of river diversion, size of temporary flood openings in the dam, and the methods and anticipated time of closing these openings.

On the other hand the contractor should not fail to make due allowance in his bid for many items which, in estimating, are often overlooked or simply included in the bid prices per cubic yard of rock excavation or concrete. The proper cleaning of the surface of the bed-rock and the joints between successive layers of concrete are especially important items. Many dams suffer from unsightly leaks, usually in some joints. Lack of adequate engineering supervision and inspection is not always to be blamed entirely for this evil.

The author cites some instances in which the sound bed-rock was found at a much greater depth below the stream bed than was anticipated. Such conditions may call for a practically complete re-design of the dam, especially in case of an arch dam of variable radius. For instance, during the construction of several dams of this type with which the writer is familiar, the excavation was carried somewhat farther into the side abutments than had been assumed in the preparation of the original designs. It became necessary, therefore, to change the arch radii at practically all elevations of the dam. Prompt co-operation between the designers and the contractors was necessary to take care of these and other incidental changes, in order not unduly to delay the construction program of the contractors.

Mr. Bent stresses the desirability of a railroad for major projects. Where the concrete aggregate is to be brought from the outside over considerable distances, a railroad is no doubt advisable. However, where cement, steel, and contractor's equipment are the main items involving transportation, the use of trucks has been found to be more economical. For the Coolidge Dam, now under construction on the Gila River, in Arizona, the contractors have installed an aerial tramway between the gravel-pits in the river bed below the dam site and the mixing plant on the side hill above the dam. All other materials are hauled by truck. The nearest railroad station is San Carlos, located less than 10 miles from the dam site. This job is completely motorized, and is conspicuous by the absence of horses and mules.

The writer has been identified with the design and construction of about twelve dams that have been built since 1918, or are now (1928) in course of construction. In more than one instance he has seen contractors lose large sums of money, quite unnecessarily, on account of the violation of one or the other of the fundamental principles that are so ably presented by the author.

Paper No. 1689

EARTH WORK BY THE HYDRAULIC METHOD*

By Roy E. Miller,† M. Am. Soc. C. E.

With Discussion by Messrs. DeWitt D. Barlow, and William Gerig.

This subject will be discussed from the standpoint of the contracting engineer, with particular reference to the aid that can be derived in making estimates of the cost of earth work from a series of laboratory tests of samples of the earth to be moved.

When a project is under consideration, one of the vital factors to be given attention by all concerned is, "What will the work cost?" The point of view of each interested party depends on his personal interest in the work. When the project has progressed to the stage where it comes to the attention of the contracting engineer, the estimate of the cost is the all-absorbing factor. The contracting engineer goes a step farther than the project engineer in that he is obliged to make good his idea of cost by personal performance and financial guaranties. This means that every assistance that he can call on makes for security in his business, and helps to stabilize engineering and construction.

The character of the soil is the controlling factor in the cost of the work where material is to be excavated and placed by hydraulic dredging or by sluicing. Throughout this paper when reference is made to an hydraulic dredge, it should be understood to mean a pipe-line dredge of the radial type, that is, one swinging from a "spud" anchorage, and with a cutter for an agitator, which machine has come to be practically a standard tool for contractors' use in the United States. Sluicing, likewise, is meant to cover excavation by giants or monitors, and delivery through flumes by gravity or by booster pumps through pipes to the place of deposit.

The character of the material determines the difficulty or ease of digging or excavating, of pumping, and of retaining within the fill area. The writer's

* Presented at the meeting of the Construction Division, Seattle, Wash., July 15, 1926.
† Vice Pres. and Gen. Mgr., Puget Sound Bridge & Dredging Co., Seattle, Wash.

experience includes fills behind bulkheads to reclaim tide lands and marsh lands, to grade streets, platted city property, and mill and factory sites, to build dams for storage and river diversion for irrigation projects and city water supply, to replace railway trestles and bridges, and to permit the construction of harbor works, piers, docks, elevators, and warehouses.

The methods of estimating the cost of such work have been unsatisfactory on account of the many unknown and incomputable elements as compared with the degree of accuracy in estimating other engineering projects involving dry earth work, concrete, steel, etc.

In December, 1921, the Puget Sound Bridge and Dredging Company took a contract for building a storage dam on the Big Wichita River, about 50 miles from Wichita Falls, Tex. This dam was to be an hydraulic fill, 100 ft. high, with a reservoir capacity of approximately 550 000 acre-ft. In determining whether to take this work the Company was faced immediately with two important problems. The first was whether the borrow field contained the proper materials for making a satisfactory hydraulic fill and dam, should a large hydraulic dredge be used as was intended. Samples of the material were obtained, and Mr. I. F. Laucks, a chemist and assayer of Seattle, Wash., was called in to assist in analyzing the materials in order to arrive at an answer to this problem. The second—the cost of the work—could only be determined by rough comparison with results achieved elsewhere and of necessity was based wholly on personal knowledge and experience of the probable monthly output of the dredge. This, in turn, largely determined the unit cost of material handled, as the cost of operating the dredge was comparatively easy to estimate.

Dams have been built by sluicing methods for many years, and it was the experience gained therein that gave the Company the added confidence necessary to undertake to build the first dam with a dredge. Believing that a new field was being entered, wherein hydraulic dredging would find a place in the construction of earth dams, and knowing the difficulty of estimating work of this kind, and, further, finding so much aid from Mr. Lauck's laboratory work, the next logical step was to define some method of examining samples of earth taken from a proposed borrow field, which would assist in estimating the cost of work, particularly the probable output of a given dredge and the action of that material in a dam or fill.

Accordingly, it was decided to learn whether it would be possible to formulate a set of standard tests to be used as a basis for comparing specimens, as has been done with cement, steel, and other materials. It was hoped that a basis of comparison of earth samples could be established which would furnish a more or less correct idea of the probable action of the earth and of the performance of the machinery to be placed on the work.

It was recognized that any basis of predicting the behavior of a new earth or soil for dredging work would have to be comparative. There were no methods of testing soil to determine the cost of dredging. However, by determining the properties of various kinds of earths of which the characteristics and cost factors were known, and comparing them with the physical properties of a new

earth it was believed that such comparisons could be used as the basis for predicting the cost of working the new earth.

After considerable preliminary work had been done, it appeared that the most important element in a soil, as affecting its ease or difficulty of working, was the clay content and the special properties of the clay. Clay is the binding element which makes soils stiff, hard to dig, hard to disintegrate, sticky, etc. There are, of course, certain earths which might be cemented by calcareous or siliceous binder, but these are not nearly so common as clay binders. Looking at this problem in another way, a pure sand or gravel, or even a pure silt, presents no particular difficulties as far as digging is concerned. It is only when the sand or silt is held together by some binding agent that difficulty begins, and the most common binding agent is clay.

Clay is merely an empirical term for particles of a certain range in size and does not signify any pure substance with certain specific properties. In other words, clays will vary among themselves very greatly, depending principally on their fineness.

In this paper all particles are considered as clay which, when suspended under proper conditions in a considerable volume of water, refuse to settle in 24 hours, through a depth of 15 cm. This gives particles of a maximum size of 0.001 mm. Some authorities have defined clay as all particles less than 0.001 mm. in size; others include as clay all material less than 0.01 mm. Taking the definition of clay and considering the maximum size as 0.001 mm., it will be noted that there are all sizes from this upper size down to particles infinitely fine; that there is as much variation between the smallest and largest clay particles as there is between a fine silt and a large cobblestone. It is generally agreed that the special properties of a clay, as, for instance, its plasticity, stickiness, binding properties, etc., depend on the fact that it is a finely subdivided material, and, moreover, that these properties vary with the fineness, and shape. The surface area of the clay particle, or rather the ratio of the surface area to the mass, seems to be the important factor, and this ratio increases enormously with the fineness, and varies with the shape, of particles.

The tests which are proposed for each sample of earth, are not meant to be necessarily final, as it may be found that certain tests are not of much value and may be dropped, or that others are needed. However, it is believed that the following tests will be fairly comprehensive:

1.—The Percentage of Water Required to Bring the Earth to the Plastic Stage.—Instead of leaving this determination to the judgment of the laboratory operator, it is proposed to measure the penetration of a weighted needle into the mass of clay, which is fairly definite and can be checked quite closely. In experimental work the ordinary asphalt penetrameter is used. A penetration of 80° in 15 sec., the needle having no additional weights added, was adopted as standard.

2.—The Percentage of Water in the Earth in Its Natural Condition.—The test is to find plasticity of the earth in its natural condition as determined by the distance to which the needle will penetrate under the same conditions as in Test 1.

Tests 1 and 2, therefore, will indicate the stage of the earth in its natural condition as compared with the plastic stage. For example, if an earth in its natural state has a penetration of the needle of 20°, it is certain that it will require much more effort to dig than it would if it were at the plastic state. So another earth having a penetration of 40° would be easier to dig than one with a penetration of 20 degrees. If an earth required 20% of water to bring it to the plastic stage, that is, with a penetration of 80°, it would be found that the earth in its natural state, with a penetration of 20°, would contain perhaps 10% of water. If, on the other hand, a natural earth had a penetration of 140°, one would expect it to be easier to dig, as far as the power requirements are concerned, but it would be very sticky and might cause trouble by adhering to the cutter, etc.

3.—Determination of the Percentage of Clay, Silt, and Sand.—Clay is considered to be all those particles that fail to settle through 15 cm. of water in 24 hours. This gives the maximum size of 0.001 mm.

Silt is considered to be all particles which settle through 15 cm., in less than 24 hours, but fail to settle in 1 min. This gives a range of particles from 0.001 mm. as the finest to about 0.01 mm. as the maximum.

Sand is all particles coarser than the silt, subject, of course, to the distinction between sand and gravel.

Wherever the sand content of an earth is considerable, a screen test should be made on the sand. In the preliminary work a number of samples were graded into six fractions finer than sand. All the fractions were obtained by water settling through various periods and were then examined under the microscope and measured, but it was not considered necessary to do this in routine testing.

4.—Absorption of Water Vapor and a Dye.—This test is designed to distinguish clays of varying degrees of fineness by taking advantage of their ability to obsorb either water vapor or a dye. The dye used has been methyline blue. The finer the clay, the more of either is absorbed. It has been found that silt and sand absorb very little, so that the main absorption is due to the clay portion. This test is made on a dry earth.

5.—Rise of Water by Capillarity.—This test is made by filling a glass tube to a depth of 20 cm. with a dry earth packed by tamping until no further subsidence occurs. The lower end is closed with loose cloth and immersed in water. The rise of the water through the earth in the tube is measured from time to time; the time required for the water to rise 20 cm. is taken as the unit. Curves of time and height of rise for various earths showed a marked difference. This is largely a comparative test, but it is believed that further experiments with it will enable it to be made of considerable value in classifying an unknown earth.

6.—Percentage of Waters Absorbed by Capillary Action.—This is determined by pushing out the wet column of earth in Test 5 after the water has risen to the top and determining the percentage of water content. This is a comparative test, and is very important in determining certain actions of the material.

7.—Percentage of Water When Saturated.—This is determined by allowing some of the dry earth to absorb all the water that it will. The percentage of water is then determined.

Tests 5, 6, and 7 would also have an immediate practical bearing where the bank of dry earth to be dug will be submerged by the dredging pond. In such case, it is important to know how this bank of dry earth will absorb water by capillary action and how it will act after the water has been absorbed.

8.—Shrinkage in Volume Between the Saturated Condition and the Dry Condition.—This is determined by drying the saturated earth of Test 7 and measuring the contraction in volume.

9.—Slaking or Disintegrating Tendency of Natural Earth.—A piece of natural earth is immersed in water and the time required for the earth to fall to pieces is measured. Great differences have been found in samples tested. This is intended as a comparative test, and also as of immediate practical importance in considering earths that are to be passed through pipe lines.

10.—Water Absorbed by an Earth in Its Natural State and the Change in Plasticity Due to Such Absorption.—A piece of the natural earth is immersed in water, the quantity of water absorbed at different periods of time being measured. The penetration of the needle is also found. This is a comparative test, but also has immediate practical interest in regard to the change of the state of an earth when immersed by a dredging pond.

11.—Presence of Organic Matters.—This is merely a qualitative test to detect considerable quantities of organic matter.

12.—Rate of Settling of a Suspension of an Earth in Water.—This is designed to detect soluble salts or alkalies which may be present in an earth and which will affect the properties of the clay portion. For example, it is known that certain salts, such as gypsum, calcium bi-carbonate, iron salts, and others affect the properties of a clay by what is known as flocculation. These soluble matters cause the minute particles of clay to adhere to each other, to "flock together" to form an aggregate particle many times the size of the component particles. A clay thus flocculated tends to act more like sand or silt because the peculiar properties of clay depend on the fineness of the particles. On the other hand, substances such as sodium carbonate tend to deflocculate a clay. Whether a clay is flocculated or deflocculated is easily seen by its rate of settling in distilled water. This test would also have practical bearing with reference to the rate of settling in a fill.

Tests 13, 14, and 15, relative to percentages of voids in a natural earth, the ratio of the volume of water to the volume of voids in a natural earth, and the specific gravity of the particles, respectively, are comparative tests. It is also likely that Tests 13 and 14 will be found to be quite important as far as the working properties of an earth are concerned.

Proposed Method of Applying Data Secured

It is assumed that cost of work depends very largely on the daily output of the dredge and that all other cost factors are subordinate. On this assumption the following method of procedure is suggested: For example, select a

fairly uniform bed of earth sufficient for the dredge, say for one week, or for whatever time is considered sufficiently long to determine accurately its daily capacity in the material. Sample the earth in several places so as to be representative of material to be removed. The capacity of the dredge for this week would then be determined in the field, together with any special conditions encountered or properties of the earth which affect the ease or difficulty of working. In other words, the capacity of the dredge for the week and the ideas of the man in charge as to why the dredge had that particular capacity would be recorded. The samples would then be sent to the laboratory for testing.

This procedure would be followed as often as possible, the number of samples depending largely on conditions. That is, if the dredge had to dig in a strata of sand and clay during the week, the capacity would be influenced both by the sand and the clay, and there would be no object in taking samples of the mixture as the results would not be dependable, because it would not be known how long the dredge would be in the sand or the clay.

This procedure would give two sets of data, one from the field and the other from the laboratory. After a considerable number of samples had been thus tested and correlated with the field figures, it is believed it would be safe to begin predicting on samples taken from projected work. The procedure on projected work would be to sample the various kinds of earth and determine the properties of each. After these properties were determined, the results would be compared with those from samples on which work had already been done and on which the cost of digging had been ascertained.

It is probable that the properties will not match exactly, but curves can be established so that the values for new samples can be plotted and thus compared with old ones.

It will not be advisable to make predictions on new samples until a considerable number have been tested, as it is only by correlating the tests with known results of cost in the field that a foundation can be laid for foretelling the action of new samples.

Sampling of Earths

The samples should represent a body of earth of fair uniformity, should be taken from the earth in place, and should be put in tight containers so that no change will take place before the sample is tested. Samples for testing should not be taken to represent too large a body of earth because considerable variations may occur over large areas.

About 5 lb. of earth will be required to make the test outlined, and a 2-qt. tin can with a full width friction top, or some other tight-fitting top, will be satisfactory for carrying samples.

In more than three years since this plan of testing was begun, the writer's Company has had occasion to make estimates on earth work, particularly for hydraulic-fill dams, at widely separated points in North America, and has found the laboratory work to be of great help. Considerable success has also been had in analyzing materials to determine their suitability for fill purposes.

The most important factor determining the estimated cost of earth work by the hydraulic method is the probable output of the contractor's plant. In sluicing work the ability of the giants to excavate the material very often determines the output. In dredging, more often than not, the ability of the dredge to excavate the material determines the output, rather than its pumping capacity. This is particularly true of hydraulic-fill dams as they generally have good foundations which means either rock, hard-pan, or clay, and it is hardly to be expected that such material as soft harbor mud, or loose, water-bearing sand, will be found in such locations. Wherever the output is dependent on the ability of the dredge to excavate the material, the study of earth samples as suggested is meant to apply.

Sufficient time has not elapsed to give a complementary set of records in the field and in the laboratory which will enable the Company to depend largely on the laboratory reports. It is too much to expect that laboratory reports may take the place of practical knowledge and experience, particularly as so many other factors have a bearing on the cost of work. It is expected, however, that in a few years the laboratory work will have been perfected, records will have been accumulated as to performance, and knowledge increased so that the laboratory will be a valuable adjunct to the earth-moving business.

If work is limited to a comparatively small field, particularly on tide-water, there may be no justification for a study such as suggested. However, the average dredging job is no longer a simple problem of excavating harbor and mud and pumping it a short distance, wasting the material, or, at best, making a simple fill with it. Broader knowledge is required by those responsible for hydraulic operations, and this, in turn, requires more dependence on laboratory research work.

DISCUSSION

DeWitt D. Barlow,* Assoc. M. Am. Soc. C. E. (by letter).—The author has described a method for classifying field data with the view to building up a store of information that will enable dredging engineers to estimate their work with less uncertainty. The proposed method is to record the hourly "capacities" of hydraulic dredges wherever they work in uniform beds of material, and simultaneously to record certain physical characteristics of the material as the same may be revealed by laboratory tests for absorption, flocculence, etc. The method seems obvious enough, especially to one not acquainted with the physics of the problem. It assumes that the output of the dredge varies with the previously mentioned characteristics of the material dredged, and with nothing else. Both assumptions are false.

In the writer's opinion the procedure described under the heading "Proposed Method of Applying Data Secured", will not produce results of any value. The capacity of the dredge is a variable quantity of great complexity, contingent on many things other than the material dredged.

The output of a hydraulic dredge (per engine-hour) is governed by two main factors, both of them complex; that is, the amount the dredge can dig, and the amount it can pump ashore. Either quantity may control. It cannot pump more than it can dig, and it cannot continue to dig more than it can pump, so that the first thing the experimenter must do, is to classify the material as to its digging and its pumping qualities.

The digging must be canvassed, not on the basis of what the dredge can do, but on the type of cutter used, the horse power and torque applied to the cutter shaft, and the tension and horse power on the swinging wires. When these data are assembled, they should be examined in connection with the physical characteristics of the material with which they vary.

The author's statement that "more often than not the ability of the dredge to excavate the material determines the output, rather than its pumping capacity", is only another way of stating that the dredges that have come within his observation were under-powered on the cutter or over-powered on the pump. It is incorrect.

The best way to classify material with respect to cutting is to measure its resistance to cutting. For this purpose the writer prefers an auger to any amount of litmus solution. Entirely satisfactory estimates are made in this manner. The hazards in hydraulic dredging estimates do not reside there. They are to be found in the extreme sensitiveness of the pumping operation to differences in the coarseness of particles to be pumped and to variations in the material excavated from the samples on which the estimates were based.

Consider the question of pumping, assuming that the cutting power is adequate. The operation of hydraulic dredging consists in maintaining a flow of water through a pipe line and of introducing into the stream, solid material which is carried in suspension and along the bottom of the pipe. The cutting

* Pres. and Director, Atlantic, Gulf & Pacific Co., New York, N. Y.

or digging, referred to, is the introducing process. The stream is kept in motion by a centrifugal pump; the solid material is introduced on the suction side. In the conduct of the operation it is possible to run more solids into the stream than the stream will carry off. That is what is meant by the statement that the pumping controls. Under that condition some of the solids settle out and lie in the bottom of the pipe, the cross-section is throttled, the output is diminished, and a limit is found to the pumping capacity. This limit is controlled by many factors; among others, the available torque on the pump, the maximum speed of the pump, its efficiency (which varies from zero through 70% and back to zero for different speeds and heads), the horse power of the prime mover, its power characteristics, the length of pipe line, its size and character (pontoon lines ordinarily consume, in power per unit of length, from 150 to 200% of that consumed by the shore line), the elevation of the end of the hydraulic grade, and the material.

In order to discover the effect of variation in material on the rate of pumping, it is necessary to eliminate or standardize the other factors. The way to do that is to ascertain, not what the dredge will do in a given material, but to determine the horse power (hydraulic) consumed per unit length of a standard pipe, per cubic yard of that material carried in suspension at the saturation point. That figure is important and is the one that dredging engineers want. It varies with several factors, more especially specific gravity and coarseness. Most sands, clays, and muds are of a silica base, so that the specific gravity is usually constant. There is, of course, the widest range in the size of particles, and a corresponding wide range in the "dredging power factor", if the writer may be allowed to coin a term. In fact, the "dredging power factor" is so sensitive to the size of particle that hardly anything else counts. As between fine beach sand and sand of the consistency of granulated sugar, there is a range of 300% or more. If one goes as far up the scale as gravel of, say, the size of lima beans, the range will be more than 1 000 per cent. The larger the particle, the more power required to move it.

The way to determine the coarseness of material is to sift it. When that is done and its specific gravity is known, one can classify it as to its power factor, but the error, due to the character of the experimental data, will be a quantity of far greater magnitude than the whole field affected by capillarity and the experiments mentioned by the author.

These remarks should not be taken in disparagement of research. It is badly needed in dredging. The writer is enthusiastic for research and wants to direct it where it will be effective. The author's method is far too empirical. It assumes a simple relation where there is a complex one, and the aspect of that relation which it investigates is negligible. It is completely masked by the major phases of the problem, which he ignores.

William Gerig,* M. Am. Soc. C. E. (by letter).—The author proposes laboratory experiments to determine the cost of work done by hydraulic methods. In view of the many unknown quantities that go to make up the cost of hydraulic work, even if the character of the material is known, the writer

* Senior Engr., Office of Chf. of Engrs., U. S. Army, Washington, D. C.

does not see how such data will be of much value. Some of these unknown factors are, capacity of the dredge, capacity and power of the cutter, design of the sand pump and cutter, efficiency of the plant as a whole and of the crews, etc. Therefore, even with the laboratory data at hand, one must also know the capacity of each piece of plant in the material under consideration.

Laymen and even some engineers appear to believe that the only requisites for hydraulic suction dredging are a pump, an engine, and the necessary suction and discharge pipes, while the cost of excavation is assumed to be about 10 cents per cu. yd. The fact is that economic hydraulic dredging by suction dredges costs from 3 to 90 cents per cu. yd., a wide range which no doubt will be questioned by many readers of this discussion, but which can be proved to be true.

While laboratory experiments are useful to the profession and the writer does not wish to discourage them, he does not feel that they are entirely dependable. Judgment and experience are the prime factors in determining the cost of hydraulic work, and no laboratory rule or method alone will enable the inexperienced engineer or layman to estimate such cost with any degree of precision.

An interesting case illustrating these statements is that of the deep-water channel for Tampa, Fla., entailing the removal of about 2 500 000 cu. yd. Borings and probings showed about one-half the material to be coral rock and the remainder, or overlying material, to be sand. The types of plant considered by the engineers to be best adapted to this work were suction and dipper dredges. Specifications were prepared and bids invited. Two bids were received, one, $5.20, and the other, $4.63, per cu. yd. These bids, being considerably in excess of the estimate, were rejected and the work was done by a Government-owned cutter pipe-line dredge.

The rock and the sand were both removed at a total cost of 90 cents per cu. yd., including interest, depreciation, insurance, etc. This cost would have considerably exceeded 90 cents, however, had any other type of plant been used. Many millions of dollars were saved by using this type of dredge.

In this case the character of the material was known and yet, due to the type and efficiency of hydraulic plants considered for the work, there was a wide difference of opinion as to the estimated costs, and the actual costs were considerably less than the estimate.

Paper No. 1690

THE HYDRAULIC DESIGN OF FLUME AND SIPHON TRANSITIONS*

By Julian Hinds,† M. Am. Soc. C. E.

With Discussion by Messrs. H. B. Muckleston, F. Theodore Mavis, W. H. R. Nimmo, Carl Rohwer, and Julian Hinds.

Synopsis

Considerable attention has been given by the United States Bureau of Reclamation to the hydraulic design of transitions for flumes and siphons, and rules have been established for the proportioning of important structures. A summary of these rules and of the experiences leading up to them is herewith presented. No attempt is made to furnish a complete treatise on transition structures, and only points on which definite experience has been gained, or opinions have been formed, are introduced.

Although the discussion is generally confined to inlets and outlets to and from inverted siphons and flumes, the principles established may be applied to any structure designed to change the shape or cross-sectional area of an open stream of water.

In this paper the following principal facts are shown:

1.—Unimportant transitions, where velocities are low, may be designed arbitrarily, by adaptation from successful structures operating under similar conditions.

Note.—The Special Committee on Irrigation Hydraulics selected the subject of "Losses in Canal Conversions" as one of ten for study and research. This paper was submitted to the Committee by the author, and the Committee recommended its publication. (See Progress Report of the Committee, *Proceedings*, Am. Soc. C. E., March, 1927, Society Affairs, p. 121).

* Published in October, 1927, *Proceedings*.

† Res. Engr., The J. G. White Eng. Corporation, Pabellón, Aguascalientes, Mexico.

2.—For important structures, especially those involving velocities in excess of 6 to 8 ft. per sec., careful detailed computations must be made. Extremely slender, and carefully constructed, transitions, if not proportioned in exact accordance with the hydraulic requirements, may prove seriously defective. Examples of such cases are shown, and a proposed method of computation is outlined.

3.—Experimental data collected by the U. S. Bureau of Reclamation are summarized, showing the efficiencies that may be expected with various types of construction, the effects of conduit curvature on outlet efficiency, and the influence of critical flow and the hydraulic jump on the action of inlets and outlets.

Division of Subject

The subject is discussed under four main headings, as follows:

1.—Unimportant, or low-velocity structures, not involving the hydraulic jump or flow at the critical depth.
2.—Important, or high-velocity structures, not involving the hydraulic jump or flow at the critical depth.
3.—Structures involving the hydraulic jump or flow at the critical depth.
4.—Experimental data.

Notations and Abbreviations.—The notations and abbreviations used are listed for convenient reference, as follows:

A = area of water prism.
Q = discharge.
V = velocity.
WS = water surface.
ΔWS = change in water surface.
h_v = velocity head.
Δh_v = change in velocity head.
B = bottom width of channel.
T = width of channel at water surface.
d = depth of water.
H = height of lining or wall.
s_f = friction slope.
h_f = head lost in friction.
W = width of channel at top of lining or wall.

1.—The Design of Secondary Structures not Affected by Critical Flow

All structures for changing the shape or cross-sectional area of a water conduit cause disturbances in flow, which may be objectionable in themselves or in the resulting losses in head. In designing an inlet, it is necessary to provide for a drop in the water surface, sufficient to produce the required increase in velocity head and to overcome friction and entrance losses. At an outlet the water surface will rise theoretically a vertical distance equal to the reduction in velocity head. The actual rise, usually referred to as recovery of head, is less than the theoretical, because of frictional and outlet losses.

No satisfactory theory for computing the transition losses for a given structure has been proposed. The magnitude of these losses can only be deter-

mined experimentally at present. The simple considerations outlined herein are often taken as sufficient for the design of a transition, the form and details being determined from precedent.

The U. S. Bureau of Reclamation, over a period of more than twenty years, has accumulated a large variety of detailed designs for transition structures of secondary importance. The preparation of a new design for a structure of this class is usually accomplished by changing the details of a previous structure, known to be satisfactory, to suit the new conditions. A collection of possible types of simple transitions, sketched from some of these designs, is shown on Figs. 1, 2, 3, and 4. These structures differ widely in degree of perfection, and in the losses which they may be expected to produce.

The simplest forms of pipe inlets or outlets are illustrated by Types (1), (2) and (3), Fig. 1. These types are used for culverts, and are satisfactory for small pipes. It is probably reasonable to assume entrance and outlet losses equal to 0.5 and 1.0, respectively, of the velocity head in the pipe for these structures. Types (4), (5) and (6), Fig. 1, are somewhat more complicated structurally, and are perhaps slightly better hydraulically. Type (7), Fig. 1, which is sometimes used for carrying small irrigation canals under roads and railroads in cuts, is poor hydraulically, and is subject to stoppage by silt and weeds. Types (8) and (11), Fig. 1, are slightly better, but more expensive to construct. Types (9) and (10), Fig. 1, are fairly efficient, involving entrance and outlet losses, respectively, of perhaps 0.25 and 0.50 of the velocity head. Types (12) to (17), inclusive, Fig. 2, illustrate trash rack, weir, and control-gate arrangements for pipe inlets.

It is considered advantageous to affect velocity changes under pressure, where convenient, and Types (18) and (19), Fig. 2, are perhaps more efficient than the somewhat similar Types (9) and (10), Fig. 1. However, it is doubtful whether their increased cost is justified. Type (20), Fig. 2, shows a device sometimes used to check high velocities at the outlet of a pipe or culvert. Types (21) and (22), Fig. 2, show pipe ends which may be constructed without the use of forms, provided the bank around the pipe can be trimmed to the required dimensions. An inside form is required for the bellmouth in Type (21). Type (23), Fig. 3, utilizes a precast bellmouth, and requires no forming. Types (24) to (28), inclusive, Fig. 3, represent the best practice in transition structures constructed without accurately computed proportions. It is doubtful whether an outlet as elaborate as those shown on Types (27) or (28) should ever be constructed without having the proportions carefully calculated throughout. Fig. 4 shows a number of flume transitions varying from a simple head-wall, Type (30), to a carefully warped structure, Type (40).

A type of structure suited to a given set of conditions may be selected from the examples in Figs. 1 to 4, the probable loss of head estimated by comparison with some structure for which the losses have been measured, and a reasonably good design prepared. The observed data given on Fig. 17 will be found helpful for estimating the losses.

FIG. 4

All the types shown on Figs. 1, 2, 3, and 4, indicate construction in concrete, but many of them may be built of timber. The hydraulic properties of timber transitions seldom receive serious consideration, for which reason purely wooden types are not shown.

2.—The Design of Important Transitions, Not Involving Critical Flow or the Hydraulic Jump

Experience indicates that the method of design outlined for simple structures is not adequate for important installations, especially where velocities are relatively high. Under such conditions, the detailed dimensions and forms of the structure, throughout its entire length, become important. Sometimes the assumption is made that perfection can be approached by reducing the angle of divergence of the transition. That this is not necessarily true is illustrated by a comparison of the structures shown on Figs. 5 and 6. The extremely slender outlet from Columnar Tunnel, Tieton Canal (Fig. 5) is less efficient than the more abrupt outlet from the North Fork Tunnel (Fig. 6). These two outlets are on the same canal, and both were designed before even the present limited knowledge of high velocity hydraulics had been developed. The comparative hydraulic efficiency of these two structures is shown by Types (*r*) and (*t*), Fig. 17.

A similar situation is shown in the two outlets in Fig. 7, which are of similar form, and are installed on the King Hill Project of the U. S. Bureau of Reclamation, in Idaho. The Big Pilgrim Outlet is good. The designed dimensions of the Deer Gulch Outlet were slightly changed in the field, to meet local conditions. As a result, the outlet is so inefficient as to require reconstruction, although this was not apparent from an inspection of the revised design for the structure. In fact, the results were so surprising that it was at first thought that some error had been made in construction. However, the structure was found to conform to the design as altered in the field and recomputation of the hydraulics showed reasonable agreement between the observed and computed actions. Figs. 8 and 9 show the Columnar and Deer Gulch Outlets, respectively, in operation.

Consideration of these, and other less glaring examples for both inlets and outlets, led to the conclusion that careful attention should be given to the detail dimensions of the transition throughout its entire length. A study of the situation showed the computed water-surface profile to be irregular, or to contain at least one sharp angle, for all known faulty structures, except a few which are influenced by curvature in the channel above, as will be noted later. Accordingly, a new criterion for design was adopted, namely, that the computed water-surface profile through the transition shall be a smooth, continuous curve, approximately tangent to the water-surface curves in the channels above and below.

Undoubtedly, there is some particular form of surface curve best suited to any given set of conditions, but no data for the determination of the correct curve are available. Also, the length of the curve, or the slenderness of the structure, probably bears a definite relation to the efficiency of the transition, which relation is yet to be determined.

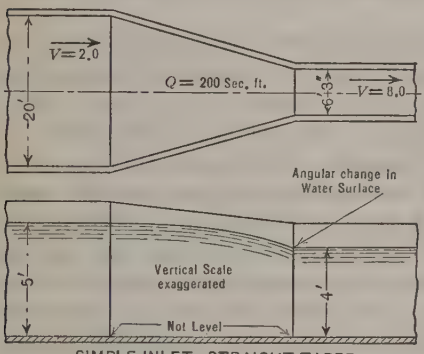
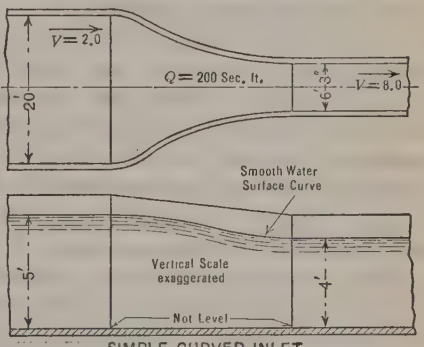
The application of the rule just given is illustrated by the two simple structures shown in Figs. 10 and 11. Before computing the hydraulics, the inlet shown in Fig. 10 might be considered good. However, if the hydraulics are computed at short intervals throughout the structure, the surface curve will be found to contain a sharp angle at the junction with the narrow channel, and marked disturbances in flow may be expected. By properly curving the walls of the inlet, as shown in Fig. 11, this condition can be avoided, the rate of change in acceleration being changed in such a way that the water-surface profile becomes a smooth, continuous curve.

A plan based on the principles illustrated in Fig. 11 is used by the U. S. Bureau of Reclamation for all important transitions. If desired, the dimensions of the structure may be assumed and the surface curve computed from Bernoulli's theorem, the dimensions being subsequently changed and the curve recalculated until satisfactory results are secured. A more direct solution is obtained if the water-surface curve is first determined and the dimensions of the structure are computed to conform. The procedure recommended will be illustrated by examples of actual designs. Before attempting to prepare designs similar to these examples the discussion of experimental data should be reviewed, especially that part which relates to the effect of curvature in flumes and siphons on the action of their outlet structures.



SIMPLE INLET—STRAIGHT TAPER

Fig. 10.



SIMPLE CURVED INLET

Fig. 11.

Example of a Flume Inlet.—Referring to Fig. 12, let it be required to design an inlet from an earth canal with a bottom width of 18 ft., side slopes of 2 : 1, to a rectangular concrete flume, 12 ft. 6 in. wide. The hydraulic properties of the canal and the flume may be assumed to be known, as shown on the diagram.

It is desirable first to determine approximately the length that will be required for the transition. In the absence of specific knowledge this must be done arbitrarily. For structures of the type under consideration the U. S. Bureau of Reclamation has adopted the rule of making the length such that a straight line joining the flow line at the two ends of the transition, as *D-E*, Fig. 12, will make an angle of about $12\frac{1}{2}°$ with the axis of the structure. In the example shown the resulting length is 50 ft.

From information given in the discussion of experimental data, it appears that, for a structure of the type contemplated, the entrance loss may be safely assumed as 0.1 the change in velocity head, making 1.10 Δh_v, the total drop to be provided, plus the drop necessary to overcome friction. If the water-surface elevation in the canal at the upper end of the inlet is known, and if friction is temporarily neglected, the water-surface elevation in the flume at the lower end of the transition can be found, and the two end points, *A* and *C*, of the water-surface profile, *A B C*, Fig. 12, determined. Between *A* and *C* the water surface theoretically may be made to follow any desired profile, within reasonable limits, the profile being controlled by the shape and size of the transition structure.

If the flow is to be smooth and the structure efficient, the theoretical water surface must be free from angles or sharp curves. The particular curve that fits the given conditions better than any other not being known, any smooth curve tangent to the normal water surface in the canal, at *A*, and in the flume, at *C*, may be used. It may be drawn arbitrarily or computed. In Fig. 12, the water surface, neglecting friction, is taken as two equal parabolas, horizontal, respectively, at *A* and *C*, and tangent at *B*. Strictly, the parabolas should be tangent to the water-surface slopes in the canal and the flume, but the small divergence of these slopes from the horizontal is unimportant in the present example.

A number of sections are next chosen across the transition at which to compute the elevations of the water surface and the structural dimensions. It is convenient to have these sections equally spaced. Referring to Fig. 12, it will be noted that the total change in velocity head, from *A* to *C*, neglecting friction, is 0.480 ft. The parabola with vertex at *A* is constructed by making the drop from *A* to the mid-point, *B*, one-half the total drop, or 0.240 ft. The drops to points between *A* and *B* are proportional to the squares of the distances from *A*. The drops for the right half of the surface curve are obtained by subtracting the corresponding drops for the left half from the total drop. The drops, computed in this way, are recorded in Line 1 of Table 1. Assuming that the conversion loss is distributed over the entire length of the transition, in proportion to the change in velocity head, values of Δh_v are obtained by dividing the computed values of $\Delta W S$ by 1.10. The velocity head is obtained by adding Δh_v to the velocity head at *A*. The velocities corresponding to the assumed water-surface curve are then determined, as recorded in Line 4, Table 1, and the required area of cross-section is computed as shown in Line 5. Except that no allowance has been made for friction, this completes the hydraulic design, the area of the section at each point of sub-division being known. It remains, however, to choose shapes for the various sections, such that they will fit with each other to produce a structure of pleasing appearance, free from angles and sharp curves. The work from this point depends largely on the skill and experience of the designer. Sections may be either arbitrarily chosen and platted until satisfactory results are obtained, or the problem may be attacked systematically.

TABLE 1.—Computations for Flume Inlet.

In flume, $V = 5.98$ $h_v = 0.553$ Elevation of water surface at 0 + 00 = 57.41

In canal, $V = 2.75$ $h_v = 0.117$ Entrance loss = $0.1\ \Delta h_v$

$\Delta h_v = 0.436$ Water surface, reversed parabola.

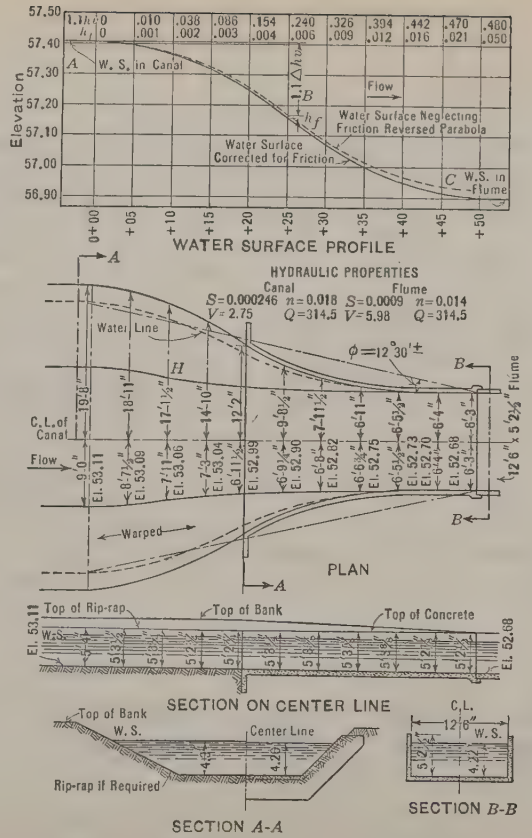

FIG. 12.—TYPICAL RECTANGULAR FLUME INLET.

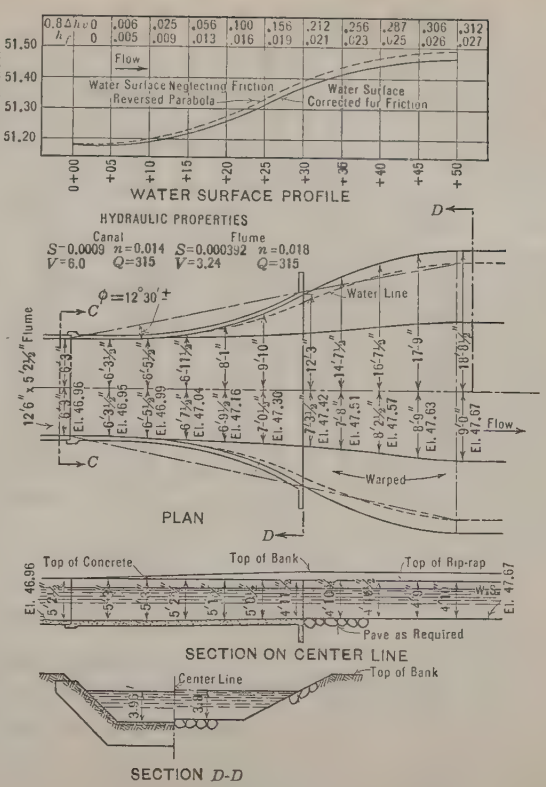

FIG. 13.—TYPICAL RECTANGULAR FLUME OUTLET.

A convenient start may be made from arbitrarily sketched plans of the water line, shown dashed in Fig. 12, and of the intersection of the side slope and the bottom. The proper trial shape of these plans is a matter of judgment. The maximum angle of divergence between the water line and the axis of the structure should not be too great. A limit of 25° is recommended. These two plans having been drawn, the half top widths and half bottom widths are scaled, as recorded in Lines 6 and 7, Table 1. The sum of these half widths gives the average width from which the depth of water may be computed.

Having determined the velocity, and the shape and depth of the channel, the friction slope, s_f, and the accumulated friction head, h_f, for each point may be computed. The water-surface profile may then be corrected for friction, and the profile of the bottom of the channel computed and platted. This latter profile should be free from objectionable irregularities. Otherwise, the assumed plan may be changed as required, to increase or decrease the depth at points of irregularity. If it is not possible to secure regularity in both the plan and the bottom profile, the assumed water-surface profile may be altered. A slight change in the elevation of the water surface at a given point usually makes an appreciable change in the dimensions of the structure.

It is advisable to plat a preliminary bottom profile before computing the friction slope. The friction makes very little change in the form of the bottom profile, and labor is saved by leaving it until the profile is otherwise satisfactory. In fact, the frictional losses may often be entirely ignored without serious error.

The last six lines of Table 1 relate to the structural dimensions of the transition, and are self-explanatory. Figures for these lines need be inserted only for the design finally adopted.

Example of a Flume Outlet.—An outlet transition from a flume is designed in the same way as an inlet, the only essential difference being that the conversion loss is subtracted from Δh_v to obtain $\Delta W S$. A typical design for an outlet from a rectangular flume to an earth canal is shown in Fig. 13. The computations are shown in Table 2.

In the example shown, the length of the outlet structure is determined on the same basis as the length of the inlet structure. It is now generally conceded that for equal efficiency an inlet may be made shorter than an outlet, for the same velocity change, and it is hoped that the discussion of the subject will bring out definite rules for determining the proper length of each type of structure. The experience of the U. S. Bureau of Reclamation indicates that for properly designed outlets of the type shown in Fig. 13, a length as determined by making $\phi = 12\frac{1}{2}°$ is sufficient for ordinary purposes. Inlets are generally made the same length because: (*a*) Sharper warps are difficult to construct; (*b*) short transitions do not afford secure anchorage to the canal; (*c*) using the same length makes the forms interchangeable; and (*d*) an average divergence of $12\frac{1}{2}°$ yields a structure of pleasing appearance and reasonable cost.

Table 2 is similar to Table 1. It will be noted that an allowance of 0.2 Δh_v is made for outlet losses, which is somewhat more than might be expected from existing experimental data. Any excess in possible recovery of head over the computed recovery affords a small margin of safety against a reduction of free-board due to fouling of the canal below the flume. If there is any doubt as to the maintenance of a clean channel below the flume a greater allowance for outlet loss should be made. In extreme cases it may be desirable to assume no recovery at flume outlets, even for structures of careful design. The full actual recovering capacity of the outlet is thus made available for raising the canal water surface above normal without encroaching on the computed free-board in the flume.

Where an allowance is made for a greater outlet loss than is actually necessary, the destruction of the excess energy must be considered. If the flume velocity is relatively low, the depth being greater than the critical depth, a recovery will actually occur at the outlet, whether provided for or not. The velocity in the flume will be increased because of the excess head, and the depth decreased, making recovery necessary. If flow in the flume is at or below the critical depth no draw-down above the outlet is possible, and the excess energy must be dissipated in waves and eddies, or by a hydraulic jump, in the canal or in the outlet. The resulting eddies may cause the canal to erode.

Example of a Siphon Inlet.—The design of a transition from an earth canal with a 12-ft. bottom width to a siphon 7 ft. in diameter is illustrated in Fig. 14 and Table 3. The procedure shown differs from that recommended for flume inlets in two particulars. Part of the change in velocity is made under cover, in the transition from square to circular conduit. Any attempt to control minutely the form of this part of the transition results in construction difficulties. The transition, therefore, is usually computed only up to the head-wall. Since the velocity is still increasing at the head-wall, it is not desirable to use two equal tangent parabolas for the surface profile through the inlet. The part of the surface curve to the right of the point, *J*, on the water-surface profile, Fig. 14, is fixed. The curve from *I* to *J* should be drawn approximately tangent to it. However, certain other necessary irregularities at *J* make exact tangency unimportant, and the practice has been established of assuming a single parabola, with a vertex at *I*, passing through the computed water surface at *J*. The parabola is chosen for convenience, and not because of any supposed superiority over other forms of curves. The drop from *I* to *J* is taken as 1.1 Δh_v, the velocity at *J* being computed from the area of the square covered conduit.

It is considered desirable to have the top of the siphon barrel at the head-wall of the transition slightly submerged at full flow. This is thought to minimize reduction in capacity due to the introduction of air into the siphon. It is the practice of the U. S. Bureau of Reclamation to place the theoretical corner at the intersection of the head-wall and the top of the siphon barrel 1.5 Δh_v below the water level at the up-stream end of the inlet, with a minimum of 18 in. This practice makes it impracticable to construct the

TABLE 2.—Computations for Flume Outlet.

In flume, $V = 5.98$ $h_v = 0.553$ Elevation of water surface at $0 + 00 = 51.18$

In canal, $V = 3.24$ $h_v = 0.163$ Outlet loss $= 0.2\ \Delta h_v$

$\Delta h_v = 0.390$ Water surface, reversed parabola.

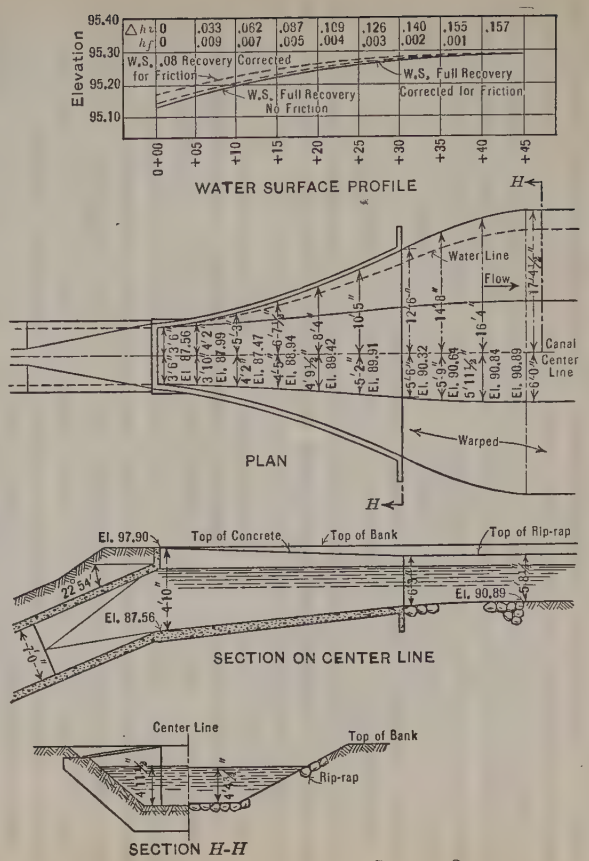

FIG. 15.—TYPICAL CONCRETE SIPHON OUTLET.

lower end of the transition strictly in accordance with the computations. Under this condition sections just inside and just outside of the siphon barrel cannot be made hydraulically equivalent. The computations in Table 3 are carried to the end of the transition, but the computed dimensions at Stations $0 + 40$ and $0 + 45$ are ignored. The conduit floor is drawn to a smooth connection between other computed points and the floor of the siphon barrel. With these exceptions the computations in Table 3 are similar to those in Table 1. The fact that the conduit is covered at points of high velocity makes it possible to take the liberties mentioned.

Example of a Siphon Outlet.—The necessity for holding the top of the siphon barrel down at the head-wall does not exist at a siphon outlet, and computed dimensions may be followed throughout. The same condition as to change of velocity under cover exists as at the inlet. Fig. 15 represents a typical outlet design, the computations for which are shown in Table 4. The water-surface profile is taken as a single parabola, as recommended for a siphon inlet. As it is not desirable to curve the floor of the siphon barrel this procedure usually results in a vertical angle at the intersection of the siphon and the floor of the transition. An angle in the floor is less objectionable than an angle in the side walls, and, if small, apparently does little harm. For an outlet such as that shown in Fig. 15, the action can be improved by arbitrarily rounding the floor angle to a short radius.

Recovery conditions at a siphon outlet are not the same as at a flume outlet. If a flume outlet fails to recover the head demanded of it, the water is backed up in the flume and the free-board is decreased. It is desirable, therefore, to design for only a part of the probable recovery, as previously indicated. In the case of a siphon, failure to realize the computed recovery means a slight increase in pressure in the barrel, which is of no importance, except as it affects the elevation of the water surface above the intake to the siphon. If the outlet is properly set any excess energy will be consumed at the inlet, or in the canal above the inlet. If the outlet is set too high the excess energy will be destroyed below the transition and may cause undesirable disturbances. It is advantageous, therefore, to set the outlet for the fullest recovery likely to be obtained, although in computing the over-all losses through the siphon proper, allowance should be made for outlet loss. For an outlet of the type shown in Fig. 15, it is recommended that the over-all loss through the siphon be sufficient to allow for an outlet loss of $0.2\ \Delta\ h_v$, and that the outlet be detailed on the basis of no outlet or friction loss.

3.—The Influence of the Hydraulic Jump and Critical Flow

The preceding discussion is strictly applicable only where the hydraulic jump and flow at the critical depth are not involved. Where these factors are encountered additional precautions are required, although rules laid down for general proportions still hold. Numerous papers on the hydraulic jump have been published in the last few years. The influence of these factors on the design of transitions was discussed by the writer in 1920.* No im-

* Friction and outlet loss ignored in detailing outlet structure. In computing total drop through siphon allow for outlet loss = $0.2 \Delta h_v + \Sigma h_f$.

portant new data on this subject have been developed by the U. S. Bureau of Reclamation.

It may be well to emphasize again the fact that the unexpected and unnecessary introduction of critical flow conditions is a frequent source of trouble in transitions. This condition is illustrated in the outlet shown in Fig. 5. Although the total length of this structure is 100 ft., the velocity actually increases to a point near the lower end, where it suddenly "jumps" to approximately canal velocity. The normal depth in both the tunnel and the canal is above critical, and, if proper attention had been given to the detailed dimensions, the jump would have been avoided and the efficiency of the outlet increased. In addition, heavy wave action in the canal would have been avoided.

A situation of this kind is not likely to escape notice with the plan of computation recommended in this paper. However, it is essential that any approach to the critical depth be carefully noted. Before attempting to plan an important transition the designer should be thoroughly familiar with the phenomenon of critical flow.

Impact Troubles in Long Siphons.—As previously mentioned, the excess energy in a pipe line is consumed in the canal above the inlet, in the inlet, or in the upper end of the pipe. If the excess fall is small it is usually absorbed in a moderate increase in velocity in the canal, which does little harm. With greater fall, racing in the canal may become serious, and a check may be required at or near the intake to the siphon. The destruction of energy is thus transferred to the inlet.

In irrigation conduits, pipe lines are seldom controlled by gates or valves, the fall provided being only that required to maintain flow at maximum capacity. In the interest of conservatism the allowance for losses is usually greater than the actual requirement. If the pipe line is long the excess fall may be too great to be entirely absorbed in the inlet, and the water will race down the pipe for a distance at part depth, to be checked suddenly where it meets the back-water from the outlet. In large siphons of considerable length, operating at part capacity, this condition often results in serious vibrations. Because of certain manifestations this phenomenon is frequently referred to as "air trouble," and many unsuccessful attempts have been made to relieve the vibrations by the installations of vents, or by revision of the inlet structure. This is not a transition problem and is treated here only because it is often considered to be related to the inlet structure.

An example of a pipe line operating in this way is shown in Fig. 16. This siphon, which is on the King Hill Project, in Idaho, was constructed by a predecessor of the U. S. Bureau of Reclamation at a time when the project was expected to embrace a larger area than that ultimately developed. The capacity is considerably in excess of the actual requirements. The conditions shown in Fig. 16 were observed in July, 1925, with a flow of 120 sec-ft. With this discharge a heavy rumbling and a very noticeable vibration were noted some distance down the pipe from the inlet.

The disturbance appeared to lie wholly below the hydraulic gradient computed from the outlet structure as a control. This is in accordance with

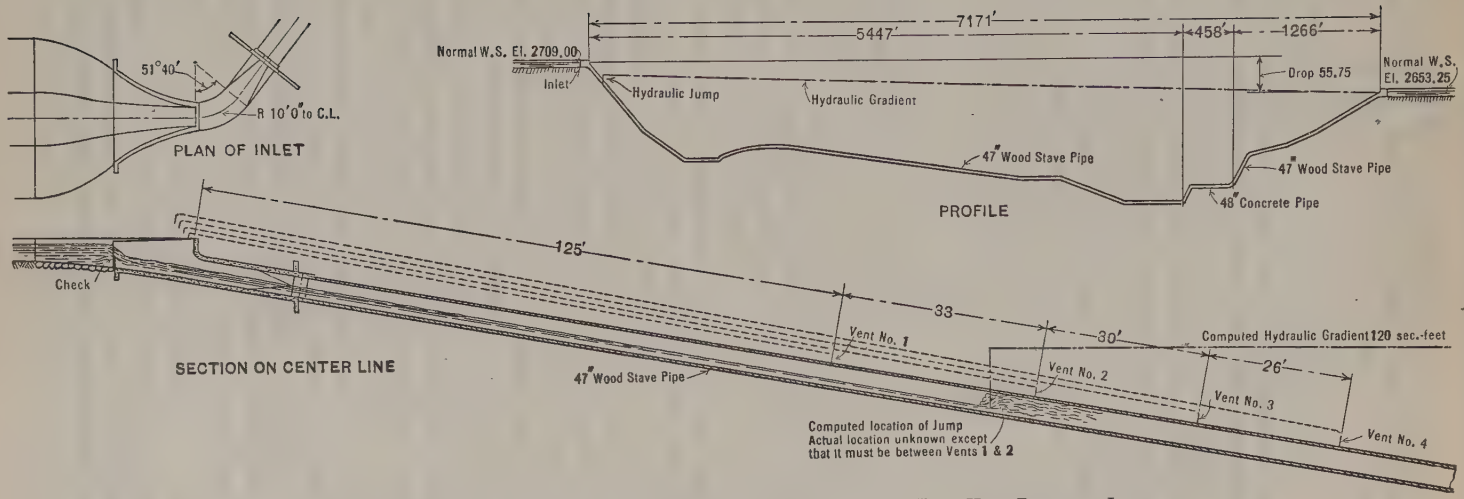

FIG. 16.—INLET AND HYDRAULIC FEATURES, GLENS FERRY SIPHON, KING HILL PROJECT, IDAHO.

theory. It will be noted that the flow theoretically changes suddenly through the hydraulic jump, from part depth to full depth, under considerable pressure. The theoretical magnitude and location of the jump are obtained by finding the point at which the factors,* $\frac{Q}{g} V + p$, for high and low-stage flow, are equal, in the same manner as for an open channel. The only special features in a pipe is that the pressure head on the high-stage side is measured down from the hydraulic gradient, computed from a control at the outlet, and that all other high stage factors are constant. The theoretical data were not available when the pipe was inspected, and the nature of the phenomenon was not fully comprehended. The position and magnitude of the jump were not determined with precision, but incidental observations indicate close conformity with theory. Four 1½-in. pipe vents, installed in a previous attempt to relieve the "air trouble," served to indicate conditions in the pipe. These vents were located as shown in Fig. 16, and were carried up the pipe and arranged to discharge any possible spray back into the canal over the inlet head-wall.

The seat of the disturbances is not stationary, but moves over a considerable length of pipe. Heavy rumblings accompanied by vibrations originate below Vent 3, Fig. 16, and move slowly up the pipe, ending in an explosion at a point above Vent 2, to be immediately repeated. Apparently, small air-bubbles released below the jump gradually accumulate in the top of the pipe until a pocket of sufficient magnitude is formed to force its way back up stream. The region of maximum disturbance seems to follow the bubble, producing the illusion that the air is the cause of the trouble.

It was thought that relief might be afforded by the elimination of the air. The vent pipes shown in Fig. 16 were originally installed for this purpose, but proved to be inadequate. A small wooden trough was temporarily bolted along the inside top of the pipe, allowing a space between the edges of the trough and the surface of the pipe for the infiltration of air, and apparently all the air was removed. The disturbances were then confined to a length of about 12 ft. of pipe, which is approximately the length that a hydraulic jump of this magnitude might be expected to occupy. The vibrations were noticeably more severe than they were before the removal of the air. The conclusion was reached that the vibrations are caused by the hydraulic jump, and are only incidentally affected by air. Two other siphons on the main canal of the King Hill Project operate in the same way.

This discussion has no relation to the introduction of air into siphons at full flow with a consequent reduction in ultimate carrying capacity. The writer has had no personal experience with this condition, which is supposed to be caused by faulty inlet design.

Experimental Data

No complete systematic series of experiments for determining the correct form and dimensions of open-channel transitions has been attempted by the U. S. Bureau of Reclamation. Observations have been made on a limited

* See "Hydraulic Jump and Critical Depth in the Design of Hydraulic Structures," *Engineering News-Record*, November 25, 1920, p. 1034.

number of existing structures, some of which have been mentioned previously. The results of others are shown on Fig. 17. These tests consist principally of measurements of outlet and entrance losses.

Methods and Precision.—The approximate nature and inconsistency of some of the data are readily apparent. For example, the abrupt inlet, (*a*), Fig. 17, shows practically no entrance loss, whereas the comparatively slender inlet, (*b*), shows a loss of 46% of the change in velocity head. Practically all the head losses shown on Fig. 17 were obtained from level readings with the end of a level rod held on the water surface. There is always sufficient oscillation to destroy the precision of readings taken in this way, especially where the fall to be measured is small. Even with comparatively smooth flow, maximum fluctuations of as much as an inch may occur. An error of $\frac{1}{2}$ in. would materially affect many of the coefficients shown on Fig. 17.

Heads within the closed conduits were obtained by drilling through the siphon barrels and inserting $\frac{1}{8}$-in pipe nipples to which a $\frac{1}{4}$-in. air-hose was connected. In concrete pipes the holes were first closed with wooden plugs which were afterward drilled for the nipples. The water pressure was determined by holding the free end of the hose at such a level that it was on the point of overflowing. Although this method is not extremely accurate the results obtained were definite. Water was allowed to run freely from the hose, except when the elevation was actually being determined, to eliminate temperature and air effects. All taps were inserted with the pipes flowing full, and the inside ends of the holes could not be inspected.

The dimensions were taken from the plans from which the conduits and structures were built, and were not in all cases checked in the field. Although it is believed that the errors resulting from this procedure are practically unimportant, they undoubtedly detract from the scientific value of the data.

It is believed that the data obtained are sufficiently reliable to be valuable for the purpose for which they were taken. Where the elevation of the water surface is uncertain, due to fluctuation, there is little practical purpose in finding the mean of the fluctuations with precision, however desirable such a procedure may be from a scientific point of view. It is believed that the assembled data show a general trend that is worthy of study.

Flume Inlet Losses.—It will be noted that of the twenty-nine sets of observations in Fig. 17, shown for ten flume inlets, only three observations show a loss greater than 0.1 Δh_v, and only one greater than 0.14 Δh_v. In a number of cases there appeared to be no loss, and the average loss is about 0.04 Δh_v. In several cases the observed loss actually appeared to be negative, probably due to error or inaccuracy in measurements. All such losses are marked "None" on Fig. 17. If the negative values are included, the average observed loss is approximately zero.

Siphon Inlet Losses.—Of the five tests recorded for four siphon inlets, three show inlet losses of zero. One of the remaining two observations shows a loss of 0.33 Δh_v, and one of 0.15 Δh_v, making the average for all five approximately 0.1 Δh_v. As previously explained, all the excess head in a siphon is concentrated at the inlet. This makes it difficult to secure a rating

Losses, U. S. Bureau of Reclamation.

under normal operating conditions. Both the tests shown for Siphon (*A*) Fig. 17, were taken under adverse circumstances, a canvas bag filled with water being suspended in the siphon barrel to cause the inlet to run full. Inlet (*B*) was not entirely normal, as is evident by the view, Fig. 18. The information shown indicates that properly designed siphon inlets, operating under full submergence, cause very little loss.

Flume Outlet Losses.—The results shown for flume outlets are somewhat erratic. Several apparently good outlets show high losses. The average loss for the sixteen observations on fourteen outlets is approximately 0.31 Δh_v. The high losses shown for structures like that at (*k*), Fig. 17, are to be expected, and the low efficiencies of structures, such as (*l*), (*n*), and (*o*), are not particularly surprising. The cause of the relatively high loss at Outlet (*r*) has been previously mentioned in the discussion of Figs. 5 and 8, and a similar explanation applies to Outlets (*q*) and (*s*). It is believed that the average loss shown on Fig. 17 for flume outlets is in excess of the losses necessary under favorable conditions.

Siphon Outlet Losses.—If Outlet (*E*), which is the Deer Gulch Outlet, shown in Figs. 7 and 9, is excluded, the average loss for the eight tests recorded on five siphon outlets is 0.07 Δh_v. Five of the tests show no loss. No explanation is available for the apparently high loss through Outlet (*H*). It is possible that this observation is in error. Figs. 19 and 20 show, respectively, Outlets (*H*) and (*J*) in operation. No important wave action is apparent. The data indicate that losses for well-proportioned siphon outlets may be expected to be smaller than 0.1 Δh_v.

The data shown at Outlets (*K*) and (*L*), Fig. 17, are of a miscellaneous nature, and of little value. For that reason they are not given in detail. The data cards referred to can be procured by any one interested in structures of the types shown.

Curvature Effects.—The heavy losses shown at Outlets (*u*), (*v*), and (*x*), Fig. 17, are apparently caused by curvature in the flume above the outlet. It will be noted that the end of the curve at Outlet (*v*) is 165 ft. up stream from the beginning of the transition. Nevertheless, the thread of maximum velocity remains near the right side of the flume throughout this length. The flow through the outlet is notably unsymmetrical and the recovery is poor. Waves, 6 to 12 in. high, are induced in the outlet structure and continue for about 200 ft. down the earth canal. The location of the thread of maximum velocity, and principal wave action, is indicated in Fig. 22, which shows this structure in greater detail. A back-flow exists along the left bank in the region marked "Dead Water". No serious cutting of the earth bank below the structure was in evidence in July, 1925. The view, Fig. 21, was taken from a bridge a short distance down stream from this structure.

The curvature above Outlet (*x*), Fig. 17, extends practically to the beginning of the transition. The action is very similar to that observed at Outlet (*v*). The center of the thread of maximum velocity and principal wave action is shown on Fig. 23. Although the wave action is severe, and follows

FIG. 21.—OUTLET, ONE-MILE FLUME, KING HILL PROJECT, SHOWING WAVE ACTION DUE TO CURVATURE IN FLUME ABOVE OUTLET.

the right bank of the earth canal closely, this structure operated several seasons with no apparent tendency to cut. Then cutting began suddenly and a 4-ft. thickness of material was eroded from the first 100 ft. of bank in a day. The eroded bank was temporarily protected, and later lined with concrete.

Similar conditions exist at Outlet (*u*), Fig. 17, but the disturbances, for some reason, are less severe. It is possible that the disturbing effect is partly offset by a reversal of curvature.

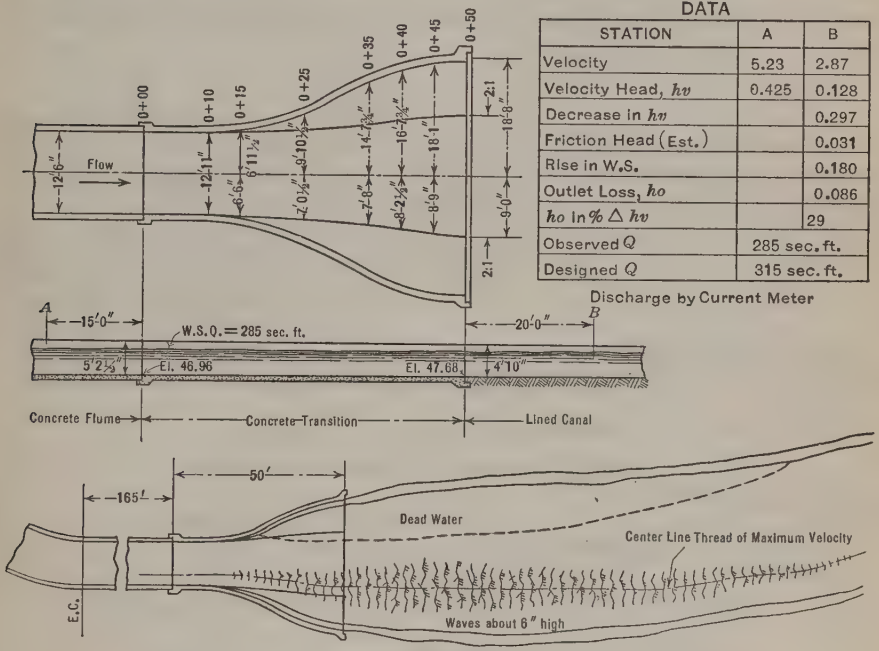

FIG. 22.—OUTLET, ONE-MILE FLUME, OUTLET (*v*) OF FIG. 17.

The flume above Outlet (*w*) is also curved, and the velocities are materially higher than for Outlets (*u*), (*v*), and (*x*). Nevertheless, the wave action is not particularly severe and the recovery is fairly good, the reason for which is not apparent. The data at hand are not sufficient to permit the determination of the cause of curvature effects. In fact, it is not definitely known that the unsatisfactory action of these outlets is entirely due to curvature. It is understood that other observers have noticed a tendency for the line of high velocity to be deflected to one side or the other at outlets from straight channels, the direction of deflection being apparently accidental.

Few comparable observations on outlets from flumes with and without curvature are available. The flume above Outlet (*p*), Fig. 17, is straight, but the velocities are low. Outlets (*k*), (*l*), (*m*), (*n*), and (*o*) are of such different forms as to render comparisons useless. Outlets (*q*), (*r*), and (*s*), as previously mentioned, involve the hydraulic jump. Outlet (*t*) appears to substantiate the assumption that the current deflection is due to curvature.

The tunnel above this structure is straight, and the transition appears to work efficiently, with moderately high velocities.

The action of the siphon outlets shown on Fig. 17 tends to disprove the theory of instability of outlet flow. All the pipes leading up to these outlets are straight in plan, and in no case was there evidence of unsymmetrical flow. However, the Glens Ferry Siphon, a profile of which is shown on Fig. 16, has a horizontal curve a short distance from its down-stream end, and the action at the outlet is very similar to that observed at Flume Outlet (x), except that the waves at the Glens Ferry Siphon outlet are higher.

SUMMARY

The present state of the art of designing transition structures, as practiced by the U. S. Bureau of Reclamation, may be summarized, as follows:

1.—Sufficient fall must be allowed at all inlet structures to accelerate the flow and to overcome frictional and entrance losses.

2.—The theoretical recovery at an outlet structure is reduced by frictional and outlet losses.

3.—At open channel outlets a small factor of safety may be obtained by setting the transition for less than its maximum recovering capacity, but erosion below the structure may be slightly increased.

4.—At siphon outlets a small factor of safety may be obtained and erosion avoided by setting the transition for more than its assumed recovering capacity.

5.—Simple designs may be prepared by adapting the details of previous designs, known to be satisfactory, if proper allowance is made for loss of head.

6.—Important structures, where velocities are high, must be carefully designed to conform to a smooth theoretical water surface. Sharp angles must be avoided.

7.—Horizontal curvature in the conduit above an outlet appears to reduce its efficiency, and to produce objectionable cutting velocities in the canal below.

8.—The transition loss through an inlet of the type shown in Fig. 12 or Fig. 14, is likely to be less than 0.05 Δh_v. An allowance of 0.1 Δh_v is safe for use in designing.

9.—The outlet loss at a properly designed transition of the type shown in Figs. 13 and 15, may be expected to be less than 0.1 Δh_v, unless the conduit above the structure is curved. An allowance of 0.2 Δh_v is safe for use in designing.

10.—No definite data as to the best form of water-surface profile, best form of structure, or most efficient length of transition, are available.

11.—Special care is required where the critical depth is approached or where the hydraulic jump is involved.

12.—The disturbances often observed in long, uncontrolled siphons, at part capacity, are not caused by entrained air, but by the hydraulic jump in the pipe.

DISCUSSION

H. B. Muckleston,* M. Am. Soc. C. E. (by letter).—The flow of water in an open channel of variable section is such a complicated phenomenon that a really exact analysis by mathematical methods is more an ideal than a possibility. By making various assumptions of more than doubtful validity, it is quite possible to arrive at a result, seemingly correct to any number of decimal places, but which is not in fact any more accurate than the assumptions on which it is founded. Present knowledge of hydraulic phenomena is entirely empirical and the resulting formulas bristle with coefficients intended to account for the many factors that are either unknown in their action or else not susceptible of measurement. Such important factors as roughness of perimeter and shape of cross-section cannot be defined in any physical unit of measurement; their influence can only be expressed by some numerical factor, chosen in the light of individual or collective experience. In view of this condition, a paper such as this, based as it is on the observation of an organization with a long and diverse experience, cannot help but be a valuable addition to engineering knowledge.

Surface Curve.—If the flow through a transition is certain to be always well above the critical depth, or, in case of an accelerating transition, whether it is or not, it is the writer's experience that time and labor are saved, with no sacrifice beyond the appearance of accuracy, if the energy gradient be assumed outright as a beginning. The hydraulic dimensions of the flume or siphon and of the canal are supposed to be known; and, therefore, the elevation of the energy gradient above the bottom of the channel is known at two points and the assumption of the total loss fixes, at once, the elevation of the bottom at the end of the transition.

The total loss of energy in the transition is usually divided, as in the paper, into friction losses, so-called, and conversion losses. In both cases they are really the losses due to the formation of eddies and whorls in the water, and the real cause of most of these is to be found in the irregularities of the surface, whether minute as in the friction loss or relatively large as in the conversion loss. In analysis it may be convenient to separate these two forms of the same thing, but the writer does not believe that this can be done in experimental determinations. For a reasonably uniform cross-section, the friction loss in a given channel can be predicted with some approach to certainty; but little is known about the law governing friction loss in channels of varying cross-section, even when the variation follows some simple mathematical rule, and still less when it follows no ascertainable rule whatever.

Very little is known about conversion losses even in circular channels. Whatever the law may be, experience with closed channels seems to show that it is not the same for converging and diverging channels; but whether these laws, if they were known, would hold for open channels is doubtful. Probably they would not, as the conditions are radically different. For this

* Cons. Engr., Vancouver, B. C., Canada.

reason, complicated analysis of friction and conversion losses does not seem a justifiable labor. The losses can only be calculated by a cut-and-try process, and the final result depends so much on assumptions that it is quite as logical to assume the losses in the first place if one has a little experience to guide him. When something like finality has been reached, there may be more logic in detailed calculation, but it is doubtful.

With the energy gradient fixed, the water-surface profile follows and the remainder of the process is a matter of adjustment by cut-and-try to obtain smooth curves for the sides and bottom. The first selection of a surface profile may result in unsuitable shapes and dimensions, in which case a new profile must be assumed and the process repeated. If a raised floor is necessary, as mentioned later, this will fix the elevation of one point on the floor and more or less determine the profile; or if a hydraulic notch is required, it will fix the cross-section at one point and influence those throughout the transition.

Velocity Head.—The apparent velocity head is somewhat less than the real velocity head. From a few gaugings, in which the distribution of velocity over the cross-section had been observed, the writer has estimated that the difference may amount to from 1 to 6%, with a mean value of about 4 per cent. The law of the increase is not known, but as the shapes of the section and the mean velocity at various points is the last thing known, the exact law is not of importance. The writer suggests that a mean increase of about 4% would be close enough. It is unimportant in the lower velocities but more so in the higher. For a velocity of 8 ft. per sec., it is 0.04 ft., which is more than the total friction loss in the whole transition.

Accelerating Transitions.—A well-designed transition should prevent the occurrence of harmful velocities up stream in the canal at all stages. If a transition is designed with only the conditions at full supply in mind, the surface drop is the difference in the velocity heads plus whatever is allowed for loss, and this fixes the elevation of the bottom at the end of the transition. If, now, conditions at less than full supply, say, at half depth, are investigated, and a back-water curve is calculated, beginning at water level in the flume, for that stage, it may happen that the water level thus found for the entrance to the transition is far below the theoretical water level for that stage in the canal. The result is that acceleration begins a long way up stream and scouring velocity may be attained before the water enters the transition. To avoid this condition, it is necessary to constrict the entrance of the water in such a way that acceleration does not begin until the transition is reached for all stages of supply. To do this absolutely for all stages would involve expensive form work for the sides and bottom, which would not be justified by the accuracy of the calculations. A notch can be designed with straight sides and walls that, in theory, will be correct for any two stages and, in practice, sufficiently correct for all stages. If the end velocity in the transition is above the critical velocity for all stages of supply, it is not very material which stages are chosen as the bases for designing the notch; the result is a true, or very nearly true, hydraulic notch, and the bottom will be at the same level as the bottom of the canal.

If the end velocity is below the critical for all stages, the two stages should be full supply and about half depth (not half supply). The resulting notch will have its bottom raised above the level of the canal bottom. Direct calculation is not practicable, and a cut-and-try process brings results more quickly.

If the end velocity is above the critical at full supply stage and below it at lower stages, the two stages chosen should be: For the higher, that stage at which the end velocity passes the critical; and, for the lower, about half that depth. There may be some acceleration in the canal at full supply, but probably not sufficient to be dangerous. If the discharge at which the end velocity passes the critical is less than about half supply, the transition may be designed as a hydraulic notch. In this case, a jump will develop in the flume at the lower discharges, but that will be of no great importance.

When the end velocity is below the critical at full supply and above the critical at lower stages (a condition common in siphon transitions), the upper design stage should be chosen as full supply and the lower at that stage where the end velocity passes through the critical. In extreme cases the notch may be quite narrow and its bottom may be depressed below the level of the canal. When this occurs, uncomfortable acceleration may be expected at very low stages and some rip-rap may be needed as a cure.

Decelerating Transitions.—If the flow in the high velocity channel is at less than critical velocity, the process of design is much the same as for accelerating transitions. The length should be much greater than is necessary for accelerating transitions. In fact, experience indicates that converging channels may be quite obtuse without great loss in efficiency; but if even moderately obtuse angles are used for diffusing channels, the water shows a tendency to stick to the center for a long distance down stream.

Decelerating transitions should be investigated for conditions at partial supply. It is quite possible for a transition that acts with satisfaction at full supply to give strong evidence of scour at lower stages. The reason is that all the deceleration does not take place in the designed length, and there is still an excess of velocity remaining when the water leaves the transition.

If the flow in the high velocity channel is below the critical depth, it is almost impossible to design a transition that will surely effect a smooth deceleration through the critical region. A jump is almost certain to occur; and as it involves a loss of head it is better to design for the loss. Otherwise, the result may be an overflowing flume.

Siphon Transitions.—At siphon inlets the design follows the same general principles as for flumes. Outlets may be designed on the same principles as flume outlets if the velocity is not greater than the critical velocity for the same quantity in the canal. If it is greater, the deceleration should be accomplished under pressure until the critical region is comfortably passed.

The length of the diffusing section may be shortened without sacrifice of efficiency if the flow through the diffuser is forced to take place along spiral lines. As shown by Mr. F. zur Nedden,* the efficiency of a polished cone

* "Induced Currents of Fluids," *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 844.

with an angle of 8° 20′ was raised from 88.3 to 98.9% by so doing, and it is probable that a similar result would follow in a cone of much larger angle. If this is true, the same efficiency might be expected from a relatively obtuse cone with spiral flow as from an acute cone with straight flow.

F. Theodore Mavis,* Assoc. M. Am. Soc. C. E. (by letter).—The flow of water through the more common types of transition sections can be calculated quite accurately by the methods which the author has discussed. Occasionally, one sees an unusual type of transition section which cannot be investigated by the analytical methods available at present, and the studies must be carried on almost entirely in the hydraulic laboratory. It may be desirable to rely, in part at least, on experimental methods if the transition sections are of unusual shape or if the velocities exceed the critical velocity.

One of the most unique examples of tunnel inlet transitions which has come to the writer's attention is that for the proposed flood diversion tunnel at Nürnberg, Germany. This tunnel is designed to divert 12 400 cu. ft. per sec. from the Pegnitz River in times of extreme floods in order to protect the "Alstadt", which is one of the oldest and most picturesque towns in Germany. Just above the tunnel inlet, 2 800 cu. ft. per sec. is to be diverted into power canals and into the old river channel through the city.

Under the direction of Professor Theodore Rehbock, extensive tests for this project were made in the Hydraulic Laboratory of the Technische Hochschule in Karlsruhe on eleven models of inlet transitions, two models of outlet transitions, and three combined models of inlet and outlet connected by a short piece of tunnel. Figs. 24, 25, and 26 show sketches and views of nine of the proposed inlet structures which were studied in the laboratory. All linear dimensions are in meters and all velocities, in meters per second in the full-sized structures as indicated by tests of the models. Most of the models were made to a scale of 1:100.

The inlet transition which was proposed in the original plans is essentially a sector of a right circular cone with side slopes of 1 on 9 and a central angle of about 70° between retaining walls. Fig. 24 (*a*) shows a plan of this inlet and Fig. 24 (*b*) a longitudinal section with the water surface in the prototype determined from the model experiments. The flow through this inlet section was marked with high waves which lapped the roof of the tunnel. Under these conditions of flow there is grave danger of air trouble which has already been discussed by the author. The changes in the velocity of flow through the section were not smooth and gradual; there were abrupt changes near the entrance to the tunnel and below the sill or weir crest where the flow passed the critical stage. The velocity changed from 1.03 m. per sec. in the approach channel to 2.92 m. per sec. at the weir crest. A hydraulic jump occurred below the weir. The velocity changes to 5.24 m. per sec. in the tunnel, with a minimum of 1.17 m. per sec. in transition. The slope of the water surface changes from 1 on 10 in transition to 1 on 700 in the tunnel. These velocity changes are shown in Fig. 24 (*c*).

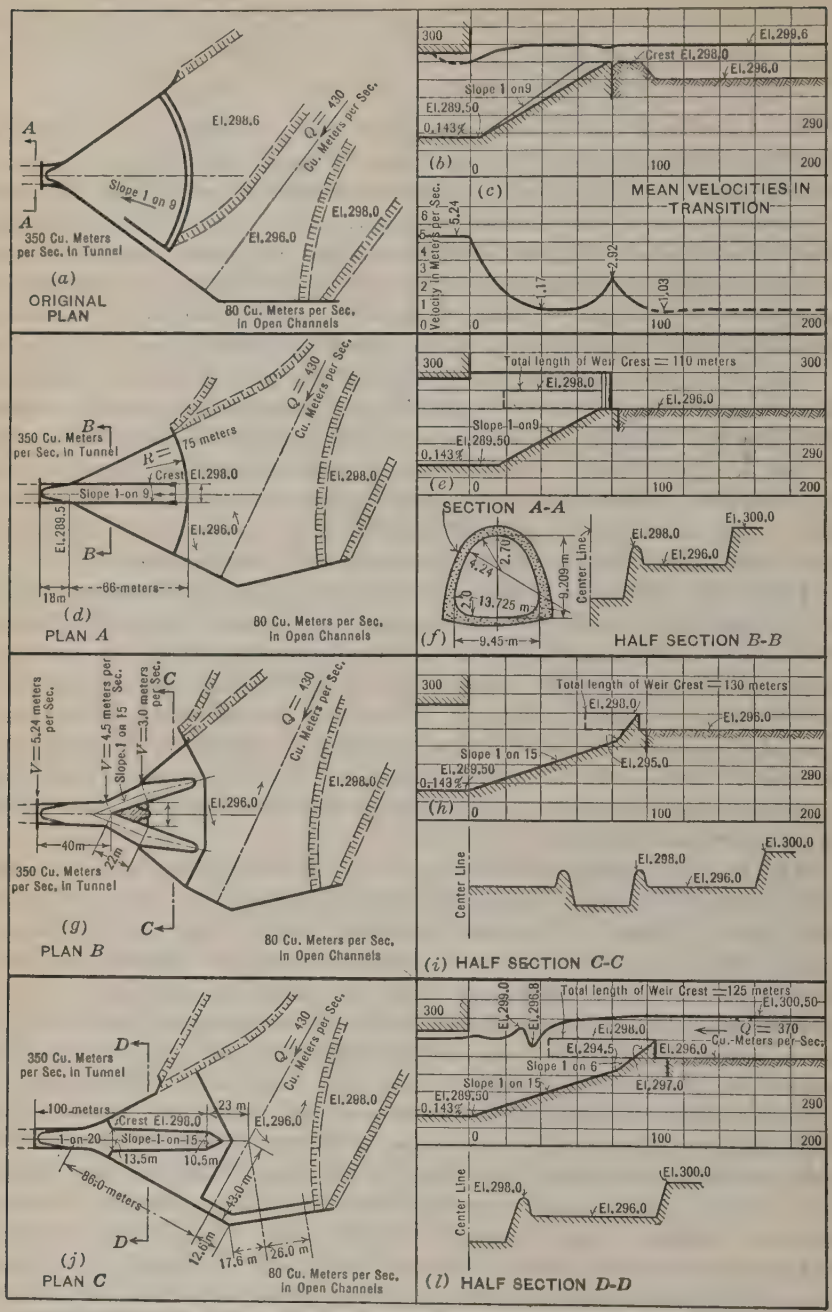

FIG. 24.—PLANS FOR DIVERSION OF PEGNITZ RIVER FLOODS AT NÜRNBERG, GERMANY.

FIG. 25.—VIEW OF FLOW THROUGH MODEL FOR PLAN *A*.

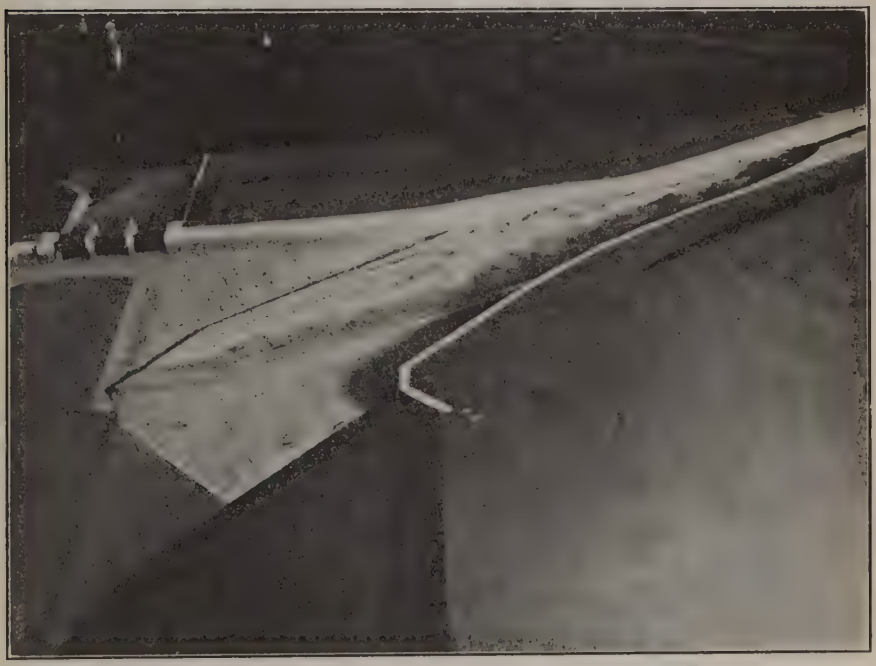

FIG. 26.—VIEW OF FLOW THROUGH MODEL FOR PLAN *E*.

The subsequent plans provided that the bottom of the river channel was to be extended to the full width of the inlet transition section. Plan *A*, Fig. 24 (*d*), (*e*), and (*f*), provided for a collecting trough 35 ft. wide and 180 ft. long, with sides or sills 6.6 ft. above the bottom of the approach channel. The bottom of this trough was sloped upward (1 on 9) from the bottom of the tunnel to the level of the river bed, but the bottom of the transition section outside the trough walls was level and at the elevation of the river bottom (Elevation 296.0). The flood water spilled over the sides of this trough and was then directed into the tunnel.

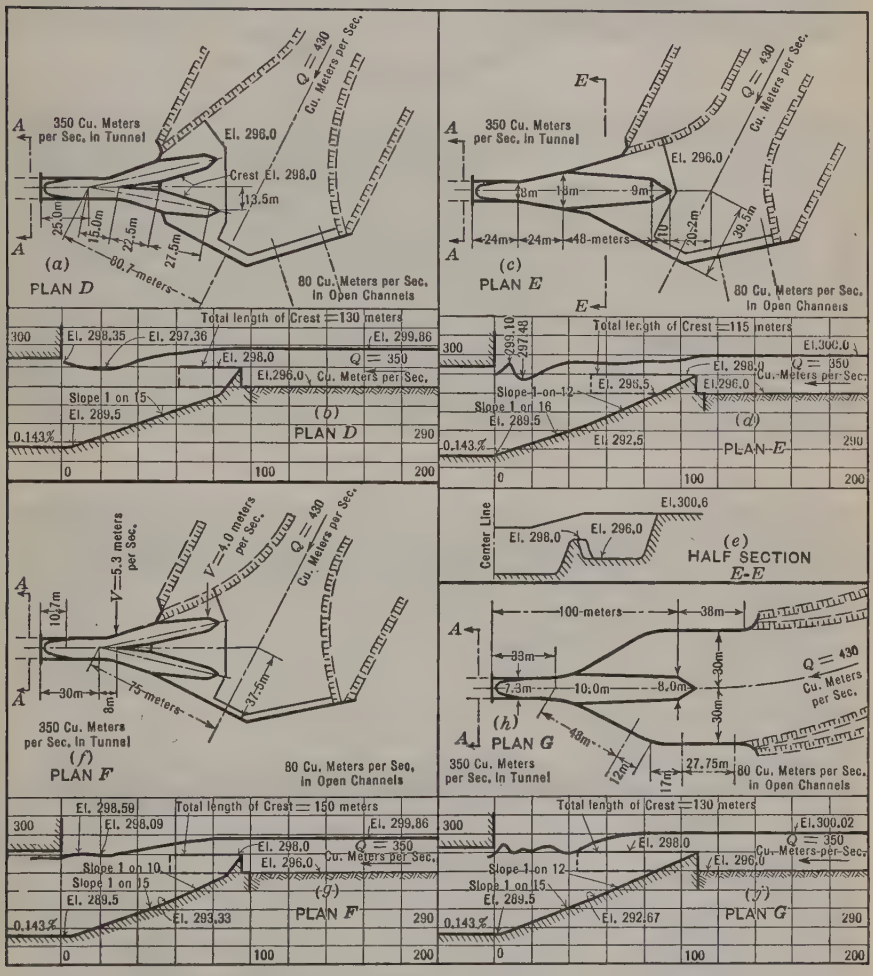

FIG. 27.—PLANS FOR DIVERSION OF PEGNITZ RIVER FLOODS AT NÜRNBERG, GERMANY.

The flow through the inlet of Model *A* was not satisfactory because, although there was a smooth flow in the approach channel, strong eddies were formed near the point where the sills of the trough joined the side walls

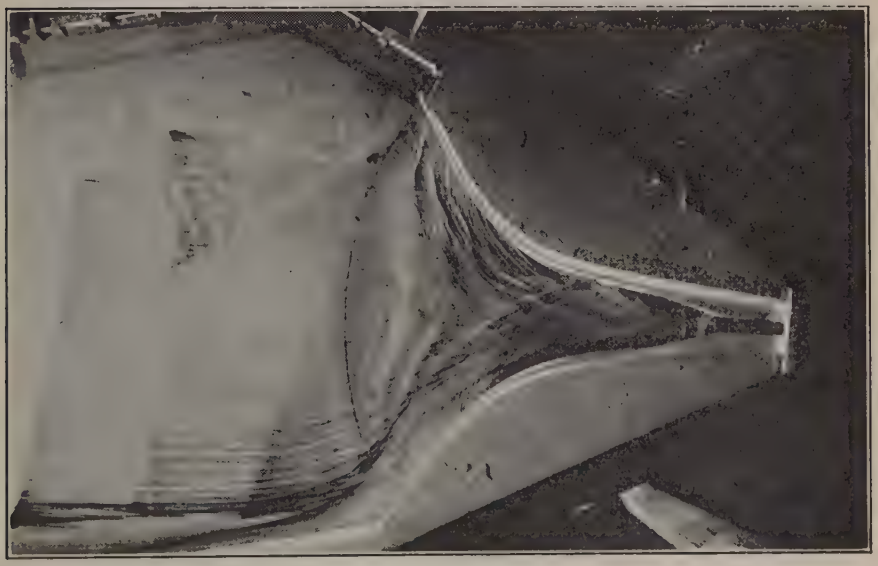

FIG. 31.—VIEW OF FLOW THROUGH MODEL *J*.

of the transition section. These eddies restricted the effective discharge area near the tunnel mouth and caused a high wave just above the tunnel entrance. Fig. 25 shows the flow through the model during a test run. The eddies and the wave in the approach to the tunnel are clearly visible.

Plan *B* (Fig. 24 (*g*), (*h*), and (*i*)), shows a double trough section in which each trough is tapered toward the up-stream end. The flow through this transition was much smoother than that through the one originally proposed or through the transition of Model *A*. The waves that form at the up-stream end of the "ships" can be eliminated by pointing the "prows".

Plan *C* (Fig. 24 (*j*), (*k*), and (*l*)), Plan *E* (Fig. 27 (*c*), (*d*), and (*e*)), and Plan *G* (Fig. 27 (*h*) and (*i*)), are single-trough transitions which have the same general shape but different sized troughs. The flow in the model for Plan *E* was much smoother than in that for Plan *C*, but was not considered satisfactory. In Plan *G* the flow was smoother than in Plans *C* or *E*, with strong eddies near the junction of the weirs and side walls. Fig. 26 shows the flow through the inlet of Model *E* during a test run. It will be noted that, although the flow is smoother than that shown in Fig. 25, it is not wholly free from eddies and that a wave is formed in the transition section just above the entrance to the tunnel.

Plan *D* (Fig. 27 (*a*) and (*b*)), Plan *F* (Fig. 27 (*f*) and (*g*)), Plan *K* (Fig. 28), and Plan *H* (Fig. 29) provide for double-trough transitions similar to Plan *B*. In the model for Plan *D* there was observed a smooth flow and no large waves. The troughs of Plan *K* are 50 ft. shorter than those of Plan *H* (Fig. 29) and the direction of flow into the transition is more nearly axial in the latter than in the former plan. The flow through Model *H* (Fig. 29) was very smooth and there were no appreciable waves or eddies in the transition section for the maximum rate of discharge corresponding to 12 400 cu. ft. per sec. Fig. 30 shows a model of the inlet, which was finally recommended as the most satisfactory one of those studied in the laboratory.

Fig. 28 (*c*) shows the cross-sectional areas, mean velocities, and velocity changes in the transition of Plan *K* and Fig. 28 (*b*) shows the water surface determined from the tests. It is interesting to compare these with Fig. 24 (*b*) and (*c*), which show the water surface and mean velocities in the transition section originally proposed. Remembering that sudden changes in velocity are accompanied by energy transformations and shock losses, it is not surprising to find that the flow in the model of the inlet shown in the original plan was not as smooth as that in the model of the inlet shown in Plan *K*.

Fig. 31 shows the flow in the model of Plan *J*, which is a modification of Model *A*. Crystals of potassium permanganate were scattered in the channel to show the direction of flow of the bottom water filaments and produced the streaks which are shown in the photograph. The flow just above the mouth of the tunnel is near the critical velocity and there is an abrupt drop in the water surface just above the portal. The maximum in the transition section of Model *J* represented a velocity of 31 ft. per sec. in the prototype, while the maximum velocity in the transition section of Plan *H* (Fig. 29) represented a velocity of 19 ft. per sec.

It is said that although the single-trough sections were more satisfactory than the transition proposed in the original plan, the heads required to produce a maximum discharge of 12 400 cu. ft. per sec. were greater than those required to produce the same discharge in the double-trough sections. The waves were smaller and the eddies were weaker in the double-trough models than in the single-trough models.

The transition which was recommended below the tunnel outlet is 450 ft. long, 200 ft. wide at the lower end, and slopes upward from the bottom of the tunnel to the canal, which is at a grade 24.6 ft. above the bottom of the tunnel.* The tests conducted for a discharge corresponding to 12 400 cu. ft. per sec. indicated that there was practically a complete recovery of head although the velocity was reduced from 17.4 to 6.9 ft. per sec. The observed water surface in the model showed a very satisfactory agreement with that calculated by methods similar to those discussed by the author.

The writer is indebted to Professor Rehbock, of the Technische Hochschule, in Karlsruhe, for permission to present this abstract of reports† and test data in his personal files and for the photographs presented herewith.

W. H. R. Nimmo,‡ Assoc. M. Am. Soc. C. E. (by letter).—The valuable paper presented by the author is of special interest to the writer who, during 1919, was in charge of the construction of a diversion project of 450 sec-ft. capacity, involving a decelerating transition from a concrete flume to a canal excavated in earth. The properties of the flume were: Grade of floor, 0.00303%; width, 9 ft.; sides, vertical; normal depth of water at full capacity, 5 ft.; average velocity, 10 ft. per sec.; velocity head, 1.56 ft.; and Kutter's $n = 0.015$. The corresponding properties for the canal were: Grade, 0.000757%; bottom width, 24 ft.; slope of sides, 1 on 1.25; normal depth, 4.32 ft.; average velocity, 3.5 ft. per sec.; velocity head, 0.19 ft.; and Kutter's $n = 0.026$.

The excavation was in firm clayey soil which would permit of the building of warped side slopes in concrete without back forms. In order to avoid turbulence, the writer proposed to construct a warped transition, 132 ft. in length, allowing for a loss of head of 0.17 ft., or 13% of the total change in velocity head from flume to canal. This length of transition would have been more than double the minimum length allowed by the author's rule (page 1435), but the whole distance need not have been in concrete. The allowance for regain of head was perhaps rather liberal, but it was intended also to have slightly increased the free-board on the flume for a short distance in case the full amount of regain was not realized. It was also proposed that the area of the cross-section occupied by water should vary proportionally to the change in kinetic energy. In view of the evidence presented by the author, it seems that the proposed transition would have operated satisfactorily.

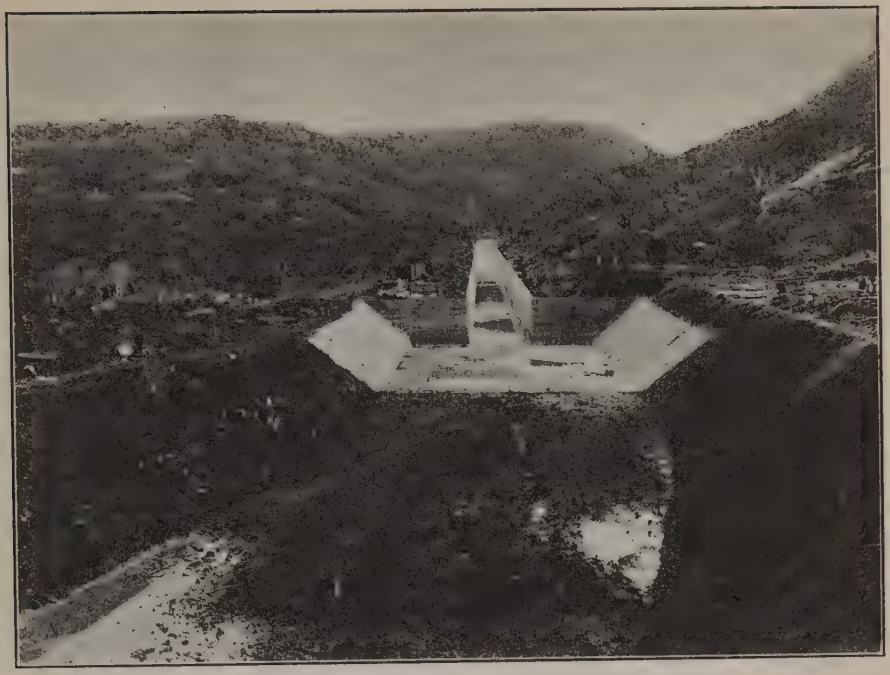

FIG. 32.—VIEW OF TRANSITION WITHOUT FLOW.

FIG. 33.—VIEW OF TRANSITION IN OPERATION.

The Department responsible for the design of the transition, however, held the view that it would not be possible to regain any head and, therefore, a transition—or rather a stilling-pool—was built in accordance with a design supplied to the writer. The transition as actually constructed is shown in plan, and longitudinal section in Fig. 34 and is shown empty and full in Figs. 32 and 33. To satisfy riparian rights provision was made for delivering water to the river, when necessary, by means of pipes leading from the bottom of two outlet pits built in the floor of the transition, the horizontal dimensions of each pit being 5 ft. 9 in. by 3 ft. 0 in. The sections in Fig. 34 illustrate the theoretical conditions for flows of 450 cu. ft. per sec. and 200 cu. ft. per sec., respectively. In these sections, d denotes depth; E, energy line (depth plus velocity head); and the suffixes, n, c, and a, refer, respectively, to the normal, critical, and actual depth.

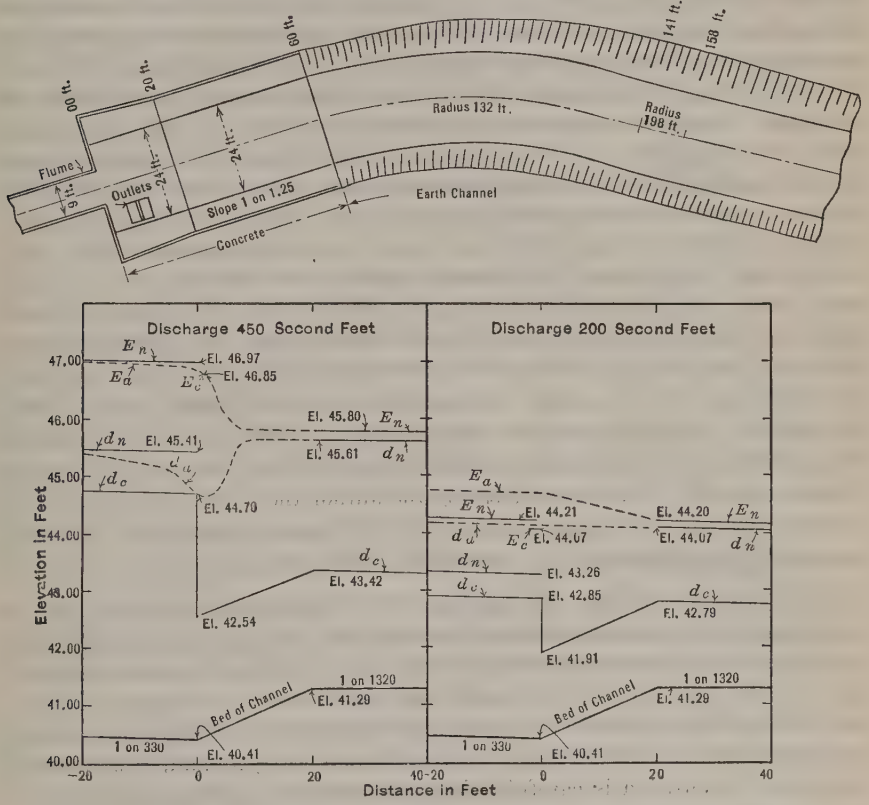

FIG. 34.—PLAN OF TRANSITION.

For a flow of 450 sec-ft., it is seen that a considerable drop in the energy line must take place in passing through the transition, but since at the entrance to the transition E_c is below E_n, the actual water surface will follow the line, d_a, passing through the critical depth and then jumping to the normal

depth for the canal. In Fig. 33, which shows a flow of approximately 450 sec-ft., the drawing down of the water surface in the flume and the turbulence due to the ensuing jump are clearly seen. The transition is, therefore, not an efficient stilling device when flowing full, since it actually increases the velocity in the flume from 10 to 11.75 ft. per sec. before the jump takes place.

For a flow of 200 sec-ft., E_c at the entrance is below E_n at the outlet and, consequently, the water surface cannot drop to the critical depth. In this case there is no jump and the actual water surface backs up in the flume on some back-water curve, such as d_a, which accounts for the observed fact that the transition operates without great turbulence at the lower rates of flow.

The flume is straight for a considerable distance up stream from the transition, and the canal curves to the right (looking down stream) at a point 40 ft. beyond the down-stream end of the transition. The stream of high velocity persists with small ripples for several hundred feet down stream, but as yet there has been no erosion of the banks of the canal. For some distance below the flume outlet, the water at the sides of the channel flows up stream and forms pronounced eddies in the corners adjacent to the outlet of the flume. One would expect that the effect of the curve in the canal would be to cause the high velocity stream to diverge to the left (looking down stream), but in Fig. 33 it is seen diverging to the right. The writer observed this on the first occasion on which the canal was filled, and thought it might be due to the effect of the outlet pits, which would absorb energy in the eddy on that side, thus causing it to become smaller than the eddy on the other side. After a trial run the flow was shut off, but the next time the head-gates were opened the high velocity line diverged to the left. Since then the writer has observed the action of the transition on numerous occasions and has found that when the water is turned into the empty canal it is a matter of chance to which side the high velocity stream is deflected, but that having been deflected to one particular side, it remains at that side until the water is again shut off. In the cases cited by the author the divergence may be due to curvature, but in this case it is not. E. W. Lane, M. Am. Soc. C. E., has observed similar phenomena in experiments with contractions.*

CARL ROHWER,† ASSOC. M. AM. SOC. C. E. (by letter).—The design of transitions is an important problem in hydraulics, and the data assembled by the author and the method of design that he has devised, are valuable contributions to the Engineering Profession and particularly to engineers interested in irrigation. However, as the author indicates, no satisfactory method of computing the transition losses has as yet been developed, and, consequently, even after a transition is carefully designed, the success of its operation can only be determined by trial.

A study of the experimental data submitted by the author shows that very little loss of head actually occurs in transitions when the velocity is increased,

* "Experiments on the Flow of Water Through Contractions in an Open Channel," *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1207.

† Associate Irrig. Engr., Div. of Agricultural Eng., U. S. Dept. of Agriculture, Fort Collins, Colo.

and, apparently, there is no correlation between the suddenness of the transition and the loss in head. The question naturally arises whether the complicated inlets shown by the author are justified when the simpler structures seem equally efficient. Much greater losses arise through structures where the velocity is decreased and the loss increases with the abruptness of the transition; but very little, if any advantage is shown by the bell-shaped outlets, which are certainly more difficult to construct.

In calibrating the improved Venturi flume,* which consists of inlet and outlet sections connected by a short throat section (see Fig. 35(*a*) and (*b*)), observations were made on the loss in head through the structure in order to find the net sacrifice of head necessary for the successful operation of the device. The gauges for determining the heads were not placed so as to make it possible to segregate the inlet and outlet losses, but it was possible to determine the inlet loss between the points, *M* and *N*, and the outlet loss between the points, *P* and *R*. The losses are based on staff-gauge readings at *M* and *R* (Fig. 35), and hook-gauge readings at *N* and *P* for the flumes with a throat width of from 1 to 8 ft. For the 10-ft. flume, the losses are based on readings with an engineer's level and rod on the water surface. The hook-gauge readings are reliable, but errors are possible in the staff-gauge and level readings which might affect the results materially. Representative results of these observations are shown in Table 5,† which is based on tests made to

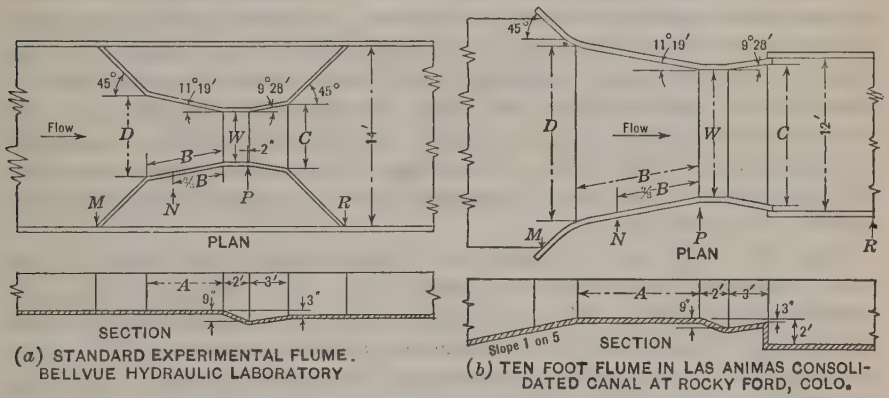

FIG. 35.—SECTION OF IMPROVED VENTURI FLUME.

determine the free-flow discharge. In Tables 5 and 6 the author's terminology is used, as follows:

Q = discharge, in cubic feet per second.
V = mean velocity, in feet per second.
Δh_v = change in velocity head.

* "The Improved Venturi Flume," by R. L. Parshall, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 841.

† Prepared from data of Irrigation Investigations of the Div. of Agricultural Eng., Bureau of Public Roads, U. S. Dept. of Agriculture, co-operating with the Colorado Agricultural Experiment Station.

E = entrance loss, in percentage of Δh_v, measured between Points M and N.

O = outlet loss, in percentage of Δh_v, measured between Points P and R.

E and O include friction losses.

The results of these observations indicate that, although there is an abrupt transition at the inlet end of the flume, very little loss occurs in this section and there is no relation between the suddenness of the transition and the loss in head. The losses are, however, somewhat greater than those reported by Mr. Hinds.

Outlet losses are, to a great extent, determined by the elevation of the water surface at the lower end of the transition, and, consequently, a wide variation in the percentage recovery is possible, regardless of the correctness of the design of the structure. In calibrating the Venturi flume under free-flow conditions, it was necessary to keep the down-stream depth low enough so that it would not back the water into the throat of the flume and raise the head above the condition of maximum flow. At this point the down-stream depth may vary considerably without materially affecting the condition of maximum flow; consequently, some of the tests chosen (see Table 5) do not show as great a recovery in head as would have been possible if the down-stream depth had been increased. However, the outlet losses of the flumes with throat widths of from 1 ft. to 8 ft. (which were tested under similar conditions in the laboratory) decrease, in general, as the abruptness of the transition decreases. The 10-ft. flume, which is an exception to the rule, is a field installation; as shown in Fig. 35(*b*), there is a vertical drop of nearly 2 ft. at the down-stream end of the structure which, in addition to the fact that submergence is less, is probably the explanation of the increase in loss through the outlet section of the flume. It should be noted, also, that the loss of head in this case is measured from the upper end of the throat instead of the lower end.

Figs. 36 and 37 show the condition of flow during the tests made on the 10-ft. improved Venturi flume at Rocky Ford, Colo. Although the water surfaces appear equally smooth in the inlet section for both the 90 sec-ft. and the 120 sec-ft. discharges, the percentage loss of head is greater for the larger discharge, but not enough to be significant. The water surface in the outlet is much smoother for the 90 sec-ft. discharge than for the 120 sec-ft. discharge, but the percentage loss of head is greater. This is due to the fact that, as is shown in Table 5, the submergence is less in the case of the smaller discharge.

The loss of head through the improved Venturi flume, when the down-stream depth has been increased until it backs the water into the throat section and causes submerged flow, is shown in Table 6,* which is based on the submerged flow calibration data of the Venturi flume. These tests were made on the same flumes that were used in the free-flow tests and on similar discharges, and any change in the loss in head is due to the increase of the rela-

tive depth of water in the outlet end of the flume. The results show that both the inlet and outlet losses are materially less than the free-flow losses and also less than the losses observed by the author. They indicate that, for low velocities at least, it is possible to obtain high efficiencies by proper control of the down-stream depth of water, even if the transitions are abrupt.

JULIAN HINDS,* M. AM. SOC. C. E. (by letter).—Many of the problems of the important subject of flume and siphon transition design remain unsolved, and an attempt was made in the paper to develop a definite method of procedure, based upon the partial data available, which might be used until something better is proposed. Many helpful suggestions and criticisms have been contributed in the discussions. The subject has, of course, barely been opened up, and it is hoped that much new and valuable data will be forthcoming at an early date.

The discussion presented by Mr. Muckleston brings up a number of interesting and important points. His first observation is to the effect that the computations for a transition can be made with greater facility if the energy gradient, rather than the surface curve, is assumed. This is a matter of opinion, and is not essentially at variance with the procedure outlined by the writer. In fact, some designers prefer to assume a structure and check its hydraulics, or to use other special devices. Often in making final adjustment several methods of attack may be combined to advantage. Failure to call attention to the various possible procedures was an over-sight. The water surface varies more rapidly than the energy gradient, making it a somewhat more stable factor for assumption.

Attention is called to the generally recognized fact that the mean velocity head is greater than the head corresponding to the mean velocity. An allowance for this difference may be necessary with high velocities, but it should be remembered that this allowance is included in the experimental losses shown in the paper.

The possibility of utilizing inlet structures as checks, or automatic controls, was purposely omitted, because of the special nature of this problem. Mr. Muckleston's discussion of this point might lead the casual reader to believe that all inlet transitions need to be designed to act as controls. Automatic checking is seldom necessary at the inlet to a short siphon or flume. For long siphons involving appreciable excess head for partial flows some form of check at the inlet is often essential.

The discussion of the relation of the end velocity in the transition to the critical velocity might also confuse those who have not given special attention to critical flow. For an inlet to control the flow above it the critical velocity must be attained or exceeded at some point within its length. If the velocity at the down-stream end of the transition is below critical, the transition does not control it. Instructions given for end velocities below critical for all flows are meaningless, because control is not possible without the elimination of this condition. The statement that when the end velocity is above critical for all stages the problem is simple, and that the floor of the notch comes at

* Res. Engr., The J. G. White Eng. Corporation, Pabellon, Aguascalientes, Mexico.

the level of the canal bottom is not thought to be entirely correct. At the least it is not complete. For a practical notch the form and bottom elevation are inter-related, the relation involving many factors. Usually, the floor of the notch can be made level with the bottom of the canal, if desirable, by making a slight sacrifice in point of theoretically correct control. As a matter of fact exact, or even approximately exact, theoretical control is seldom essential. It is only necessary that scouring velocities be avoided. It should be remembered that "normal" canal velocities are lower for partial flows than for full flows, and that some "racing" for low discharges is permissible. An occasion demanding a deep narrow notch, with "uncomfortable acceleration" for very low flows has never been encountered by the writer.

The general subject of critical flow has received a great deal of attention in the last decade. The writer has previously discussed, in published form, the principles involved in the present problem.*

The examples of Nürnberg Tunnel inlet experiments presented by Mr. Mavis are extremely interesting. Mr. Mavis does not state whether the various plans tested were obtained mathematically, or by simple trial. A theoretical analysis of the flow through the double trough would be interesting, and might lead to a better understanding of the general laws of flow through transition structures.

The variable position of the "thread of maximum velocity" below the flume outlet described by Mr. Nimmo illustrates the state of instability which exists in many outlet structures. It is difficult to "push" water up hill. Wherever a large recovery is to be made it is important that conditions be such that each water particle can rise to its new level by its own momentum, with the smallest possible manifestation of impact. The conditions noted by Mr. Nimmo were also observed in some of the outlets cited in the paper.

The data presented by Mr. Rohwer have no important bearing on the subject of transition losses or design. The "improved Venturi flume" as illustrated in Fig. 35, is not perfect from the point of view of smooth hydraulic flow. This fact need not detract from its usefulness as a meter. It should be noted that the inlet to the improved Venturi flume is not particularly abrupt, the angle of inclination of the sides to the axis being about 11°, or less than the average divergence recommended by the writer.

If the statement, in regard to inlets, that "there is no relation between the suddenness of the transition and the loss in head", is intended to apply specifically to the data shown in Tables 5 and 6, it may be considered correct, there being no variation in the suddenness of the transitions. The statement has no general application, however, being known to be untrue. Mr. Rohwer's idea that the recommended lengths can be materially shortened without detriment to the practical hydraulic performance is believed to be well founded, but it is not substantiated by the examples presented.

In discussing outlet losses the statement is made that these losses are rendered uncertain by the accidental relation of the water level in the receiv-

* "The Hydraulic Jump and Critical Depth in the Design of Hydraulic Structures," *Engineering News-Record*, November 25, 1920, p. 1034; "Venturi Flume Data Throws Light upon Control Weir," *Engineering News-Record*, December 23, 1920; and discussion on "The Improved Venturi Flume," by Ralph L. Parshall, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 859.

ing canal to the elevation of the bottom of the flume. Each velocity-reducing transition has a definite recovering capacity, and its performance can be computed for one depth of tail-water as well as for another. The depth of the tail-water is one of a number of factors affecting the performance of the outlet, and the efficiency may vary with this, as with other conditions. The view taken of this factor is probably responsible for the impossible outlet losses shown in Table 5. For six outlets the losses exceed 100%, one running as high as 305 per cent. Such apparent losses indicate that the throat velocities recorded were not the maximum velocities in the structure. To secure rational results it is necessary that the recovery be computed from the point at which the reduction in velocity begins. If this is done the depth of tail-water has no arbitrary effect on the coefficient of recovery. The efficiency of the structure is, of course, affected by the velocity of flow, and particularly by the velocity change. Almost any transition is good enough for a small change at low velocity. For large reductions from high velocities great care may be required.

The question of the expensiveness of the well-designed transition has been mentioned. It is evident that a straight head-wall can be built more cheaply than the more or less intricate warped surfaces recommended in the paper for important structures with high velocities. However, after allowing for increased free-board, larger losses of head, and additional bank protection required with the poorer design, the apparent economy will in many cases disappear.

Usually, a certain length of transition is required to connect the flume or siphon properly with the earth canal. If the transition is shortened the main structure must be lengthened. This is one factor that has led to the use of relatively long inlet structures by the U. S. Bureau of Reclamation. The main structure, especially in the case of a flume, may be less costly than the transition structure, in which case some saving can be effected by a shorter inlet or outlet.

In conclusion, it is believed well to state with emphasis again that not all transitions need be proportioned in accordance with the rules given for important structures. The rules, which are only tentative, are given only for use where needed.

Paper No. 1691

SURVEYING AND MAPPING IN THE UNITED STATES*

By C. H. Birdseye,† M. Am. Soc. C. E.

With Discussion by Messrs. T. P. Pendleton, C. L. Hall, John C. H. Lee, and C. H. Birdseye.

The history of surveying and mapping is the history of civilization. A complete collection of maps would be the best kind of a record of man's activities on earth, but it would be a bulky volume. Just as all early industrial efforts were crude, so were early maps—some of them mere sketches that would not be a credit to a modern school boy. As civilization progressed, however, methods and instruments were improved and the art of surveying and mapping was developed to keep pace with man's need for more accurate records.

At least as far back as 3000 B. C., man discovered that some sort of graphic representation of the earth's surface was a far more reliable record than written or oral description. The first surveys were guesses as to distance and direction. The first maps were of small areas and were pictorial in form, representing features by means of drawings. These maps had little geographic value, but, as the need for more accurate data developed, maps of larger areas were made and features were represented in more nearly correct geographic position. During this period the world was continually engaged in warfare and success in wars of conquest was based largely on knowledge of the fields of operation. Consequently, from the very beginning, maps were made mostly for military and naval activities. In fact, the history of mapping can be divided into two major periods, the first for military purposes, and the second for economic or engineering uses.

Prior to the Seventeenth Century little effort was made to show relief, and map data were confined to representation of the natural and artificial features.

* Presented at the meeting of the Surveying and Mapping Division, Philadelphia, Pa., October 6, 1926.

† Chf. Topographic Engr., U. S. Geological Survey, Washington, D. C.

In 1674 a map of Paris and vicinity was made on which relief was represented by hachures. The first use of contour lines is recorded in 1728, and rapid development in the portrayal of comparative relief followed in response to a need for more accurate military data.

Early in European history fragmentary surveys around fortified places were connected by other surveys, and a systematic plan was adopted to survey and map the entire country, so that, to-day, most of the European nations have maps of their territory adequate for most military and civil needs. It is surprising that the United States did not profit by the experience of Europe and start a systematic program of surveying and mapping immediately after the Revolution. To be sure, one of the first problems was to dispose of the public land, and as early as 1796 Congress authorized the appointment of a Surveyor General, under whose direction public land surveys were started in what is now the State of Ohio. Soon after this work was begun Congress directed the Surveyor General to "cause a fair plat to be made of the townships and fractional parts of townships contained in the lands, describing the subdivisions thereof and the marks of the corners." This direction has resulted in the preparation of plats of all the surveyed public lands, but these plats are not much more than graphic records of the surveyed lines. If those responsible for the early planning of public land surveys had used a little more foresight, adequate topographic maps of most of the original public land in the United States would now be completed.

The two periods in the history of American mapping can be divided roughly at the time of the Civil War. Before that the surveys were largely for military purposes, but afterward the exploratory surveys were inaugurated purely for scientific and economic study.

The need for topographic maps was recognized during the Revolutionary War, and on July 22, 1777, Congress authorized the appointment of a "geographer and surveyor of the roads, to take sketches of the country and the seat of war." On March 3, 1813, Congress authorized the appointment of eight topographic engineers and eight assistant topographic engineers under the direction of the General Staff of the Army. These officers formed the nucleus of the first Army Corps of Topographic Engineers. The Corps continued to function as an independent unit until the Civil War, but early in 1863 it was absorbed by the Corps of Engineers.

Before the Civil War many expeditions under the direction of officers of the Army explored the vast territory lying west of the Mississippi River. At first, the instruments and methods used were rather crude, but later improvements gradually resulted in better maps. However, practically none of the results secured prior to the Civil War could be incorporated in the standard map of the United States. During that period several systematic surveys were started by the Federal Government and by some of the Eastern States. The most far-reaching move was the creation of the United States Coast and Geodetic Survey in 1816. This organization made an accurate hydrographic and topographic survey of a narrow strip along the Atlantic Coast line, and in this connection established the first accurate system of triangulation in the

United States. Its surveys included the topographic mapping of the principal rivers entering the Atlantic Ocean. Relief was shown by hachures. Not until 1846, when it mapped an area around the Harbor of Boston, did the Coast Survey use contour lines for representation of vertical heights. This, however, was not the first contour map made in the United States, for in 1835 the Geological Survey of Maryland issued a contour map of a small area that is believed to be the first American map of this kind.

At the outbreak of the Civil War all surveys, except those needed for military purposes, ceased; but after the war the territory west of the Mississippi River again became the center of mapping activity, and many exploratory surveys were carried on by the Federal Government and by universities, railroad companies, etc. The most important of the Government surveys were as follows:

1.—The U. S. Geological and Geographical Survey of the Territories, directed by Professor F. V. Hayden, from 1867 to 1879, under the Interior Department.
2.—The geographical surveys west of the 100th meridian, directed by Capt. George M. Wheeler, from 1868 to 1879, under the War Department.
3.—The U. S. Geographical and Geological Survey of the Rocky Mountain Region, directed by Maj. J. W. Powell, from 1869 to 1879, under the Smithsonian Institution.
4.—The U. S. Geological Exploration of the Fortieth Parallel, directed by Clarence King, from 1871 to 1879, under the War Department.

These four surveys were alike in character—all were exploratory, but they covered large areas completely and resulted in the first really comprehensive topographic maps made in America. Astronomic observations were made, base lines were measured, and an accurate system of triangulation was extended over the areas mapped. Differences of elevation were determined by vertical angles and by barometers. The representation of physiographic forms was somewhat crude as compared with present-day practice, but it was such an improvement over previous work that in the period from 1867 to 1879 more progress was made in geographic research than any other period of similar length in American history. The Hayden, Wheeler, Powell, and King Surveys ceased in 1879 when Congress created the U. S. Geological Survey.

Four Federal organizations, the Coast and Geodetic Survey, the General Land Office, the Corps of Engineers, and the Geological Survey, have continued to the present day as the principal surveying and mapping agencies.

The survey of the coasts of the United States was authorized by Congress on February 10, 1807, but no field work was undertaken until 1816. The Coast Survey was a bureau of the Treasury Department until 1903, except for a brief period under the Navy. It was then transferred to the newly organized Department of Commerce and Labor; and, in 1913, was placed under the jurisdiction of the Department of Commerce.

For half a century its work was confined to surveys along the coasts and navigable rivers of the United States, but in 1871 Congress appropriated funds for connecting the surveys along the Atlantic Ocean with those along the Pacific Ocean by a system of triangulation. As a logical result of this action

the name of the organization was changed in 1878 to the Coast and Geodetic Survey.

Practically all the coast lines of the United States, Porto Rico, Hawaii, and the Philippine Islands have been surveyed, and hydrographic charts made of the adjacent waters. Similar surveys and charts have been made for a considerable part of the Alaskan Coast. Because of the rapidly changing channels formed by sand-bars and shoals, resurveys are required from time to time; consequently, this work will never be completed.

The Coast and Geodetic Survey performs a work absolutely essential to the Geological Survey and other map-making organizations of the United States, for, in addition to preparing the charts of the coasts, it furnishes the main control points for all other local surveys. Its elevations and geodetic positions are surpassed in accuracy by no other organization. It computes and publishes tidal constants for the principal ports of the United States. It determines magnetic declinations, its mathematicians have devised and developed new methods for computing geodetic constants relating to the size and shape of the earth, and its investigations in isostasy are known all over the world. Its publications are numerous and invaluable to navigators and students in all lines of geodetic work.

The sub-division of the public domain into townships and sections was authorized by Congress in 1785. The first public land surveys were made in 1796 in the area north of the Ohio River and west of the Pennsylvania State line.

In 1812 the General Land Office was organized as a bureau of the Treasury Department. In 1849 it was transferred to the Department of the Interior, where it has remained until the present time. The General Land Office has jurisdiction over the survey and sale of the public lands of the United States, including Alaska.

Previous to 1910 all field surveys were made by contract surveyors, a procedure which resulted in much work of doubtful accuracy. Since 1910 the surveys have been made by regular employees of the Land Office, with resulting decrease in costs and great increase in accuracy.

The sub-division and sale of the public land require cadastral surveys only. Such topographic features as are shown on the plats are incidental to the regular cadastral work. The shores of lakes and large rivers are meandered, but, in general, the accurate location of streams, roads, trails, and other natural and artificial features are determined only at the crossings of the public land lines, and the intermediate data are sketched on the plats. Relief is shown generally by hachure lines, but in a few special surveys contour lines based on accurate elevations have been used. The horizontal control is furnished by a system of base lines, principal meridians, standard parallels, and guide meridians, but only recently has an effort been made to tie these control lines to the standard triangulation scheme of the United States.

Public land surveys have been carried on in all States except the thirteen original States and Tennessee, Kentucky, and Texas. Seventeen of the older States have been completely surveyed, but as some of the early surveys were

inaccurate or insufficiently marked, parts of these States are being resurveyed at the rate of about 1 000 000 acres per year. Original surveys are being extended annually over about 2 000 000 acres.

The Corps of Engineers of the Army was amalgamated with the Corps of Topographic Engineers of the Army in 1863, and in the early days engineer officers were the surveying pioneers in the West. Since that date the Corps has executed or supervised practically all the mapping operations of the Army. Prior to the entry of the United States into the World War the mapping operations of the Corps of Engineers were usually reconnaissance in nature, except on river and harbor and fortification projects, and in the Philippines, Hawaii, and Panama. However, experience in the World War demonstrated the importance of accurate topographic maps for all kinds of military operations (a fact always known to military engineers) and a new impetus was given to military mapping. The Corps of Engineers has trained a Topographic Battalion, and its men are engaged on accurate topographic mapping within, as well as without, the United States. Modern methods of topographic mapping form an important part of the training of all engineer troops. Especial stress is laid on full use of airplane photographs. The best camera for mapping purposes was developed by an engineer officer, who received his mapping training in the Geological Survey.

Close co-operation exists between the Corps of Engineers and the Geological Survey so that the mapping efforts of the Army are confined to surveys of strategic importance, to resurveys which have been inadequately mapped, and to surveys which the Geological Survey for any reason has been unable to map. Each year, a substantial part of the Army appropriation for military surveys and maps is made available to the Geological Survey for special work urgently needed by the Army.

The organic act of the Geological Survey provided that the Director "shall have the direction of the Geological Survey and the classification of the public lands and examination of the geologic structure, mineral resources, and products of the National Domain." Clarence King was the first Director. From his experience on the King Survey he realized that no adequate classification of lands and no geologic examination could be made without topographic base maps; hence in the earlier years topographic maps were made a part of the general work of the Geological Survey, and allotments of funds for this purpose were made from the general appropriation. The first specific appropriation for topographic surveys was made in the Sundry Civil Act of October 2, 1888, and amounted to $199 000. Appropriations for topographic mapping have been continued each year. The amounts have fluctuated somewhat, but reached $300 000 in 1903. During the next twenty years the appropriations remained between $300 000 and $350 000. In 1924 the appropriation was raised to $500 000 and has continued to this year (1926) at approximately that figure. Including funds allotted in the early years from the general appropriation of the Survey, approximately $13 200 000 has been expended for topographic mapping. The Geological Survey has also received special appropriations (amounts approximate) for surveying National forests, $2 200 000; for

military surveys and maps, $1 400 000; and allotments by co-operating States, $5 100 000; so that the total expenditures for topographic mapping, including those for the present fiscal year (1926), amount to approximately $21 900 000. The current Federal appropriation for topographic mapping by the Geological Survey is $451 700; the allotment for military maps is $12 500; and State allotments amount to $380 000, so that the total amount available for topographic mapping during the current fiscal year is about $844 200.

The area of the Continental United States, exclusive of Alaska, is more than 3 000 000 sq. miles. In the 47 years of the Survey's existence about 43% of this area has been surveyed and the results are published in nearly 3 400 different topographic maps. Some of the early maps were made by methods so crude that the area must be resurveyed. Consequently, only about 30% of the area of the country is covered by maps that are adequate for present-day uses. Some of the States are already completely surveyed. Notable among these are Ohio, West Virginia, and Maryland, which are covered by modern maps resulting from an early adopted and well co-ordinated plan of co-operation. Other States, such as Massachusetts, Rhode Island, Connecticut, New York, New Jersey, and Delaware, are also completely surveyed, but some of the maps are old and out of date and need revision or resurvey. New York has just started a program of revision, and other States have indicated a desire to follow.

During the current year (1926), co-operation is being maintained in 24 States and Hawaii. Exclusive of the States that are completely surveyed, co-operative mapping is being carried on in all but 17, and work of purely Federal interest has been undertaken in 3 of these, so that surveys are in progress in 27 States and 1 Territory. At the past rate of progress it would take nearly 100 years to complete the mapping of the United States. That is too long a period, and American engineers have united in demanding more rapid progress, so that this generation may reap a larger benefit. After carefully considering the problem the Geological Survey proposed a 20-year program. This was approved by Congress in what is known as the Temple Act. The Act authorizes the completion of the mapping in 20 years and contemplates appropriations gradually increasing for a number of years and then decreasing toward the end, both for geodetic and topographic work. As the Act only authorizes the first year's appropriation and does not actually appropriate any money, further legislative action is required.

The Geological Survey long ago adopted a policy of State co-operation by which those States that desired could pay one-half the cost of the work in order to expedite the mapping of the areas within their borders. The Temple Act recognizes this co-operation and contemplates the continuation of the policy. In areas in which the Federal interest is supreme, such as the National Forests, National Parks, and Indian Reservations, the Federal Government should pay the entire expense, but in other areas the States will be expected to bear one-half the cost of the surveys.

The estimated cost of completing the mapping of the United States is $49 200 000. Of this amount, $4 200 000 will be spent for precise surveys—

triangulation, traverse, and spirit leveling—to obtain horizontal and vertical control. This work is done by the Coast and Geodetic Survey and must be executed a year or more in advance of the mapping operations. It is estimated that the several States, or their sub-divisions, will contribute about $12 000 000, so that the Federal cost of the mapping will be about $33 000 000. Spread over a period of 20 years this is not a large investment—not much more than the cost of a single battleship—and the investment will be more than returned to the taxpayer by direct savings made in the construction of public works, etc.

The President, by Executive order of December 30, 1919, created a Federal Board of Surveys and Maps, composed of representatives from each of the Government organizations engaged in surveying and mapping. This Board has made great progress in the co-ordination of mapping operations and in standardization of results. Little serious duplication of effort was found to exist. Most of the lack of co-ordination has been corrected—not by orders or regulation, for the Board has only advisory powers—but by bringing together into close contact the men responsible for the immediate supervision of the mapping efforts of the Federal Government. These men are brought in closer touch with the map-using public through an Advisory Council. This close personal contact is the secret of real co-ordination.

The Advisory Council is made up of representatives of non-Federal agencies interested in mapping. The mapping needs of the United States have been presented and plans have been made to meet them. The existence of much valuable survey data from non-Federal sources has been discovered, and these data have been made available to the Federal mapping agencies, so that now a Government project is rarely undertaken without examining all available data and using all that have merit.

The Executive order creating the Board of Surveys and Maps also directed the establishment of a central Map Information Office to classify, index, and distribute to the map-using public information regarding survey and map data. This Office has proved to be of great assistance to the Federal organizations interested in mapping as well as to individuals seeking map data. The Office is not a distributing agency, but it has recorded most of the Federal map data and much non-Federal map material. Use of this Office is recommended to all who do not know whether the data they desire are in existence or where to find them if they are.

Among some of the noteworthy results of the work of the Board may be mentioned the following:

Standard specifications for control surveys.
Standard map symbols.
Adoption of standard projections for different types of maps.
Selection of a standard series of base maps.
Standard instructions for executing control surveys and topographic surveys.
Research in problems of aerial photography.
Establishment of an efficient Map Information Office.

No discussion of mapping is complete without reference to aerial photography. Much misleading information has been given to the public. Claims

have been made in the public press that the entire area of the United States will be mapped immediately by use of aerial photographs and at a cost much lower than by ground methods. The Federal mapping agencies wish that these claims were correct, but the truth is that aerial photography will never replace ground surveys entirely, although it will aid them, expedite them, and lessen the final cost.

Under certain conditions the use of aerial photography will eliminate most of the ground survey work. It is especially useful in flat areas that are open or not too densely timbered, such as the marsh lands in the deltas of some of the Southern rivers, where there are no roads, trails, or houses, and where a single determination of elevation may be sufficient for contouring a large region. In mapping large cities the use of aerial photography is of tremendous value. In the revision of old surveys, made necessary by changes in the works of man, aerial photographs may make it possible to publish an up-to-date map without the necessity of any resurvey by ground methods.

However, the whole of the United States will not be photographed for many years—probably never, at least for use in mapping. In certain areas the photographs would be of so little help to the map maker that the expense of making them would not be warranted for the purpose of map making alone. Any densely timbered area presents an example of conditions that are most unfavorable to photographic surveying, either from the air or from ground stations. The meanders of the streams would of course be indicated on the pictures, but the topographer must traverse these streams to determine their fall, measuring accurately differences of elevation, particularly where possibilities of power development exist. He must locate every trail and house and must tie his surveys to the section and township corners of the public-land survey. The pictures can not show these features in such an area, and new processes must be perfected before aerial surveys will be of much help to topographic mapping in dense forests.

In areas of considerable relief the use of aerial photographs is of doubtful value for small-scale topographic mapping. For example, in the high Rocky Mountains the scale usually employed by the Geological Survey is 2 miles to the inch, and surveys by ground methods cost about $20 per sq. mile. An aerial photograph is only a perspective view from the lens of the camera, and every plane of elevation in a single picture will of course have a different scale. These differences in scale can be co-ordinated, but the process is laborious and expensive, and with present developments the cost of taking the pictures and rectifying the photographic data may exceed the cost of a ground survey. Moreover, the use of photographs of such a region requires an abundance of control points accurately located by triangulation, an operation performed by the topographer in the course of his ground survey. The topographer has to climb all over the region in any event, not only to make the control surveys, but to make the connections with the public land lines.

No practicable method has been devised for determining elevations and portraying contour lines on small-scale maps of large areas by the use of

aerial photographs. Some who are familiar with developments in mapping from photographs may challenge this statement, but the writer knows of only one firm in the United States that has successfully solved the problem of the accurate portrayal of contour lines from aerial photographs, and this only in surveys on a very large scale.

Aerial photography is welcomed as a supplement to ground surveys, but it does not promise to replace them to any large extent, particularly in the Western Mountain States. In 1925 the Navy Department and the Geological Survey spent considerable money in making aerial photographs of an area adjacent to the naval oil-shale reserve near Grand Valley, Colorado. The field surveys were completed before the pictures were available, and about the only use it was possible to make of them was in inspecting and checking the field mapping. In Texas, on the other hand, hardly a square mile has been mapped during the last two years without the aid of aerial photographs, thus saving about 30% of the ordinary cost.

Aerial photography has passed the experimental stage, and future improvements in apparatus and economies of procedure promise a much larger use than is now possible. It will pay to use this new method when and where the map data can be gathered by it cheaper than by surveys on the ground. It will not pay when and where the expense of taking the photographs and of reducing the data is greater than the cost of collecting the information from ground surveys. The Geological Survey will use aerial photography where it pays and will not use it when the evidence indicates that it will not save time and money.

It has been the experience of the Geological Survey that as fast as improvements are devised in methods and instruments, which might be expected to cheapen the product, a demand has arisen for more detailed maps, and the increased cost of meeting this demand has offset the saving made by the new methods. Therefore, the topographic surveys now in progress in the United States may be expected to yield better maps rather than cheaper ones, because of this new aid to the topographic engineer.

DISCUSSION

T. P. Pendleton,* Assoc. M. Am. Soc. C. E. (by letter).—This interesting paper presents very concisely the history of surveying and mapping in the United States, in so far as it relates to National surveys. It shows that the first crude surveys of large areas were made in the West and were largely of an exploratory nature. It is interesting to learn that the first contour map in the United States was made in 1835, although it was not until after the Civil War that the method was extensively adopted. It was only natural that many methods were tried and discarded in the search for that which presented the most advantages. A description of the various methods that were used in the days of the Hayden, Wheeler, Powell and King surveys would make interesting reading, as would no doubt the personal experiences of these pioneers in the art.

Maps that are classified as small scale would have been called large scale by these early surveyors, and the accuracy that is now obtained would probably seem to them sufficient for many years to come. However, the need of the country continually calls for better and better maps, and that this need is recognized by the Geological Survey is clearly shown by a casual inspection of maps made at 10-year intervals since the first appropriation for topographic surveys was made in 1888.

The United States not only needs better maps, but more of them. This need can be met by existing organizations and bureaus on short notice whenever Congress realizes that ample appropriations for this purpose are an investment that will make big returns to the country. It is necessary to look into the future in mapping, for it is for future needs that maps are made. The safest policy is to supply maps as good as can be made at the moment, for there is little doubt that unless this is done they will be found inadequate in the not distant future. A well-made map should be constructed on a framework consisting of accurate triangulation or traverse to assure reliable map positions. The contours and elevations should be dependent on near-by precise level lines; all other level lines should be so carefully run that it will not be necessary to make adjustments for any but very small circuit closures; and, finally, the contour lines should be located so well that any check that can be applied to them will indicate that they are not incorrectly located more than a short distance. This last requirement is admittedly difficult when surveys of brushy or timbered areas are made by methods now commonly in use, but recent tests of maps made by aerial photography prove that such terrain is no longer impossible to map with accuracy.

A strict observance of the conditions mentioned will assure a map that can be revised from time to time at small cost and kept as up to date as are mariners' charts. The map then becomes a living thing, as it were, that is constantly changing as the country grows. Unfortunately, such revision cannot be made unless the map, as first constructed, is sufficiently accurate to serve as a base to which new cultural features can be added. To revise a

* Topographic Engr., Brock & Weymouth, Inc., Philadelphia, Pa.

map successfully, it should only be necessary to add the new features and delete those that have disappeared, but not to change other details. It is impossible to use an inaccurate map as a base for revision if satisfactory results are expected, as the changes that occur due to expansion of industry and growth of population have a perverse habit of manifesting themselves in weak spots of old maps. That re-survey and not revision is needed in the case of many Government maps is appreciated when their method of construction and the cost of the original surveys are investigated. Fine maps, like most other things, cannot be obtained for "a song", and unless they are well made in the first place they will be a continual source of expense for maintenance, and of loss to industry due to their inherent errors.

The author shows that this country might have had adequate topographic maps of the public lands, had it not been for a lack of foresight in the days when this work was inaugurated. The loss due to the inaccurate early public land surveys was immeasurably increased by the fact that this splendid opportunity to secure topographic maps of all the public domain was entirely overlooked. The country is still paying the cost of that mistake.

About 57% of the Continental United States, exclusive of Alaska, has never been mapped even in the roughest manner. What the percentage may be that is mapped accurately enough to justify revision, it is difficult to state, although it can be said without hesitation that it is small. For these reasons it is to be hoped that the Temple Act providing for the completion of the topographic map of the United States will soon be put into effective operation, and that the maps produced under this Act will be of such a high standard of accuracy that they will serve satisfactorily for many years. The entire cost of all maps made by the U. S. Geological Survey has undoubtedly been returned to the country many times, but this usefulness and the corresponding savings would surely have been greatly increased had their accuracy been greater. Who can say how many times their cost would have been repaid had accurate maps of the Mississippi Valley been in existence during 1927? What would they now be worth for the study of river control?

Observations by the writer indicate that the general purpose map, on the scale 1 to 62 500, is widely used for general studies and for studies of many special problems of relatively small areas by engineers in the business world. In order to use these maps in such studies, it is necessary for the engineer to enlarge the map so that the proposed structure will be of appreciable size and can be properly visualized in relation to other features. This introduces a grave difficulty, as the enlargement is always much greater than the field scale used by the topographer in the original survey. Consequently, his map suffers by comparison with even a crude map made on a larger scale. It seems that by increasing the original map scale it would be possible greatly to extend the usefulness of these small scale maps without changing the publication scale or greatly increasing the cost. This increase in accuracy is worthy of consideration, for not only would the value of the maps be enhanced for present needs, but it would assure their satisfactory revision when this is needed.

The author fully appreciates the possibility that future mapping will be done by aerial photographic methods to a large degree. As he states, such methods will probably never entirely replace ground surveys; nor is this desirable, as place names, political and property boundary lines, and a certain amount of fundamental control will always have to be obtained on the ground. In certain areas it may even be necessary to gather other essential data, although it should be possible to arrange the field work so that this may be obtained when other necessary information is secured.

The accuracy and ease with which contours may now be drawn by stereoscopic methods in timbered country is a never-ending cause of surprise, and to attempt to state what will eventually be done by this method in such areas is impossible.

In his comments on the use of aerial photography, the author undoubtedly had in mind the method now used by the U. S. Geological Survey, in which planimetric detail only is taken from the photographs and the contours are added in the field. Otherwise, it is difficult to account for his statement that streams must be traversed to determine their fall when photographic methods are used. It can confidently be said that any method of applying aerial photographs in mapping, that fails to make use of image displacements caused by ground relief, omits the most valuable aid that such photographs can render the topographer. This partly accounts for the unsatisfactory results that were obtained in 1925 near Grand Valley, Colorado, for there is no reason to believe this area would have offered any difficulty had it been photographed for mapping by stereoscopic methods.

The writer quite agrees that there is little chance for small scale maps to be produced at lower cost in the future, as the demand for increased accuracy will offset any new economy in operation. For this reason, aerial mapping methods that can promise greater accuracy without a great increase in cost should be judged by comparing their cost per square mile with those of ground surveys of equal accuracy, and not by a direct comparison of costs per unit of area.

C. L. Hall,* M. Am. Soc. C. E. (by letter).—There seems to be but one assertion made by the author, on which critical comment is in order.

Colonel Birdseye divides the history of mapping into two major periods: One in which mapping was performed "for military purposes", and the other in which it was performed "for economic or engineering uses". These periods are not, however, as the author seems to indicate, epochs in world history, nor even in National history, since they are of radically different duration in different parts of the world. A considerable portion of the mapping now going on in the world, including some being paid for by the United States, is intended primarily for military purposes. In France and Great Britain, while the economic importance of maps may now exceed their military importance, surveys are still conducted under military control and largely by military personnel. On the other hand, in pre-war Germany, as one example, intensive surveys were often conducted by civil personnel under civil control, primarily

* Maj., Corps of Engrs., U. S. A., U. S. Engr. Office, Rock Island, Ill.

for military purposes. It is believed that the military value of a map of an area exceeds its economic value if there is a good chance of a war occurring in that area before the map becomes hopelessly out of date. The major periods of the mapping history of the United States named by the author are, in reality, based on the good fortune of this country in keeping its territory—outside of a few Indian areas—clear of the horrors of war since 1865.

Colonel Birdseye's excellent review of the present status of the art of aerial surveying should be of special interest. Particular attention should be drawn to his statement that in the revision of old surveys, made necessary by changes in the works of Man, aerial photographs would make it possible to publish an up-to-date map without the necessity of re-surveying by ground methods. This use of the airplane in surveying points the way to the possibility of keeping topographical maps up to date with reasonable economy. If any constant demand could be stimulated among the general public for up-to-date topographical maps, the political authorities of the nation would doubtless provide the comparatively small sums necessary for the annual revision of maps of the more quickly changing areas. The road map maker has to revise his maps annually; the commercial atlas publisher has to revise his atlas annually; and the Post Office Department has to revise its maps at frequent intervals. The U. S. Geological Survey should not be the only mapping agency in the world required to print re-editions with culture so out of date that often the map is of interest only to local historians.

Colonel Birdseye properly calls the attention of the profession to the backwardness of the United States in mapping activities. This situation, while probably known to most engineers, does not seem to have appealed to them as a matter requiring urgent representations to the political authorities, National and State. This National ignorance of topography has recently become a matter of some interest to the general public.* The basic law which should ensure the mapping of the country has been passed.† All that is needed is popular demand produced by educated leadership which is also enthusiastic. This leadership should be supplied by the Engineering Profession.

John C. H. Lee,‡ Assoc. M. Am. Soc. C. E. (by letter).—This interesting and instructive paper accurately describes the harmonious relation and efficient co-operation which have been developed between the U. S. Geological Survey and what Army engineers like to consider its old parent organization, the Corps of Engineers. The same general specifications and standard requirements of accuracy are recognized, so that the economically important topographical maps of the Geological Survey are becoming, in all essential respects, satisfactory tactical maps for the military forces. Also, the accurate military surveys are being accepted as standard topographic sheets.

The author gives an interesting résumé of the widely needed project for completing the general topographic map of the United States. How important the completion of this survey project is to National defense, can perhaps be appreciated with the realization that among the 60% of uncompleted sheets,

* Editorial, *Saturday Evening Post*, October 15, 1927.

† Act of February 27, 1925, Chapter 360, 68th Cong., 2d Sess.

‡ Maj., Corps of Engrs., U. S. A.; Dist. Engr., Vicksburg, Miss.

there are many vitally important strategic areas. Modern military doctrine recognizes the importance and almost the necessity of correct topographical maps as military plans for large troop concentrations and for successful field operations. Divisions and larger units cannot be rapidly and reliably moved or supplied without good maps. American military forces are all trained under this principle. The use of maps becomes second nature to them. Without maps their operations would be greatly hindered and their success jeopardized. Nevertheless, the fact remains that along wide stretches of this country, including areas of vital strategic value, there are still no maps worthy of the name. From a military standpoint, therefore, the program authorized under the Temple Act should be carried to completion, especially along the borders of the United States.

From the Army engineer's standpoint, moreover, the project should be completed within the borders as well. Studies of flood control and waterway improvement not only can be materially facilitated through good topographic maps, but, as was the case recently in the Mississippi Valley, can be seriously hampered without them. This need was brought into bold relief during the high-water fight of 1927. There were no reliable maps available for much of the back-water country over which extremely important relief operations were being conducted.

The Army engineer recognizes also the value and importance of good topographic maps in planning railway and highway communications with which he is charged in time of war within the period of operations. Whereas no one now sees the eventuality which would bring warfare within the borders of this country, it may be recalled that five or ten years prior to the World War, practically no one ever thought that American troops would fight in Europe.

Since this problem confronts the Army—the problem of no maps for important strategic areas—the task of making emergency maps during actual operations must be faced. The solution of this difficulty is being sought through experiments in aerial photographic surveying and map reproduction in the field. The problem of rapid field triangulation that can be carried on without molestation of the enemy; the rapid and reliable means of obtaining the necessary over-lapping photography; and, finally, a swift and certain method of reproducing the completed map in quantity under field conditions, becomes a task worthy of high engineering talent. This work is all under the direction of the Chief of Engineers. It is of the highest importance in a military sense and not without its peace-time economic value.

As stated by Colonel Birdseye, aerial photographic surveying has become an important adjunct to the general project, the total cost of which would seem to justify the expenditure of sufficient funds to develop the new art in a thoroughly practical sense.

C. H. Birdseye,* M. Am. Soc. C. E. (by letter).—This paper was presented at the first meeting of the Surveying and Mapping Division with the idea of giving the members a brief résumé of the history of surveying and

* Chf. Topographic Engr., U. S. Geological Survey, Washington, D. C.

mapping. The writer did not intend it to be a comprehensive presentation of the subject, and he is not surprised that the discussion uncovered several incomplete and immature statements.

Major Hall questions the writer's division of the history of mapping into two major periods, "the first for military purposes and the second for economic or engineering uses." One would need to be well equipped to debate this subject with Major Hall, who is one of the most profound students of military engineering in the United States Army, and the writer is quite willing to admit that the division of mapping activities into these two periods is inadequate.

Mr. Pendleton is correct in his assumption that the writer had in mind the use of aerial photography as practised by the Federal mapping agencies at the time the paper was written (1926). It should be noted, however, that he specifically referred to densely timbered areas in connection with the statement, "but the topographer must traverse these streams to determine their fall * * *." At the time the paper was prepared the writer was only vaguely familiar with the stereoscopic methods used by the firm of engineers with which Mr. Pendleton is associated. Later, opportunity to investigate these methods carefully has convinced him that the stereoscopic use of arerial photographs will provide elevations along rivers even in timbered country, well within the allowable error of small scale mapping. However, the writer has been unable to find any solution, by aerial photography, of the problem of locating section corners in the timbered areas of the Western Public Land States.

The U. S. Forest Service is a large user of topographic maps, and one of the principal requirements of that organization is the correct location of section lines and corners with relation to streams and other physical features. The principal point which the writer tried to bring out is that aerial photography cannot be expected to replace ground surveys entirely, and in densely timbered areas of the Western Public Land States it does not promise any great reduction in the cost of small scale mapping. The writer is still convinced of the soundness of this view, but does wish to emphasize his statement that, in most cases, the use of aerial photography will yield better maps.

Major Lee stresses the value of the standard topographic map for military purposes, and emphasizes the importance, from the standpoint of National defense, of completing the mapping program authorized by the Temple Act.

The writer is exceedingly interested in Major Lee's testimony that studies of flood control in the Mississippi River Valley have been seriously handicapped by the lack of adequate topographic maps, particularly in view of recent statements of some members of the Corps of Engineers that such maps are not essential to the solution of the flood problems. The area of the alluvial valley of the Mississippi River is about 30 000 sq. miles, of which about 20 000 sq. miles was flooded in 1927. Only 1 400 sq. miles, or about 7% of the alluvial valley, is topographically mapped, and it is inconceivable that any engineer engaged on flood control or flood relief problems does not need all the knowledge he can secure of the topography of the area subject to floods.

Paper No. 1692

SURVEYS ON THE COAST OF NEW JERSEY*

By Victor Gelineau,† M. Am. Soc. C. E.

With Discussion by C. V. Hodgson, M. Am. Soc. C. E.

All surveys of a coastal region should be based on the fact that shore lines shift their positions, thereby changing land ownership. This applies with particular force to New Jersey, for it is almost surrounded by water. The shore line is a property boundary and its variations, within historic times, are most interesting to the physiographer, the surveyor, and the civil engineer. Probably these changes are not in fact more extensive than have occurred in other ocean-front States, but the relatively high degree of development of the New Jersey Coast has compelled the study of shore-line variations and of measures to preclude radical change of contour. The only means of measuring the changes in shore line is by executing repeated surveys referred to a common datum.

Shifting of Shore Lines

Whenever water waves beat on a shore they tend, in general, to level down land forms. The result of tidal and wave forces is to carry beach material in one dominant direction. Thus, in New Jersey, Barnegat Inlet is approximately the division point of the shore drift. From Barnegat Inlet northward to Sandy Hook, the beach material generally tends to drift northward, while south of Barnegat the direction of the alongshore drift is southward. This is not always true, for certain storms will cause a quick reversal of drift and there are sections where local movements are almost always opposite in direction to the general movement.

* Presented at meeting of the Surveying and Mapping Division, Philadelphia, Pa., October 6, 1926.

† Director and Chf. Engr., New Jersey Board of Commerce and Nav., Jersey City, N. J.

The travel of this material along the beach is the primary cause of (*a*) the alteration in direction and position of the inlet gorges; and (*b*) the tendency of certain inlets to close, particularly those the lagoon areas of which are relatively small.

Examples of Shifting Inlets

The shifting and the closing of inlets and their subsequent re-opening by natural or artificial agencies and the formation of new inlets have served to complicate the location of property lines and have in fact obliterated large land holdings. A series of inlets existing on the New Jersey Coast within recent times were of virtually no value from the standpoint of navigation, but were always a menace from the standpoint of coast erosion, and could be rather confidently expected to close up every year or two. The inlets leading into Deal Lake, Sunset Pond, Wesley Lake, Goose Pond, Duck Pond, Silver Lake Inlet, and Sea Girt Inlet were examples in point. To-day, these inlets are all permanently closed, except for flumes or gates that permit drainage of the pond or basin.

Shark Inlet and Manasquan Inlet, the lagoon areas of which are relatively restricted, are two interesting examples of the tendency of inlets to shift and, occasionally, to close. Their behavior prior to the improvement of Shark Inlet was almost parallel. The normal position of the inlet gorge would be approximately at right angles to the general line of the beach, making a most favorable condition for the ebb and flood flows. The gorge would remain in this position for a more or less indeterminate period, but the actively moving alongshore drift of sand would gradually shift the inlet gorge to the northward so that its channel would flow that way nearly parallel to the beach for several hundred feet before swinging eastward into the ocean. Ultimately, a position would be reached, owing to the great length of the gorge, where the velocity of the tidal current would be insufficient to scour the sand out and the inlet would close. An abnormal difference in the water levels between the lagoon and the ocean, accompanied by storm conditions, might result in the inlet's gorge re-establishing itself in the normal position; or the opening might be made by dredging a ditch or a small canal across the sand-bar. Then the cycle would repeat itself.

Shark Inlet was fixed in position after 1911 when the State enacted legislation and made the necessary appropriations. Manasquan Inlet was closed from April, 1926, to January, 1927. At the time of the U. S. War Department Survey in 1878 it was fully 1 100 ft. north of its normal position. A number of other inlets, referred to in old works and records, have been closed for perhaps 100 years or more. Their location must now be guessed by such evidence as the meadow islands and soundings will furnish. Cranberry Inlet comes within this description. There is some evidence that it was used during the War of the Revolution. Its former existence furnishes an explanation for giving the name of Island Beach to the beach that extends northward

from Barnegat Inlet. Attempts were made by Michael Ortley, in 1821, and Anthony Ivins, Jr., in 1847, to re-open an inlet in this vicinity, but without success.

Triangulation Control

The foregoing demonstrates conclusively how vital it is, in surveying on the ocean front, especially wherever a yielding, mobile shore material is impinged upon by swift currents or large waves, to fix all stations accurately from reference points of reasonable permanence. Monuments should be placed well back from the high-water line and all important points should be referenced and located by triangulation or by an adaptation of the three-point method. Three points, however, may not be enough; partly because they may be poorly located and, therefore, fail to give a good intersection, but primarily because of the probability that some of them may be destroyed within a relatively few years. In 1912, for instance, the traverse points of a survey were referenced by the three-point method to a lighthouse and two water towers, all very substantial structures. The towers were removed when the pumping plants were enlarged and, in a re-survey of 1925, the traverse monuments had to be recovered by other methods.

The writer urges an application of the triangulation system. It is almost invariably superior to traverses for surveying in the vicinity of waterways other than the ocean front. The inter-visibility of the stations, the ease with which adjustments can be made, the facility with which stations can be recovered, and the impracticability of chaining across large bodies of water, are strong arguments for its use.

Authority for Making Surveys

There is no unit of the State Government of New Jersey that applies itself primarily to the making of surveys and maps. Each State Department the operations of which require surveys (and there are several) has its own individual surveying organization to execute the surveys and plans required by that Department. The first "system" of surveys established in New Jersey includes the necessarily scattered locations of tracts granted by the ancient Proprietors of West Jersey or East Jersey. It seems advisable to explain the source of land proprietorship or title in New Jersey.

Land Titles

New Jersey was originally a Dutch Colony, settled under the auspices of the Dutch West India Company. Many years after the Dutch settlement, the activities of the Dutch marking them as dangerous enemies to Sweden, Gustavus Adolphus of Sweden, in 1638, sent out an expedition which settled on both sides of the Delaware. Prosperous for a time, the Swedish settlements weakened and, in 1655, the Dutch conquered New Sweden. From this year until 1664, New Jersey was absolutely a Dutch Colony.

On March 12, 1664, Charles the II, of England, granted to his brother, James, Duke of York, all of what is now New Jersey, as well as Long Island and other territory to the north and east. During that year the British Naval

Power compelled the surrender of the Dutch claims. In the meantime (June 23-24, 1664), the Duke of York, by indenture of lease and release, conveyed to John, Lord Berkeley, and Sir George Carteret, lands which include what is now New Jersey. These are described* as follows:

"All that tract of land adjacent to New England, and lying and being to the westward of Long Island, and Manhitas Island, and bounded on the east part by the main sea, and part by Hudson's river, and hath upon the west Delaware bay or river, and extendeth southward to the main ocean as far as Cape May at the mouth of Delaware bay; and to the northward as far as the northermost branch of the said bay or river of Delaware, which is forty-one degrees and forty minutes of latitude, and crosseth over thence in a strait line to Hudson's river in forty-one degrees of latitude."

The famous quintipartite deed which defines the division between East and West Jersey was executed in July, 1676. This was preceded by some other conveyances which it is not necessary to consider. The southeasterly terminus of the partition, or province line, is described in this quintipartite deed as "the most southardly point of the east side of Little Egg Harbour aforesaid;" but Little Egg Harbor Inlet has shifted over several miles in location during the intervening centuries.

The Proprietors, who derived their title in the manner just outlined, sold parcels to applicants. Briefly, the procedure was to send out a deputy surveyor who located the lands applied for and then made his return to the Proprietors. Much of this survey work of the Eighteenth Century and the early part of the Nineteenth Century was very inaccurate, as might be expected in view of the very low value of the lands.

Earlier Surveys

From relatively early times, the State of New Jersey did show a commendable desire to obtain good maps and probably was pre-eminent among the States of the early Nineteenth Century in endeavoring to obtain them, but all that was accomplished still left much to be desired. The first real system of surveys, worthy of the name, was that established by the United States Coast and Geodetic Survey about 1840. To-day, this furnishes the chief reliance in defining the position of shore lines before the more detailed surveys, made necessary by the development of the coastal cities. It must be remembered here that the magnificent cities of the New Jersey Coast are institutions dating back very few years. Let this great evolution serve as an example to people of other localities, who may believe that their beaches will not develop into valuable lands in the near future.

The State Geological Survey of New Jersey made a valuable contribution in producing the surveys which form the basis for the maps now published by the Board of Conservation and Development. The topographical survey of that Department is reviewed in the report of the State Geologist of 1887, which recommended that the entire State be covered by a cadastral and economic survey. It consisted essentially, as to the coastal region, in transit and stadia surveys of the marshes and waterways, and was controlled by the U. S.

* See Leaming and Spicer, "Grants and Concessions of New Jersey," p. 8 *et seq.*

Coast and Geodetic Survey monuments and triangulation stations. Unfortunately, the Legislature did not carry out the recommendation of the report.

Modern Water-Front Surveys

The Board of Commerce and Navigation (successor to the Riparian Commission), the Department of Inland Waterways, the Harbor Commission, etc., are extending their surveys over the water-front of the State as rapidly as possible. They require surveys for such different purposes as the establishment of riparian or pierhead and bulkhead lines; the improvement of inland waterway channels; and the measuring of rate of erosion or accretion on the beaches. As far as practicable, each survey is planned to meet the needs of all Departments. It is hoped that within a very few years the Board will have accurate detailed surveys of the entire tidal water-front of the State. This information is of untold value to land owners. It will remove from future litigation, the element of uncertainty in the location of high-water mark boundaries.

Most maps of the former Riparian Commission of New Jersey are very valuable, but they necessarily cover rather limited areas because they were made merely to meet the demand for the establishment of riparian lines. The former Department of Inland Waterways which constructed the inland waterway system from Cape May to Bayhead, covered some of this area with surveys of high precision.

Lack of Accurate Surveys

The legal complexities which arise through a confusing description of a beginning point are most serious and discouraging. A most striking example is the mischief caused by uncertainty in the location of the Province Line between East and West Jersey. The line was run by George Keith, Surveyor General of East Jersey, in 1687; but it has been stated* that, "the western proprietors thought too much of their best lands were surveyed to the eastward, and were uneasy with it." In Governor Coxe's report (1687) to the Proprietors of West Jersey, he compares the excellent maps of his adversaries of East Jersey with the unsatisfactory maps of his associates of West Jersey. He states,†

"They * * * of East Jersey have in this respect, exercised the highest prudence, knowing the whole country to a little, and thereby have both overreached you. I have seen their draughts than which nothing can be more exact;"

A map, dated 1747, shows another location of this line as run by Lawrence in 1743.

New Inlet, at the southerly end of Long Beach, opened in about 1800, during a violent storm. The position of Little Egg Harbor Inlet affects vitally the division line between properties. It entered prominently into the establishment of the county lines. In fixing the county line about 1885, it was found necessary to rely almost entirely on tradition to establish the time that New

* Smith's "History of New Jersey," p. 196.
† *Loc. cit.*, p. 546 *et seq.*

Inlet was opened because Beach Haven Inlet was not then in existence. A large number of the elderly people gave their ancestors' statements as evidence of its time of opening and its position at that time.

Comparison of Two Major Inlets

Thus, there are now two inlets: What is known as New Inlet, which opened in about 1800, and Beach Haven Inlet, farther north, which opened in 1920. A survey of Beach Haven Inlet was made in 1923 by the U. S. Coast and Geodetic Survey and the New Jersey State Board of Commerce and Navigation. Whether the two inlets will co-exist for any length of time is a question for the future. In the meantime the submerged lands have practically no value, and the isolated area known as Tucker's Beach has also very little value. The behavior of this inlet, or pair of inlets, is in some degree paralleled by the behavior of Great Egg Harbor Inlet between Longport and Ocean City, which has, at times, had two branches separated by a large sand-bar island. The Lake Survey of 1881 shows a single inlet, with Longport Point far south of its present position. Longport has since lost approximately 184 acres (see Fig. 1).

Example of Accretion

Sand beaches tend to shift oceanward or landward in the course of years. The tendency of sand dunes to move is well known and the existence of a series of lines of sand dunes indicates movement of the beach line. The late Henry S. Haines, M. Am. Soc. C. E., in fixing a survey on an undeveloped section of one New Jersey beach, drove iron pipes which extended 3 or 4 ft. above the ground level. They were set at the foot of the sand dunes on the ocean side. Some years later, when called upon to retrace this survey, he found the beginning corner almost buried and on the opposite, that is, landward, side of the sand dune. In other words, the sand dune had moved oceanward perhaps 150 ft.; yet this change was not apparent to the eye. Most beaches change slowly at points remote from the inlets; but at the inlets serious changes may be caused by one storm, if coast-protection measures have not been provided.

Survey Methods

The State has received about $12 000 000 from the sales and leases of lands under water and has expended about $2 000 000 in the improvement of its inland waters and protection of its beaches. The surveys of the New Jersey Board of Commerce and Navigation should be made for three purposes in order to be of maximum value, namely, the establishment of riparian grant lines; the possible improvement of the waterways; and, the measurement of the rate of change in the shore line. By shore line is meant the line of mean high water, for that is a property division line in New Jersey. This necessitates somewhat more detail than would be required for navigation maps and the accuracy should approximate 1 in 10 000. Traverse lines, carefully referenced to existing curb lines, board walks, and street monuments, are used in and near cities on the beach front. Frequent cross-sections of the beach are

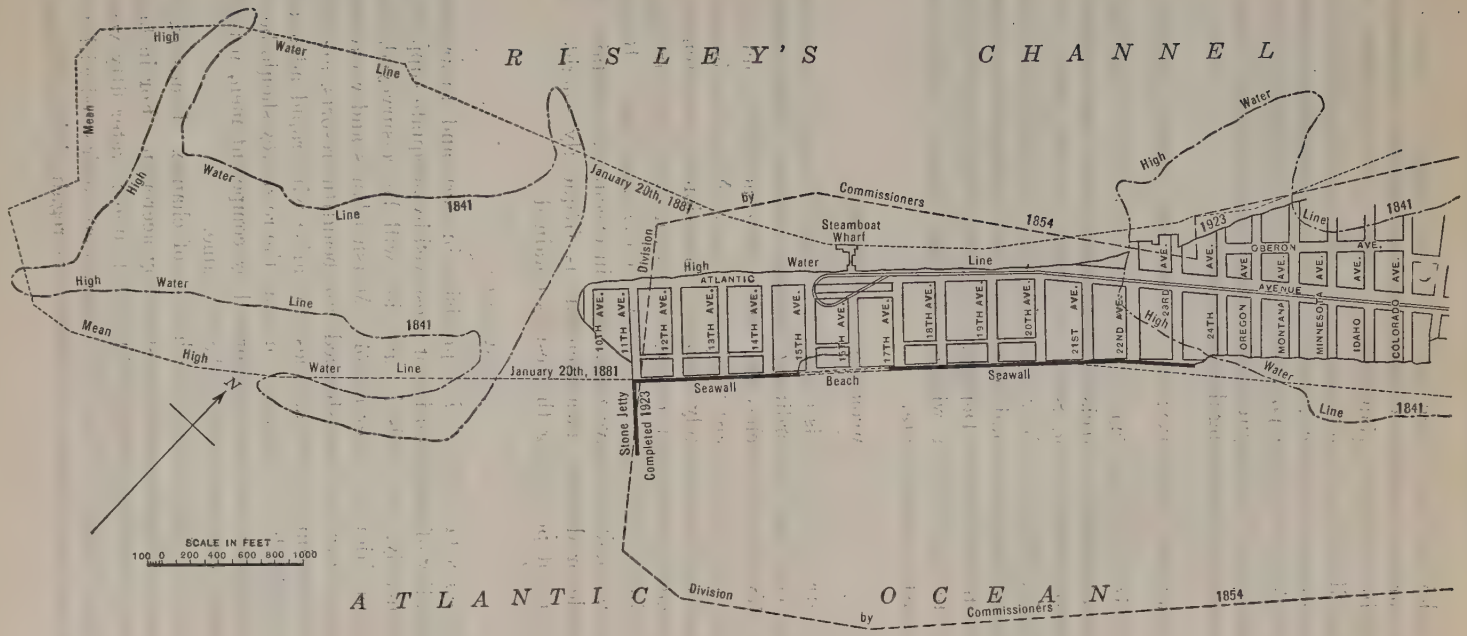

FIG. 1.—MAP SHOWING SHORE LINE CHANGES AT LONGPORT, N. J.

taken out to low water or beyond, as the mere running of a traverse along the high-water mark of a certain date does not give all the information desired. Where visibility permits, triangulation systems are established, the details usually being filled in by transit and stadia. The sextant and range method of sounding is used in the inlets; and the range and two-transit method in the bays and creeks. Wherever possible, a chain of triangles or quadrilaterals forms the control, with distant point angles for references. Check bases are always measured in the triangulation systems.

Suggested Co-Ordination of State and Federal Surveys

An effort is now being made to persuade the U. S. Coast and Geodetic Survey to re-establish its precise triangulation system and leveling net over the New Jersey shore. The State has offered to adopt the Coast Survey standards and methods of observation for the extension of the triangulation and leveling. This plan would furnish an ideal medium of co-operation between the State and Federal Departments, leaving each Department to devote its energies to the field for which it is best adapted; thereby tending to extend the existing survey data.

Importance of Control

Strong control of surveys is essential and may frequently be obtained without excessive cost over the ordinary traverse methods. The history of coast surveys in New Jersey teaches the lesson that accurate control and good reference points are of the most vital importance. No survey is worthy of the name unless it can be accurately retraced. Precision of measurement is only a means of securing consistent comparisons with other similar surveys, particularly adjoining surveys and re-surveys of the same tract. By proper control it is often possible to save much time in execution of details. Fine precision of angle or distance measurements is frequently sought without any adequate means of preserving the results obtained.

Conclusion

What is the need of a fine degree precision in angle and linear measurement if the high quality of execution is not preserved by adequate supporting monuments? Ultimately, the lands in question will be re-surveyed, whether for sub-division, partition, or other reason. Marsh islands and waste dunes of 15 or 20 years ago have been transformed into beautiful resorts, and this process will certainly continue. Serious questions arise with rapid advances in land values. Theoretically, the original work and the re-survey should be consistent, and if the two operations were performed by competent men, using the same axes and origin, the results should be the same.

The history of shore lines is the history of change. Lands may be swept away by erosion and subsequently restored by accretion. For instance, in the Absecon Inlet Section of Atlantic City, lands under water fifty years ago are now worth many million dollars. The Courts were confronted with the problem of deciding who was entitled to the lands thus regained from the sea.

How should these accretions be apportioned? The broad legal principle, perfectly simple and just, is that the accretion shall be equitably admeasured among the riparian owners. In the application of this legal principle it is often very difficult to determine who the riparian owners are, and how the regained land shall be apportioned. Important questions must first be solved. Where was the shore line at the time of a transfer of title? Did the vendor retain a strip of land adjacent to the water? The calls in the deed may or may not indicate what the vendor and vendee contemplated as to this vital point. In other words, the difficulties are due primarily to meager or contradictory evidence.

In these circumstances there is no substitute for maps plotted from good surveys. The work done by the U. S. Coast and Geodetic Survey has been invaluable in establishing the location of shore lines as they were years ago, and surveyors of coastal land would do well to profit by its experience. The shifting of inlets especially should serve as a striking warning that surveys on the seashore must be very thoroughly and accurately referenced to mainland points of reasonable permanency.

DISCUSSION

C. V. Hodgson,* M. Am. Soc. C. E. (by letter).—Three factors necessary to a satisfactory survey have been admirably stressed by Mr. Gelineau, these being adequate accuracy in angle and length measurements, permanent monumentation, and connections to the National system of triangulation surveys. All three factors are important to any survey, but the last two are especially so in regions where the boundary monuments are subject to disturbance by natural causes or by the hand of Man. A slight amplification of these three points may be warranted.

Accuracy.—Mr. Gelineau states that the three purposes which the survey of beach lands must serve, demand that the principal lines of traverse or triangulation be in error not more than 1 part in 10 000, or 1 ft. to 2 miles. This corresponds to what is known as second-order accuracy in Federal surveys. At first thought this accuracy may seem excessive until it is recalled that one object of the New Jersey survey is to define the boundaries of riparian grants, and that the beach lands have a very high value.

For years the U. S. Coast and Geodetic Survey was criticized for what was considered to be the excessive accuracy of its coastal surveys—a specified error of not to exceed 1 part in 5 000 for its main lines of third-order triangulation. It now appears that for many purposes that accuracy is not sufficient, although ample for charting and mapping. It is doubtful, however, if the surveying agencies of the Federal Government would be justified in increasing the accuracy of detailed control surveys at the present time. Greater accuracy may frequently be needed for cadastral or improvement surveys, but they usually lie outside the province of the Federal Government.

An accuracy represented by a maximum error of 1 part in 10 000 in determined distance is neither difficult nor expensive to secure if proper instruments and methods are used. Where an extensive area is involved, or where there is a strong probability that the value of the land will increase considerably in the future, the accuracy specified by Mr. Gelineau is by no means excessive.

Monumentation.—To monument a survey permanently in a region subject to erosion is a practical impossibility. It is also very difficult to establish monuments which can be easily recovered in a region where accretion or sedimentation is noticeable or where movements of sand dunes are changing the surface of the ground. Various expedients have been tried by the Coast and Geodetic Survey in regions subject to these shore-line changes, including deep sub-surface marks and cypress or cedar posts as witness marks. The present practice is not to mark the station permanently if it is in a location subject to erosion, but to reference it by two monuments placed far enough back from the shore to be secure for a number of years and yet near enough to serve in relocating the old station at any time, with an error of not more than about 1 in.

If the coastal control is by the triangulation method and a line of stations has been established inland on solid ground in locations easily visible from

* Asst. Chf., Div. of Geodesy, U. S. Coast and Geodetic Survey, Washington, D. C.

the coast, the preservation of the outer line of exposed station marks is not so important, for they can be relocated at any time from the inner line of stations. In localities where sand drifts or sediments may cover up the marks, witness posts are used in connection with fairly large concrete monuments at the station. These monuments can be readily located by prodding with an iron bar through a considerable depth of mud or sand.

Where the ground is stable it is economy to establish permanent marks. A slight increase in the cost of monumentation may double the period of years during which the survey may be retraced. Underground marks separate from the surface marks, and substantial reference marks placed in property lines, will perpetuate a survey for a long period of years at slight additional expense.

Connection to National Datum.—There are two ways in which a survey may be connected to the North American datum. By the first method one or more control stations on the National datum are tied in by traverse or triangulation to the new survey, but are used simply as reference points. By the second method the origin of a local system of plane co-ordinates is either made to coincide with a station on the National datum or is connected to it. The latter system is usually followed when detailed surveys are to cover a considerable area. Either method has the effect of making every control station in that region which is on the National datum a reference mark for the new survey, and is the surest method of perpetuating it. If the connection to the National datum stations is made part of the legal record, there is little doubt that any Court would give such evidence great weight in any retracement surveys.

Paper No. 1693

A GRAPHIC METHOD FOR DETERMINING THE STRESSES IN CIRCULAR ARCHES UNDER NORMAL LOADS BY THE CAIN FORMULAS*

By Frederick Hall Fowler,† M. Am. Soc. C. E.

With Discussion by Messrs. B. F. Jakobsen, William Cain, Walter L. Huber, Glen Edgar Edgerton, Lars R. Jorgensen, Fred A. Noetzli, and Frederick Hall Fowler.

Synopsis

This paper presents a series of curves for determining the stresses, in pounds per square inch, at the extrados and intrados of crown and abutments of circular arches under normal loads.

The curves fall in three groups based on three separate sets of formulas developed by William Cain, M. Am. Soc. C. E.:

Group I.—Arches with "fixed ends" (neglecting shear). (Figs. 3, 4, 5, and 6.)
Group II.—Arches with "hinged ends" (neglecting shear). (Figs. 7, 8, and 9.)
Group III.—Arches with "fixed ends" (including influence of shear). (Figs. 10(*a*), 10(*b*), 10(*c*), 10(*d*), 11(*a*), 11(*b*), 11(*c*), 11(*d*), 12(*a*), 12(*b*), 12(*c*), 12(*d*), 13(*a*), 13(*b*), 13(*c*), and 13(*d*).)

The curves represent the stresses due to a full water load corresponding to a 10-ft. head; but, by the methods outlined, they may be used for any head. They afford a quick and easy method of applying a very complicated and rigorous method of analysis.

The problem of determining with reasonable accuracy the stresses in arch dams has commanded an important place in engineering literature, partic-

† Cons. Civ. Engr., San Francisco, Calif.

ularly during the past six years. In the *Transactions* and *Proceedings* of the Society alone, from 1919-20 to date (1927), there have been seven papers* devoted exclusively or in large part to the study of stresses in the ordinary arch dam, and three others† devoted to the special problems of the multiple arch.

These papers propose formulas that range from rough approximations to the most rigid mathematical determinations. Two valuable contributions of the group were by Professor Cain. In the first of these, "The Circular Arch Under Normal Loads", the author developed, by refined mathematical methods, formulas for computing moments and thrusts, and the resulting stresses in arches with "fixed" and "hinged" ends.

Fig. 1 taken from this paper is supposed to represent a horizontal circular arch, 1 ft. thick, perpendicular to the plane of the paper.

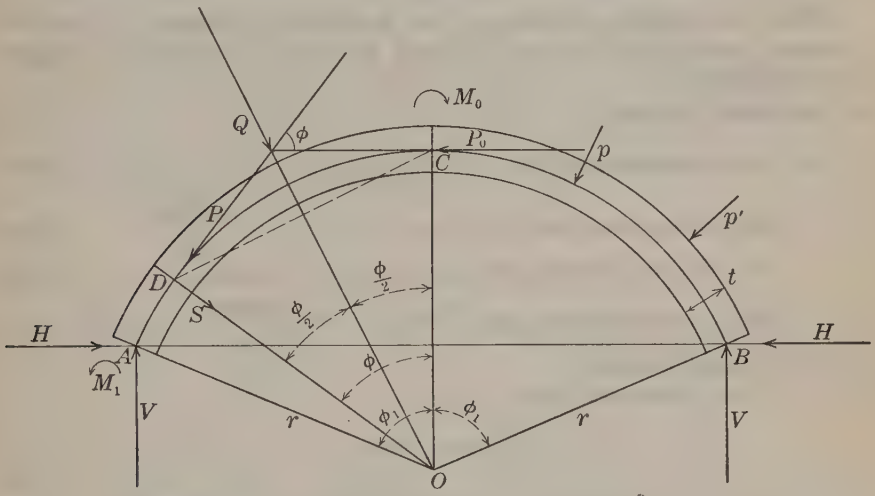

FIG. 1.—CIRCULAR ARCH OF UNIFORM RADIAL THICKNESS, FIXED AT THE ENDS AND SUBJECTED TO A UNIFORM NORMAL, RADIAL PRESSURE.

The notation used‡ (omitting symbols that did not enter into the formulas for moments and thrusts), was as follows:

Let t = uniform radial thickness of arch, in feet;

r = radius of center line of arch, in feet;

r' = radius of extrados, in feet;
p' = normal radial pressure, in pounds per square foot, on extrados;
p = normal pressure, in pounds per square foot, on center line

$$= \frac{p' r'}{r};$$

ϕ = angle with radius of crown for any point, D;
ϕ_1 = half central angle, $A O B$;
s = length of arc, $C D = r \phi$, $\therefore ds = r\, d\phi$;
M_0 = moment at crown, taken positive clockwise;
P_0 = thrust at crown;
M and P are, respectively, the moment and tangential component of the thrust at D (r, ϕ).

With this notation, Professor Cain proceeded to develop a series of formulas, among which were the following for moments and thrusts at crown and abutment:

Arch fixed at ends:

$$P_0 = \text{thrust at crown} = p\, r - \frac{p\, r}{D}\, 2\, \phi_1 \sin \phi_1\, \frac{k^2}{r^2} \quad \ldots\ldots\ldots\ldots\ldots (10)^*$$

$$M_0 = \text{moment at crown} = -(p\, r - P_0)\, r \left(1 - \frac{\sin \phi_1}{\phi_1}\right) \quad \ldots\ldots (12)^*$$

$$P_1 = \text{thrust at abutments} = p\, r - (p\, r - P_0) \cos \phi_1 \quad \ldots\ldots\ldots\ldots (4)\dagger$$

$$M_1 = \text{moment at abutments} = r\, (p\, r - P_0) \left(\frac{\sin \phi_1}{\phi_1} - \cos \phi_1\right) \quad \ldots (13)^*$$

Arch hinged at ends:

$$P_0 = \text{thrust at crown} = p\, r - \frac{2\, \frac{k^2}{r^2}\, (p\, r) \sin \phi_1}{\phi_1 (2 + \cos 2\, \phi_1) - \frac{3}{2} \sin 2\, \phi_1 + \frac{k^2}{r^2} \left(\phi_1 + \frac{1}{2} \sin 2\, \phi_1\right)} \quad \ldots\ldots (18)\ddagger$$

$$M_0 = \text{moment at crown} = -(p\, r - P_0)\, r\, (1 - \cos \phi_1) \quad \ldots\ldots (3)\S$$

$$P_1 = \text{thrust at abutment} = p\, r - (p\, r - P_0) \cos \phi_1 \quad \ldots\ldots\ldots (4)\dagger$$

$$M_1 = \text{moment at abutment} = 0.$$

The stresses s, in pounds per square inch, at the extrados and intrados at the crown and the abutments were computed by substituting the values of thrust and moment in the well-known formula:

$$s = \left(\frac{P}{t} \pm \frac{6\, M}{t^2}\right) \div 144$$

It should be noted regarding these formulas for thrust and moment that (*a*) they did not include the influence of shear; (*b*) they were referred to the center line of the arch ring and not to its neutral axis; and (*c*) the water pressure, p, was at the center line of the arch ring and not at the extrados.

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 237.
† *Loc. cit.*, p. 236.
‡ *Loc. cit.*, p. 242.
§ *Loc. cit.*, p. 236.

A separate formula for shear, S (Equation (14)* was included in the body of the paper, several valuable observations on that subject followed in the discussion, and in his closure,† Professor Cain developed a more detailed formula for the value of $(p\,r - P_0)$, including shear.

The mathematical treatment of the problem was so clear and complete that the formulas were accorded wide acceptance and were extensively used (either with or without supplementary studies for shear). Subsequently, Professor Cain‡ developed further formulas for stresses in circular arches under normal loads. The more rigorous method here adopted differed from the original in the following important particulars: (*a*) The formulas for moment and thrust included the influence of shear; (*b*) both moment and thrust were referred to the neutral axis of the arch ring; and (*c*) water pressures were referred to the extrados.

The revised notation§ adopted by Professor Cain was, as follows:

"The arch to be considered is a horizontal circular arch of constant radial thickness, t, and a vertical height of 1 ft., fixed at the ends, and subjected on the extrados to a water pressure of p_e lb. per sq. ft. Generally, this is not the full water pressure at the level of the medial plane of the arch, but the part carried by the arch, the remainder being carried by the supposed cantilever.

"In Fig. 2, representing the half arch,

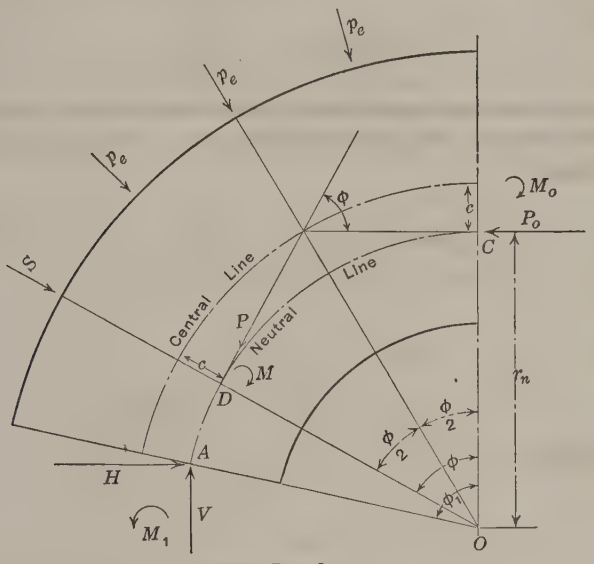

FIG. 2.

t = uniform radial thickness of arch, in feet;
r = radius of the center line, in feet;
r_n = radius of neutral line, in feet;

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 238.

† *Loc. cit.*, p. 269.

‡ "Stresses in Thick Arches of Dams," by B. F. Jakobsen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 475, containing a discussion and solution by the method of least work, by William Cain, M. Am. Soc. C. E., p. 522.

§ *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), pp. 528-529.

r_e = radius of extrados, in feet;
r_i = radius of intrados, in feet;
p_e = normal radial pressure, in pounds per square foot, on the extrados;
ϕ = angle with radius of crown for any point, D;
ϕ_1 = one-half the central angle = $A\ O\ C$.

"The arc, $A\ D\ C$, is the neutral line, so that if s = length of the arc, the distance, $C\ D = r_n\ \phi$, $d\ s = r_n\ d\ \phi$.

P_0 = thrust at the crown, acting at C, on the neutral line;
M_0 = moment at crown, taken positive when clockwise;
M, P, and S = respectively, the moment, normal component, and shear on the section through D ($r_n\ \phi$);
$c = r - r_n$;***"

The revised formulas for thrust and moment developed with this notation are:

$$P_0 = \text{thrust at crown} = p_e\ r_e - X \quad \ldots\ldots (103)^*$$

$$M_0 = \text{moment at crown} = -\ X\ r_n \left(\frac{1 - \sin\ \phi_1}{\phi_1}\right) \quad \ldots\ldots (105)^*$$

$$P_1 = \text{thrust at abutment} = p_e\ r_e - X \cos\ \phi_1 \quad \ldots\ldots (99)^\dagger$$

$$M_1 = \text{moment at abutment} = +\ X\ r_n \left(\frac{\sin\ \phi_1}{\phi_1} - \cos\ \phi_1\right) \quad \ldots\ldots (106)^*$$

In all cases,

$$X = \frac{p_e\ r_e}{D_n}\ 2\ \sin\ \phi_1\ \frac{k^2}{r_n^2}$$

Stresses, in pounds per square inch, for the extrados and intrados of the crown and the abutment are then computed by the following formulas:

At the crown:

$$\left.\begin{aligned} s_e &= \frac{M_0}{I}\ \frac{\frac{t}{2} + c}{r_e}\ r_n - \frac{P_0}{r_e \log_e \left(\frac{r_e}{r_i}\right)} \\ s_i &= -\ \frac{M_0}{I}\ \frac{\frac{t}{2} - c}{r_i}\ r_n - \frac{P_0}{r_i \log_e \left(\frac{r_e}{r_i}\right)} \end{aligned}\right\} \quad \ldots\ldots (107)^\ddagger$$

At the abutment:

$$\left.\begin{aligned} s_e &= \frac{M_1}{I}\ \frac{\frac{t}{2} + c}{r_e}\ r_n - \frac{P_1}{r_e \log_e \left(\frac{r_e}{r_i}\right)} \\ s_i &= -\ \frac{M_1}{I}\ \frac{\frac{t}{2} - c}{r_i}\ r_n - \frac{P_1}{r_i \log_e \left(\frac{r_e}{r_i}\right)} \end{aligned}\right\}$$

* *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 531.
† *Loc. cit.*, p. 529.
‡ *Loc. cit.*, p. 533.

The complete analysis of stresses at the crown and abutments of a dam, by any of these formulas, involves a large expenditure of time.

Even neglecting shear, the conditions are so complex that analysis by the rigorous mathematical methods results in complicated equations, the solution of which is a slow and laborious process. This fact was clearly recognized by Professor Cain, who strove to lighten the labor by including in his first paper, previously mentioned, a tabulation giving the values of the complicated variable expression, $\frac{2\,\phi_1}{D_0}$. Originally the tabulation* included values for this term corresponding to five different central angles and seven different values of $\frac{t}{r}$; in the discussion, B. F. Jakobsen, M. Am. Soc. C. E., plotted the results of the tabulation, somewhat amplified, in a chart† showing, on a semi-logarithmatic scale, curves for central angles varying from 40 to 180° by steps of 10°, and for values of $\frac{t}{r}$ ranging from 0.02 to 0.30; in his closure, Professor Cain further amplified the data by presenting them in both tabular and diagrammatic form.‡ This later table covers twenty-seven values of central angle (40 to 55° by steps of 2.5°; 55 to 130° by steps of 5°; and 130 to 180° by steps of 10°); in the diagram mentioned (Fig. 10),‡ in order to avoid complication, it was necessary to omit some of the curves, but, notwithstanding these omissions, the curves included facilitate the determination of any value of $\frac{2\,\phi_1}{D_0}$ for central angles ranging from 40 to 180°, and of $\frac{t}{r}$ from 0.02 to 0.30.

Even with these aids the computation of stresses at four points (the extrados and intrados at the crown and the abutment) in a single arch ring requires:

1.—Abstracting from tables five trigonometric functions or constants; and

2.—Performing thirty or more arithmetical computations (multiplications, divisions, additions, and subtractions), involving both positive and negative quantities and numbers varying from millions down to ten thousands.

Not only are these various computations laborious, but they offer many chances for arithmetical errors, and no opportunity for checks save by duplicate computation. The revised formulas, including the effect of shear, published in the discussion on Mr. Jakobsen's paper on "Stresses in Thick Arches of Dams",§ are even more rigorous in their treatment and, hence, more complicated.

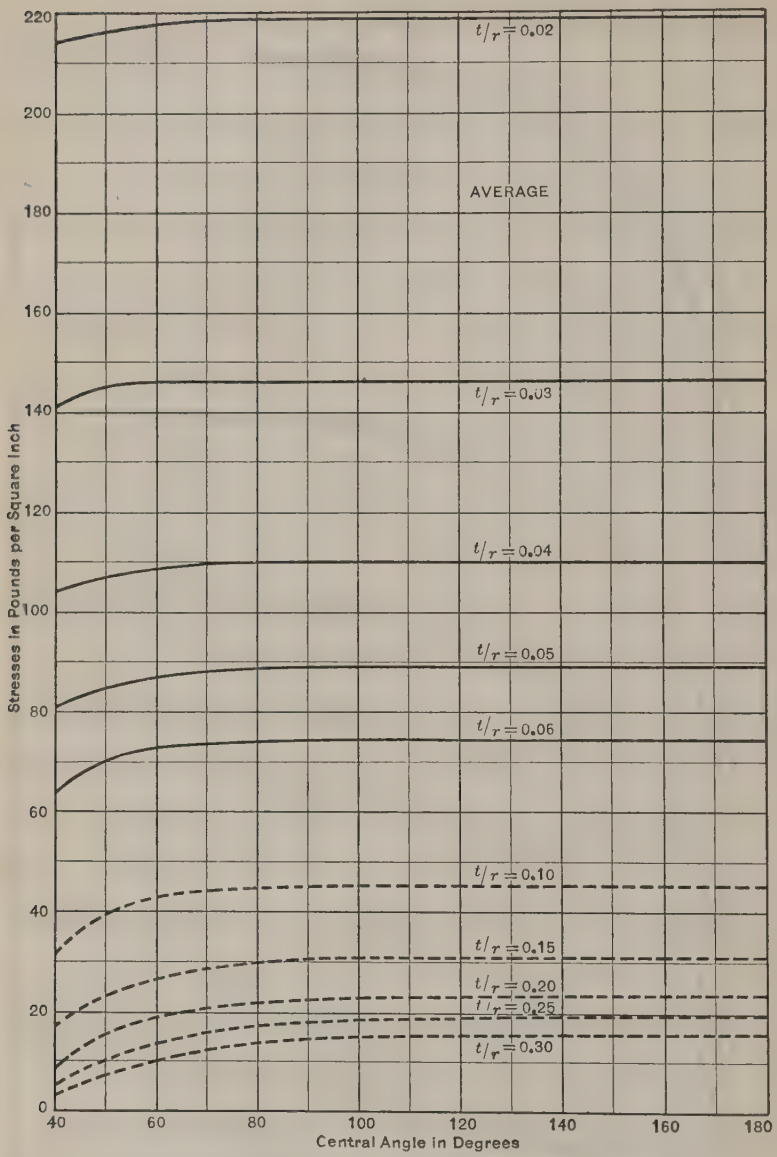

FIG. 9.—AVERAGE STRESSES AT ABUTMENTS—HINGED ENDS.

The curves presented in this paper resulted from an attempt to simplify the use of these valuable contributions to a complex engineering problem.

Due to the number of variables it would appear, at first glance, impossible to devise a simple graphic solution. For example, practically all dam sites decrease in width from top to bottom. The dam itself increases in thickness from top to bottom in order to withstand the head, which increases in like manner. The central angle of the arch may vary in practice from, say, 40 to 130°, or more. The radius varies with the width of the site at any given level and with the central angle. It is obvious, therefore, that with the different conditions encountered at various elevations in any structure there is no direct relation between the stresses at any two given levels.

If, however, an imaginary arch dam is assumed, of fixed central angle and radius and uniform thickness throughout its entire height, the stresses in the arch rings at any two levels will be in proportion to the heads, and the computed stresses for a convenient head—say, 10 ft.—when multiplied by 10, will give the stresses for the arch ring under 10 $\times$ 10, or 100-ft. head; this relation permits the use of a single set of computations as a measure for the stresses at all heads.

The value of r used in such computations is immaterial, since when the head and the central angle are equal, the stresses in any two arch rings remain equal and constant so long as the ratio, $\frac{t}{r}$, remains constant—even if the length of the radius of each ring is freely changed. It is this constant relation of stresses to values of $\frac{t}{r}$ that makes it possible to show the formulas graphically.

In preparing the curves the stresses at the extrados and intrados of the crown and abutment of an "imaginary" arch were computed for a head of 10 ft., for central angles ranging from 40 to 180°, and for varying ranges in the values of $\frac{t}{r}$ depending on the formulas.

The three groups of curves are based on the three sets of formulas developed by Professor Cain:

Group I.—Arches with "fixed ends" (neglecting shear). Formulas developed on pages 235 to 238, *Transactions,* Am. Soc. C. E., Vol. LXXXV (1922); this set of curves (Figs. 3, 4, 5, and 6) covers central angles (2 ϕ_1) ranging from 40 to 180°, and values of $\frac{t}{r}$ ranging from 0.02 to 0.30. The curves for values of $\frac{t}{r}$ = 0.10 to 0.30, are included, however, only for comparison with curves of Group III, which are more accurate since they include the influence of shear.

Group II.—Arches with "hinged ends" (neglecting shear). Formulas developed on pages 241 to 243, *Transactions,* Am. Soc. C. E., Vol. LXXXV (1922); this set (Figs. 7, 8, and 9) covers the same range and values of $\frac{t}{r}$.

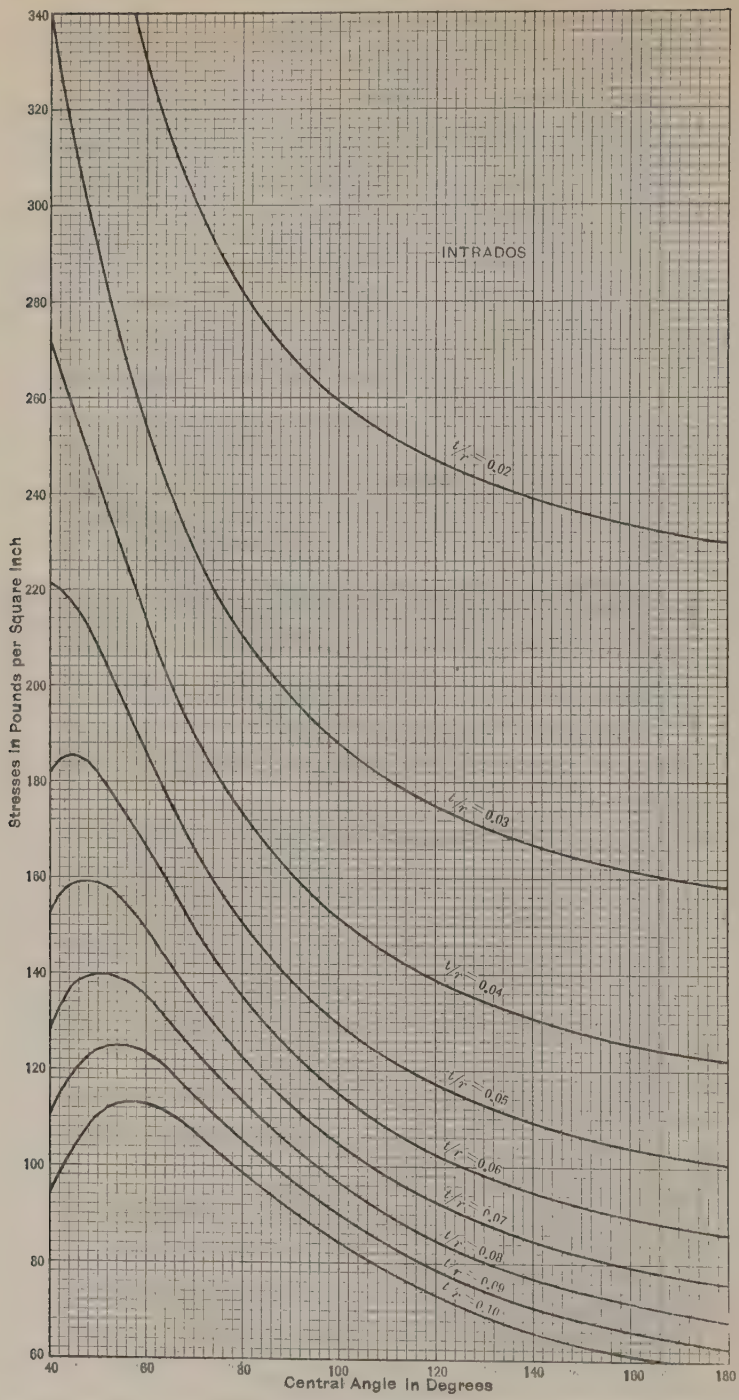

FIG. 13(*a*).—STRESSES AT ABUTMENTS—INTRADOS. FIXED ENDS, INCLUDING SHEAR. FOR 10-FOOT HEAD.

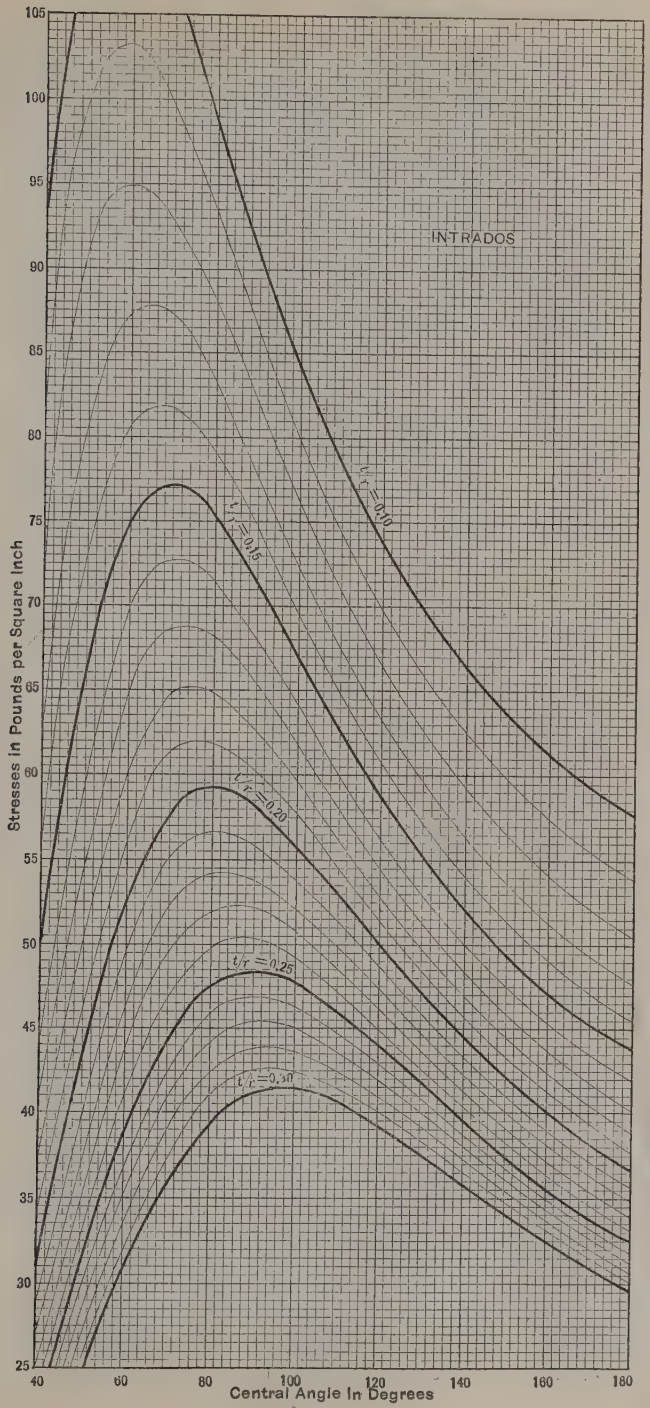

FIG. 13(b).—STRESSES AT ABUTMENTS—INTRADOS. FIXED ENDS, INCLUDING SHEAR, FOR 10-FOOT HEAD.

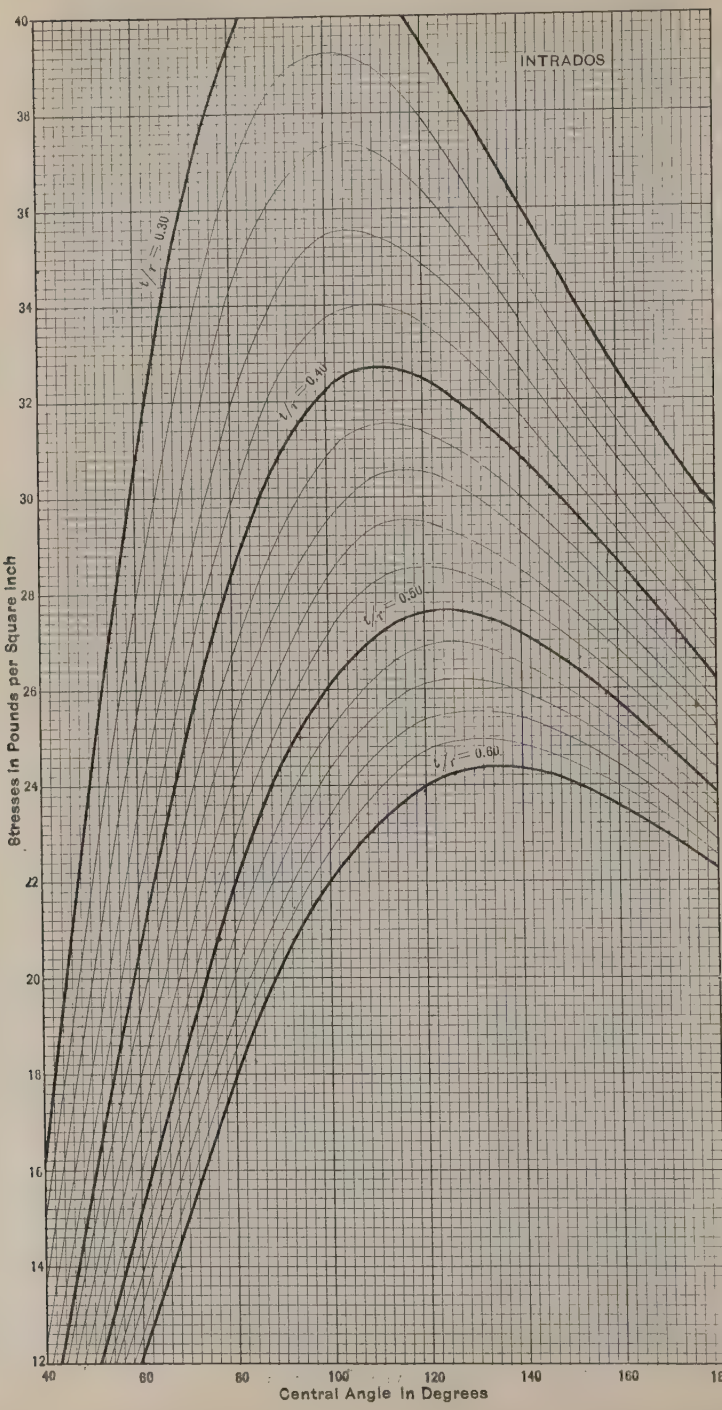

FIG. 13(c).—STRESSES AT ABUTMENTS—INTRADOS. FIXED ENDS, INCLUDING SHEAR. FOR 10-FOOT HEAD.

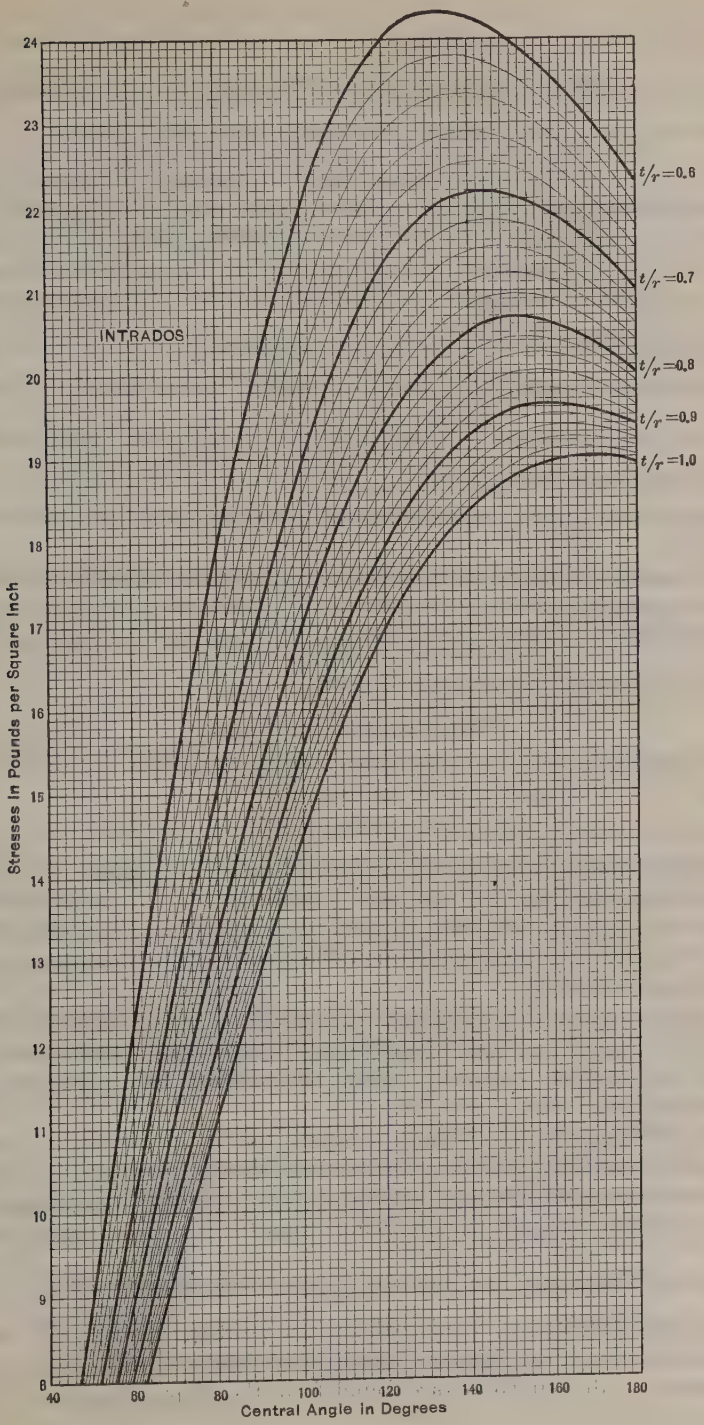

FIG. 13(*d*).—STRESSES AT ABUTMENTS—INTRADOS. FIXED ENDS, INCLUDING SHEAR. FOR 10-FOOT HEAD.

The curves for the higher values of $\frac{t}{r}$ are included, however, only for purposes of comparison since the condition, "hinged ends", is probably realized only in very thin arches; that is, arches having very small values of $\frac{t}{r}$.

Group III.—Arches with "fixed ends" (including influence of shear). Formulas developed by the principle of "least work" on pages 522 to 534, *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927); this set of curves (Figs. 10(*a*), 10(*b*), 10(*c*), and 10(*d*); 11(*a*), 11(*b*), 11(*c*), and 11(*d*); 12(*a*), 12(*b*), 12(*c*), and 12(*d*); and 13(*a*), 13(*b*), 13(*c*), and 13(*d*)) covers central angles ranging from 40 to 180°, and values of $\frac{t}{r}$ from 0.02 to 1.00. The curves of this group should be used in preference to those of Group I which duplicated the curves for $\frac{t}{r} = 0.10, 0.15, 0.20, 0.25$, and 0.30; these curves were included in Group I only for purposes of comparison.

Compression in all cases is shown positive (+); and tension, negative (—).

The curves of Group III, including shear, should be used throughout their range in preference to the curves of Group I, which do not include shear; the curves of Group I can be used without great error for the smaller values of $\frac{t}{r}$ (0.02 to 0.06), not covered by Group III.

Methods of Using Curves

The curves may be used with equal facility for either (*a*) design, or (*b*) analysis.

Design

Problem.—At a given level in a proposed dam it is desired to use an arch ring with a central angle of 120° and a radius of 200 ft., the maximum head being 50 ft., and the ends being assumed as "fixed". What arch thickness will be required if the maximum allowable stresses are: Compression, 500 lb. per sq. in.; tension, 0?

Solution.—Since the curves are for 10-ft. head, or one-fifth of the actual head of 50 ft., the allowable stresses to be read from the curves must be reduced in the same proportion, giving compression, 100 lb. per sq. in., and tension, 0.

The conditions and constants assumed fall in the range of curves of Group I. Since the greatest compression is always found at the intrados of the abutment, and the greatest tension at the extrados of the abutment, it is best in designing to enter Fig. 6 of this group (or Fig. 13 of Group III) first, and having determined the value of $\frac{t}{r}$, to check it against Fig. 5 (or Fig. 12, in Group III) to see whether there is a resulting tension. If tension is found, another central angle will have to be tried; if no tension is shown, the stresses at all four points are found from the proper diagrams.

In the present case it is found that the curve, $\frac{t}{r} = 0.06$, passes through the intersection of the vertical line for 120° and the horizontal line for 100 lb. per sq. in.; checking by Fig. 5, the stress horizontally opposite the intersection of the vertical from 120° and the curve, $\frac{t}{r} = 0.06$, is + 48 lb. per sq. in., or 48 lb. compression, which satisfies the condition that there shall be no tension. The stresses in the actual arch are given in Table 1.

TABLE 1.—Stresses in Proposed Arch Dam.

Point.		Stresses read from diagram, in pounds per square inch.	Multiplying factor.	Stresses in arch, in pounds per square inch.
Abutment:	Intrados	100	5	500
	Extrados	48	5	240
Crown:	Intrados	60	5	300
	Extrados	87.5	5	438

The radius on the center line of the arch ring being 200 ft. and $\frac{t}{r}$, 0.06, the thickness, t, is 12 ft. The radius of the up-stream face (extrados) is 206 ft. and that of the down-stream face (intrados) is 194 ft. Had the stress and $\frac{t}{r}$ been assumed in the problem, the required angle could have been read from the curves.

Analysis

Problem.—What are the stresses in the Kerckhoff Dam (already constructed) at Elevation 900, (*a*) neglecting shear, and (*b*) including shear?

Measurements* show that at that level the head is 95 ft., $t = 28.9$ ft., $r = 143.3$ ft., $\frac{t}{r} = 0.201$, and the central angle, $(2\ \phi_1) = 82°\ 40'$.

Solution.—

(*a*) Neglecting Shear.—The stresses read from Figs. 3 to 6, horizontally opposite the intersection of the vertical through 82° 40′, and an interpolated curve, $\frac{t}{r} = 0.201$, are given in Column (2) of Table 2, and the actual stresses in the given section of the dam $\left(\frac{95}{10} = 9.5 \text{ times as great}\right)$ in Column (3). Minus signs in all cases denote tension.

(*b*) Including Shear.—The stresses read from Figs. 10 to 13, horizontally opposite the intersection of the vertical through 82° 40′ and an interpolated curve through $\frac{t}{r} = 0.201$, are given in Column (2), and the resulting stresses under a 95-ft. head in Column (4), of Table 3.

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 258.

The solutions represented by the curves of Group III were made on the basis of m (in Poisson's ratio) $= \alpha$; σ_x (vertical unit stress on the arch ring) $= 0$; and $I_n = I$.*

TABLE 2.—STRESSES IN KERCKHOFF DAM, NEGLECTING SHEAR.

Point. (1)		Stress read from diagram, in pounds per square inch. (2)	Multiplying factor. (3)	Stress in dam, in pounds per square inch. (4)
Crown:	Extrados	37	9.5	352
	Intrados	— 7.5	9.5	— 71+
Abutment:	Extrados	—26	9.5	—247
	Intrados	60	9.5	570

All the curves were computed on the basis of the arch ring at 10-ft. depth taking the full water load; in using them to compute the stresses in a ring at, say, 100-ft. depth, carrying the full water load, the unit stresses shown by the curves should be multiplied by 10; but if it is assumed that the ring at the 100-ft. depth carries only 0.8 of the water load (the remainder being carried by the vertical cantilever), the stresses read from the curves should be multiplied by 8 and not by 10.

TABLE 3.—STRESSES IN KERCKHOFF DAM, INCLUDING SHEAR.

It is possible that future experimental data secured from actual structures may lead to some modification of the Cain formula, but in the meantime it is hoped that the diagrams presented herewith may prove of practical assistance to those using Professor Cain's most valuable method of analysis.

* For comparison of unit stresses under different assumptions, by the Cain and by the Jakobsen formulas, see *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), Table 10, p. 540.

DISCUSSION

B. F. Jakobsen,* M. Am. Soc. C. E. (by letter).—The real value of this paper lies in the information it affords about the relation between $x = \frac{t}{r}$, the central angle, $2\phi_1$, and the stresses. For stress calculations the curves and tables prepared by William Cain, M. Am. Soc. C. E.,† were quite sufficient, but the curves prepared by the author give an excellent picture of what happens when either $\frac{t}{r}$, or $2\phi_1$, or both, is varied, and, therefore, they should assist the designer by enabling him to see more quickly what may be accomplished in a specific case by varying the design in a certain direction. The writer has found it necessary, when designing arch dams, to plot for a limited region such curves as the author submits, but has never made a systematic investigation, such as that presented by Mr. Fowler.

In analyzing the stresses in the Kerckhoff Dam at Elevation 900, the author's solution involves a tension of 165 lb. per sq. in., which should exist between the concrete and the rock abutment. The existence of a tension of this magnitude between concrete and rock, however, is highly improbable and, at any rate, something on which a careful designer would not rely. The usefulness of the Cain formulas is due to the fact that in such cases a fairly accurate estimate of the maximum stress can be obtained by applying the theory of the secondary arch.‡

Referring to Fig. 14, *F D B N* is the original arch, which has tension at, and around, Point *D* and possibly also at, and around, Point *N*. Assuming that the arch cannot withstand any tension, the concrete will move away from the rock abutment, beginning at Point *D* and continuing to a point, *E'*, where the stress is zero. The load is now carried on the secondary arch, *F E' B M*, and this secondary arch is determined by the fact that the stress at Point *E'* is zero, when the water is assumed to act on the arc, *F E'*. The actual load is on the arc, *F D*, but water may also be assumed to act on *D E'* and these two loads combined equal the water load on arc *F E'*.

From the curves in Figs. 5 and 12, it may be seen that for any value of $x = \frac{t}{r}$, there is a definite value of the central angle that gives zero stress at the abutment of the up-stream face. If the central angle remains the same, but $\frac{t}{r}$ is increased, tension will occur at the abutment of the up-stream face; if $\frac{t}{r}$ is decreased, compression will occur. Consequently, a curve may be plotted

‡ "Stresses in Thick Arches of Dams," *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 510, where reference is made to the work of L. J. Mensch, M. Am. Soc. C. E., Prof. Cain, and Prof. Résal.

from these limiting values of $x = \frac{t}{r}$ and $2\,\phi_1$. Such a curve has been plotted in Fig. 15 by utilizing the author's diagrams. As an illustration, for $x_0 = \frac{t_0}{r_0} = 0.3$, Fig. 15 gives $2\,\phi_0 = 142°$ for the limiting central angle, and this angle was obtained from Fig. 12(*b*) for $\frac{t}{r} = 0.3$ and zero stress.

In general, it is necessary to try several secondary arches before the right one is found. By determining a constant, B, as a function of $\frac{t}{r}$ and $2\,\phi_1$ and also as a function of the limiting values, x_0 and $2\,\phi_0$, and plotting B in Fig. 15, the secondary arch can be determined directly. The following considerations lead to the curve, B, in Fig. 15.

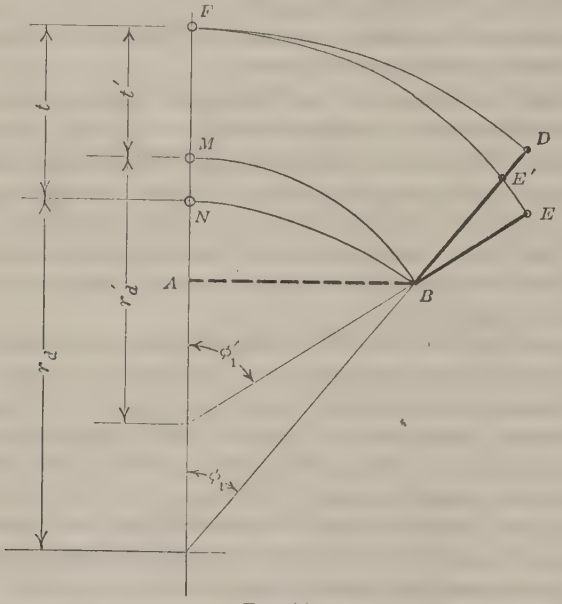

FIG. 14.

In Fig. 14, a secondary arch is shown as $F\,E'\,B\,M$; assume that the secondary arch is $F\,E\,B\,M$ instead of $F\,E'\,B\,M$. This assumption will not introduce any objectionable errors, but will facilitate the calculations. The dimensions of the original arch are t, r, r_d, and ϕ_1, as shown in Fig. 14, and the dimensions of the secondary arch are t', r', r'_d, and ϕ'_1. Then, from Fig. 14:

$$A\,B = r_d \sin \phi_1 = r'_d \sin \phi'_1$$

or,

$$r'_d = r_d \frac{\sin \phi_1}{\sin \phi'_1} \qquad \ldots\ldots(1)$$

Also, from Fig. 14:

$$F\,A = t + r_d\,(1 - \cos \phi_1) = A \qquad \ldots\ldots(2)$$

Let,

$$B = \frac{A}{r_d \sin \phi_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The value of A can be determined from Equation (2) as soon as the dimensions of the original arch are known and, likewise, the value of B may be determined from Equation (3).

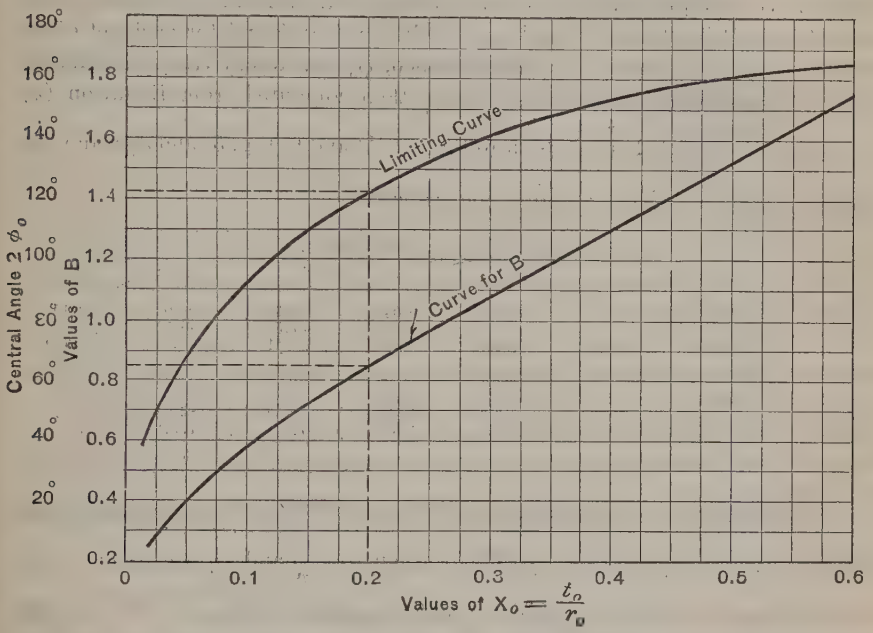

FIG. 15.—CURVES FOR DETERMINING SECONDARY ARCHES.

A and B, however, may also be expressed in terms of the dimensions of the secondary arch. From Fig. 14:

$$F A = A = t' + r_d' (1 - \cos \phi_1') \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

From Equations (3) and (1):

$$B = \frac{A}{r_d' \sin \phi_1'} = \frac{t' + r_d' (1 - \cos \phi_1')}{r_d' \sin \phi_1'}$$

$$= \frac{t'}{r' - 0.5\, t'} \operatorname{cosec} \phi_1' + \frac{1 - \cos \phi_1'}{\sin \phi_1'}$$

in which, r' is the mean radius of the secondary arch. Dividing the first term on the right-hand side of the equation sign by r', and multiplying by 2:

$$B = \frac{2\, x'}{2 - x'} \operatorname{cosec} \phi_1' + \tan \left(\frac{\phi_1'}{2}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

From what precedes, it is evident, that:

$$B = \frac{2\, x}{2 - x} \operatorname{cosec} \phi_1 + \tan \left(\frac{\phi_1}{2}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Equation (6) shows that B is a function of the dimensions, x and ϕ_1, of the original arch and may be computed as soon as these are known. On the other hand, Equation (5) shows that B is a function of the dimensions, x' and ϕ_1', of the secondary arch. Of all the different corresponding values that it is possible to give to x' and ϕ_1' in Equation (5) while B remains constant, only those corresponding values of x' and ϕ_1' that lie on the limiting curve are desired. If, in Equation (5), the corresponding values from the limiting curve are introduced in place of x' and ϕ_1', a value of B is found for each set of the values, x_0, ϕ_0. In Table 4, x_0 was assumed, ϕ_0 was found from the limiting curve in Fig. 15, and the value of B was then computed from Equation (5). The value, $\frac{t}{r} = 0.1$, belongs both to Fig. 12 (b) and to Fig. 5, and a mean value has been used in order to obtain a smooth curve.

TABLE 4.—VALUES FOR B.

The stresses in an arch, expressed in terms of the water pressure on the extrados, p_e, are completely determined when $x = \frac{t}{r}$ and ϕ_1 are given. Any set of values of x and ϕ determine a definite point in Fig. 15. If the point is located above the limiting curve, as, for example, the arch, $x = 0.1$ and $2\phi_1 = 120°$, there is compression throughout the arch. If the point lies on the limiting curve, there is compression throughout the arch, except at the point, E, of Fig. 14 where there is zero stress. If, finally, the point lies below the limiting curve, there is tension at the extrados of the abutment and possibly, also, at the intrados at the crown. In this case the theory of the secondary arch must be utilized in order to determine the maximum stress. This is accomplished by computing the value of B from Equation (6) and then, from Fig. 15, determining the corresponding values of x_0 and $2\phi_0$. Then, x_0 and $2\phi_0$ determine the secondary arch for the given primary arch, and the maximum stress, which occurs at the intrados of the abutment, may be taken from the author's diagrams, bearing in mind that the stresses found in the curves are for a 10-ft. head.

For example: Suppose the original arch gives $B = 0.845$; then, from Fig. 15, using "Curve for B", it is found that $x_0 = 0.2$ and the limiting angle, which corresponds to $x_0 = 0.2$, is $2\phi_0 = 122$ degrees. This is the secondary arch. If the conditions at the abutments are not as shown in Fig. 14, some modifications may be necessary, but the writer has found the two curves shown

to be of considerable value in actual design, even for very thick arches, although for these the yielding of the abutments must be taken into account.*

The question proposed by the author, "What are the stresses in the Kerckhoff Dam?" may now be solved with the understanding that the maximum stress found is most likely somewhat in excess of the actual existing maximum stress, but will be a good guide in design and quite reliable except perhaps for very short thick arches. At Elevation 900, the dimensions are $x = \frac{t}{r} = 0.201$ and $2\,\phi_1 = 82°\ 40'$; this gives $B = 0.7154$ from Equation (6), and from "Curve for B", in Fig. 15, is found $x_0 = 0.145$ and $2\,\phi_0 = 108$ degrees. These are the dimensions of the secondary arch (r_d' can be determined from Equation (1)) and the maximum stress may now be read from Fig. 13(b); this gives 66 lb. per sq. in. for a 10-ft. head and 627 lb. per sq. in. for a head of 95 ft. The stresses at the crown may be found by referring to the author's diagrams. Generally, however, the stress at the intrados of the abutment is the maximum stress occurring and if there is not tension at the extrados of the abutment, there is no tension in the arch; that is, when the stresses are determined by the Cain formulas and the yielding of the foundation is neglected.

The author, as he states, took the dimensions of the Kerckhoff Dam from the writer's discussion of Professor Cain's paper,† in which the water surface was considered as standing 10 ft. above the Taintor gates. When designing the Kerckhoff Dam, the writer took as the maximum possible head, that which might come on the dam if all the gates were closed and an extreme flood of about 100 000 sec-ft. was flowing in the river. The actual maximum operating head is only 85 ft. on the section at Elevation 900, the top of the Taintor gates being at Elevation 985;‡ therefore, the maximum stress is found to be:

$$\frac{627 \times 8.5}{9.5} = 561 \text{ lb. per sq. in.}$$

When the writer, in May, 1919, took charge as Designing Engineer for the Kerckhoff Development of the San Joaquin Light and Power Corporation, Fresno, Calif., he found a gravity arch dam design, that would have cost $1 000 000 to build. The saving of the arch dam as re-designed amounted to approximately $400 000, or 40% of the total, and the stress calculations show that the factor of safety of the arch dam is much greater than for most gravity dams.

The curves plotted by the author also give information as to how the maximum stress varies when the central angle is held constant, while the ratio, $\frac{t}{r}$, is varied. For example, for $2\,\phi_1 = 140°$, $\frac{t}{r} = 0.02$, 0.05, 0.10, and 0.20, the maximum stress being, respectively, 237, 107, 66, and 44 lb. per sq. in. for a 10-ft. head.

* See discussion by Dr. Fredrik Vogt, *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 554.

† *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 258.

‡ *Loc. cit.*, Vol. LXXXIV (1921), p. 107.

In other words, when $\frac{t}{r}$ is increased 10 times, from 0.02 to 0.20, the stress is decreased only 5.4 times, or, the arch, $\frac{t}{r} = 0.02$, is nearly twice as efficient as the arch, $\frac{t}{r} = 0.20$, when the central angle is 140 degrees. This gives an indication of the great importance of utilizing a high strength concrete produced under competent inspection. The writer's experience while in charge of the construction of the Pacoima and Big Santa Anita Dams,* and the experience of other engineers, have shown that when the water-cement ratio is kept under close control, it is possible to produce a high grade and uniform concrete under actual construction conditions. The fact that the thinner arch is so much more efficient than the thick arch, is bound to have a considerable influence on concrete production.

The curves presented by Mr. Fowler are a welcome addition to the literature of stresses in arches and should be helpful in the design and study of arched dams.

WILLIAM CAIN,† M. AM. SOC. C. E. (by letter).—Any one who has computed the unit stresses at extrados and intrados, at crown and abutment, for even one circular arch subjected to uniform normal loads, can readily appreciate the enormous amount of labor required to construct the many diagrams given in the author's Figs. 3 to 13. Mistakes are easily made for any one example, but they are readily discovered where successive values are plotted. A smooth curve gives confidence in the results. The author's diagrams are very clear and cover every desirable central angle and many ratios, $\frac{t}{r}$, and they should prove of great value to the busy designer. The writer has only checked the values of s_e and s_i, given in Figs. 10 to 13, for $\frac{t}{r} = 0.3$, with central angles, $(2\ \phi_1)$, of 40°, 90°, and 180°, and has found all of them to be correct.

As it is not evident from the equations given for "thick arches", for a given head and central angle, that the stresses, s_e, s_i, vary only with the ratio, $\frac{t}{r}$, a proof will be given.

By reference to the writer's discussion,‡ it is seen that,

$$\frac{t}{r_n} = \log_e\left(\frac{r_e}{r_i}\right) = \frac{t}{r}\left(1 + \frac{1}{12}\left(\frac{t}{r}\right)^2 + \frac{1}{80}\left(\frac{t}{r}\right)^4 + \cdots\right)$$

Also, since $I = \frac{1}{12}\ t^3$ and $k^2 = \frac{1}{12}\ t^2$, the value of D_n§ can be written,

---

* *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 585.

† Prof. Emeritus, Univ. of North Carolina, Chapel Hill, N. C.

‡ *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 524, Equation (94) and footnote.

§ *Loc. cit.*, p. 531, Equation (104) and footnote.

$$D_n = \left(\phi_1 + \frac{1}{2}\sin 2\,\phi_1\right)\left(1 + \frac{1}{12}\left(\frac{t}{r_n}\right)^2\right) - \frac{1 - \cos 2\,\phi_1}{\phi_1} + 0.24\left(\frac{t}{r_n}\right)^2\left(\phi_1 - \frac{1}{2}\sin 2\,\phi_1\right).$$

Thus, since $\frac{t}{r_n}$ can be expressed in terms of $\frac{t}{r}$, D_n can be written as a function of $\frac{t}{r}$ and constants for a given central angle.

It will now be shown that the unit stresses, s_e and s_i, at the extrados and intrados at the abutment section, making the angle, ϕ_1, with the crown section, for a constant head and central angle, vary only with $\frac{t}{r}$. On substituting the value of

$$X = \frac{p_e\, r_e}{D_n}\,\frac{\sin\phi_1}{6}\left(\frac{t}{r_n}\right)^2$$

in the values for P_1 and M_1, the last two formulas of Equation (107) (page 1516), can be written (after reduction),

$$s_e = p_e\left\{\frac{2\sin\phi_1}{D_n}\left(\frac{\sin\phi_1}{\phi_1} - \cos\phi_1\right)\frac{\frac{t}{2} + c}{t} - \left[\frac{1}{\frac{t}{r_n}} - \frac{\sin\phi_1}{6\,D_n}\left(\frac{t}{r_n}\right)\cos\phi_1\right]\right\}$$

and,

$$s_i = p_e\frac{r_e}{r_i}\left\{-\frac{2\sin\phi_1}{D_n}\left(\frac{\sin\phi_1}{\phi_1} - \cos\phi_1\right)\frac{\frac{t}{2} - c}{t} - \left[\frac{1}{\frac{t}{r_n}} - \frac{\sin\phi_1}{6\,D_n}\left(\frac{t}{r_n}\right)\cos\phi_1\right]\right\}$$

The values of s_e and s_i for the crown can be similarly derived. In fact, these unit stresses may be written down from the last two formulas on replacing $\cos\phi_1$ by 1 and leaving the other terms unaltered.

On noting that,

$$\frac{\frac{t}{2} + c}{t} = \frac{1}{2} + \frac{r - r_n}{t} = \frac{1}{2} + \frac{1}{\frac{t}{r}} - \frac{1}{\frac{t}{r_n}}$$

$$\frac{\frac{t}{2} - c}{t} = \frac{1}{2} - \frac{r - r_n}{t} = \frac{1}{2} - \frac{1}{\frac{t}{r}} + \frac{1}{\frac{t}{r_n}}$$

and,

$$\frac{r_e}{r_i} = \frac{r + \frac{t}{2}}{r - \frac{t}{2}} = \frac{1 + \frac{t}{2\,n}}{1 - \frac{t}{2\,r}}$$

and since $\left(\frac{t}{r_n}\right)$ has been expressed in terms of $\left(\frac{t}{r}\right)$, it is seen that, for a given p_e and ϕ_1, s_e and s_i vary only with $\frac{t}{r}$. This is not true for P_0, M_0, P_1, and M_1.

but it is true for s_e and s_i at either crown or abutment. It is thus seen that the same values are derived for $t = 15$ and $r = 50$, as for $t = 30$ and $r = 100$, since $\frac{t}{r} = 0.3$ in both cases.

In using Equation (107) (page 1516), any convenient values of t and r that have the assumed ratio, can be used. The values of s_e and s_i thus derived can be checked by the formulas for s_e and s_i just given. Evidently, these formulas furnish the shortest solution for the unit stresses.

In using them, for assumed values of t and r, giving the required ratio, it is best to compute c from Equation (95),*

$$c = r - r_n = r - \frac{t}{\log_e \left(\frac{r_e}{r_i}\right)}$$

and thus derive, directly,

$$\frac{\frac{t}{2} + c}{t} \quad \text{and} \quad \frac{\frac{t}{2} - c}{t}$$

Also, $\frac{t}{r_n} = \log_e \frac{r_e}{r_i}$ is directly computed without the use of the infinite series.

As Mr. Fowler, in drawing his diagrams, has assumed a 10-ft. head,

$$p_e = \frac{10 \times 62.5}{144} = 4.34 \text{ lb. per sq. in.}$$

to agree with the diagrams. The stresses vary directly as p_e, or as the head.

The formulas for s_e, s_i, reduce to those for a prismatic beam on assuming, for t finite, that r increases indefinitely, so that $c = 0$, $r_n = r$, and $p_n = p$. This will be evident if, in the usual formula for the unit stresses in a straight beam,

$$\frac{P}{t} \pm \frac{6\,M}{t^2},$$

the values of P and M (page 1514) are substituted; when, on reduction, the previous values for s_e, s_i, corresponding to $c = 0$, $r_n = r$, and $p_e = p$, are derived.

In deriving the formulas for thick arches, the writer ignored the work of the radial stress, as its influence was found to be small.† Also, Poisson's ratio was assumed equal to zero. This ratio is easily included, as B. F. Jakobsen, M. Am. Soc. C. E., has shown.‡ His pioneer work on this subject, and the effect of water-soaking, are both important contributions. However, it may be remarked, that the experiments for determining Poisson's ratio have been made on very small specimens and it is very doubtful if the ratio thus found applies to arches 30 to 50 ft. thick.

In addition to this uncertainty, there are others that militate against the hope of an exact solution, such as the unknown shrinkage of concrete in drying out, the changes in E with stress and time, the effect of plasticity, water-

* *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 525.

† *Loc. cit.*, p. 538.

‡ *Loc. cit.*, p. 488; also, see "Example," p. 539.

soaking, and the elastic yielding of the foundation and abutments. Besides, there is doubt about the uniformity of the water pressure on a horizontal arch, and as to the relative proportion of the water pressure carried by the arch and the cantilever; so that the computation of stresses for the given hypotheses, which are so greatly facilitated by the author's diagrams, although a necessary step, is not the complete solution, for the engineer must consider all the influences mentioned in the design of arch dams. Mr. Jakobsen has stated* that "he had hoped to install some resistor type of cartridges for measuring deformations in both the Pacoima and the Big Santa Anita Dams, but was unable to obtain the necessary funds". This is greatly to be regretted. Experiments on thin arch dams that buckle and crack are valuable for such conditions, but they do not represent the conditions for thick dams where the device of grouting to avoid cracks has been used and where buckling is not experienced. Experiments on such dams will tend to clear a number of doubtful points, and it is to be hoped that they may be instituted in the future.

Walter L. Huber,† M. Am. Soc. C. E. (by letter).—The writer has made much practical use of the diagrams prepared by Mr Fowler. Before accepting them as a substitute for the more laborious methods of exact calculation he made some comparisons of the two methods. The difference is, in every case, very small, being much less than various uncertainties of assumptions governing practical designs. William Cain, M. Am. Soc. C. E., through his formulas, made a very valuable contribution to engineering literature. Mr. Fowler has made this contribution readily available to the designer of arch dams and for this service deserves the thanks of all members of the profession engaged in designing structures of this character.

Glen Edgar Edgerton,‡ M. Am. Soc. C. E. (by letter).—The curves presented by Mr. Fowler should prove to be of great assistance to engineers engaged in the design or investigation of dams of the arch type. The increasing number of structures of this type that have been erected in recent years and the indisputable economies made possible by them when circumstances are favorable, indicate that more and more frequently in the future, engineers will be required to consider arch dam design, even, perhaps, in many cases in which other types may finally be adopted.

Designs for arch dams that show reasonably conservative unit stresses under analysis by the Cain formulas have been approved in several instances by the Federal Power Commission, and by State and local public officials as well. To that extent, at least, these formulas may be considered to have become established as acceptable standards in practice as well as in theory.

Without attempting to make a general check of the curves presented by Mr. Fowler, several designs previously analyzed by the Cain formulas and computation methods have been investigated by means of them. The critical stresses calculated by the two methods agree very closely. Figs. 3, 4, 5, and 6 were used. The central angles for these calculations ranged

* *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 586.

† Cons. Engr., San Francisco, Calif.

from 84° 44′ to 134° 0′; $\frac{t}{r}$, from 0.0448 to 0.312 (the latter value requiring extrapolation); and the head, from 25 to 185 ft. The maximum difference between the unit stresses determined by the two methods amounted to 19 lb. per sq. in.

Mr. Fowler has made a valuable contribution to the engineering art in developing these time-saving charts.

LARS R. JORGENSEN,* M. AM. SOC. C. E. (by letter).—Most engineers who have had to make calculations of arch dams, have no doubt been looking for a method to simplify this tedious work. The first that suggests itself is the plotting of curves to avoid as much of the routine calculation as possible. The writer has seen at various times several sets of curves intended for the simplification of arch dam calculation. Such curves have also been used to great advantage for several years in the office of the Constant Angle Arch Dam Company; but until Mr. Fowler's diagrams appeared the writer had never seen a set where the result sought could be obtained by looking for it in just one place, on just one curve. When the writer saw the curves for the first time, he wondered where Mr. Fowler had made a mistake, since he had so easily been able to simplify arch dam calculation to the limit.

The author is to be highly commended on his work in plotting these curves because they are of very great help to any one interested in arch dam calculation. In Figs. 10 to 13, inclusive, the principal part of the information necessary for the calculation of stresses in any arch dam is available. Mr. Fowler has seized upon the clever idea of using the ratio, $\frac{t}{r}$, for plotting purposes, which is the main reason for the simplicity.

At and toward the very bottom of an arch dam, arch action is very ineffective since other actions (principally punching shear along the contact area) will resist the load with less deformation required and, consequently, will take the greater part of the load. Inasmuch as it is generally difficult to design an arch dam (using the conventional arch formulas) where the arch is short and thick, as is mostly the case at and near the bottom of a dam, the ability of the punching shear developed along the contact area to hold the dam in place should be investigated.

Whenever this punching shear stress is less than 65 lb. per sq. in., for instance, on the contact area between the rock and the concrete, the structure should be entirely safe, assuming all load to be resisted by shear.

If the bottom is calculated as an arch, carrying the full water load and using conventional formulas, such as those of Professor Cain, stresses of 800 lb. compression and as much as 200 lb. per sq. in. tension should be allowable. Such calculated stresses may generally be more conservative in this part of the dam than one-half these values would be at a point higher up where the arch has to take the load acting as an arch. The load, at the bottom especially, divides between punching shear, arch action, cantilever action, etc., with punching shear generally taking the largest share. In

* Cons. Engr., Constant Angle Arch Dam Co., San Francisco, Calif.

calculating the structure as an arch close to the bottom, it is safe to use larger unit stresses, both in compression and in tension, as it is known that the actual stresses will be considerably lower than the calculated stresses.

FRED A. NOETZLI,* M. AM. SOC. C. E. (by letter).—This paper is of much value to designers of arch and multiple-arch dams. The labor of calculating the stresses in the elementary arch slices of such structures is reduced to the very minimum by the use of the curves presented by Mr. Fowler.

In order to get an idea of the degree of accuracy that may be obtained with these curves, the stresses in one of the arch slices of the Stevenson Creek Test Dam were calculated and compared with the stresses as determined from the tests.† Table 5 gives the data for the elementary arch slice at a height of 30 ft. above the base of the dam. For this elementary arch, $\frac{t}{r} = \frac{2}{99} = 0.0202$. The central angle is $2\phi = 43° 30'$. The head of water for full reservoir is 30 ft., but according to the results of the tests only about 84% of the water pressure at this elevation was carried by the horizontal elementary arch, the remainder being supported by the vertical cantilever.‡ The full water pressure being $30 \times 62.5 = 1\,875$ lb. per sq. ft., the net load on the arch element as determined from the test was, therefore, approximately, $0.84 \times 1\,875 = 1\,570$ lb. per sq. ft. Consequently, the "multiplying factor" to be used in connection with Figs. 10 to 13, inclusive, is $\frac{1\,570}{62.5 \times 10} = 2.52$, corresponding to a net head of water of 25.2 ft. The stresses in the dam as determined by means of the curves (for "fixed" arches) are given in Table 5, Column (4). The stresses as found from the tests in 1926 are given in Column (5), and by way of comparison there are shown in Column (6) the values of the stresses as determined in the design of the dam made by the writer in 1925 for the Committee on Arch Dam Investigation.

The agreement between the various values is reasonably close considering the fact that in the design of the dam the net water pressure supported by the arch at the 30-ft. elevation was found to be 1 335 lb. per sq. ft., while the tests gave the somewhat larger figure of 1 570 lb. per sq. ft. Therefore, in order to afford a comparison on the proper basis between the values of the stresses as determined by the use of the author's Figs. 10 to 13 and those computed in the design, these latter values must be multiplied by $\frac{1\,570}{1\,335} = 1.175$. The corresponding design stress would then be as listed in Table 5, Column (7). Thus, if the same water pressure as determined in the tests, is used as a basis for the computations, there is found a reasonably close agreement between the theoretical values of the stresses and those calculated from the strains measured in the dam.

‡ See Fig. 5, *Bulletin No. 5*, Arch Dam Investigation, Engineering Foundation.

By the use of Figs. 7, 8, and 9 and the "multiplying factor" of 2.52, the stresses of this arch (for hinged ends) are as given in Column (8), Table 5.

A comparison of the values of the stresses found in the tests (Column (5)) with those computed from the curves for "fixed" (Column (7)) and "hinged" (Column (8)) arches, respectively, would indicate that undoubtedly there is a much better agreement between the test values and the theoretical stresses for a "fixed" arch than for "hinged" end conditions. Inasmuch as the arches of the Stevenson Creek Test Dam are probably thinner than those encountered in most service dams of the single-arch type, it may be concluded that the curves for fixed arches, including shear, are the ones that should be used in all practical cases. The thicker an arch dam the more nearly correct will probably be the assumption of "fixity" at the abutments.

‡ Average values.

The stresses in the arches of the Stevenson Creek Dam as determined in the design made in 1925 prior to construction, were computed by treating rib-shortening as separate from axial arch compression.* In many cases, there is a certain advantage in this method in that it gives a clearer conception of the influence of the rib-shortening pull and of the corresponding stresses. The rib-shortening pull may be assumed as acting in the center of gravity of the arch. If the arch is not of uniform thickness from abutment to abutment, the rib-shortening pull acts in the center of gravity of the elastic weights.

The author's Figs. 10 to 13 do not permit of the determination of the temperature stresses. These stresses can be readily computed by means of the curves and formulas given by Wegmann.*

Temperature stresses in arch dams are of considerable importance as are those due to the shrinkage of the concrete. The stresses resulting from a uni-

* "The Design and Construction of Dams," by Edward Wegmann, M. Am. Soc. C. E., Eighth Edition, 1927, p. 448.

form swelling of the arches due to water-soaking may be computed in a manner similar to those due to temperature. Water-soaking tends to expand the concrete and the effect on the stresses in an arch dam is beneficial rather than harmful.

The author's Figs. 10 to 13 will diminish the labor of computing the arch stresses from water pressure to such an extent that the analysis of an arch ring, either of a single arch dam or of a multiple-arch dam, can be accomplished in a few minutes.

FREDERICK HALL FOWLER,* M. AM. SOC. C. E. (by letter).—The discussion of this paper has brought forth formulas and curves of distinct value to the profession, and some comments to which the writer desires to add a few words.

Mr. Jakobsen has further developed the theory of the secondary arch and has presented curves (Fig. 15) for the ready determination of secondary arches. These curves will be of great value to engineers who desire to apply this theory. In citing the computations for the Kerckhoff Dam as an example, however, the writer had no thought that the question of secondary arches would be brought under discussion. Reference was made to these computations merely because they had been published,† were therefore available to the profession, were the result of detailed and laborious computations, and thus served as a standard of comparison for the results that could be secured by use of the curves.

In his closing paragraphs, Mr. Jakobsen has well illustrated the value of the curves in exploring the range of arch stresses when one element of the design, such as central angle, is held constant and the others are varied.

Professor Cain, author of the original formulas that form the bases for the graphic method, has contributed a detailed proof that the stresses, s_e and s_i, vary only with the ratio, $\frac{t}{r}$. The writer is in full accord with Professor Cain's statement that the computation of arch stresses for the given hypotheses, by use of the curves, "although a necessary step, is not the complete solution", and that "the engineer must consider all the influences mentioned,‡ in the design of arch dams." A computation of arch stresses under given assumptions is, however, an unavoidable step in the design of an arch dam, and without the use of curves it is a very laborious step. It was for this reason that the curves were prepared, and not with the thought that they would be a complete solution of the many other factors that enter into the design of such structures. The curves will go no farther in that direction than the original set of formulas on which they are based, which, by the way, includes only a few of the valuable formulas developed by Professor Cain.

Mr. Noetzli's discussion is of great interest since it points out that the stresses read from the curves for "fixed ends", agree more closely with the design and test data for the very thin arch of the Stevenson Creek Dam, than do the stresses given by the curves for "hinged ends". The question

* Cons. Civ. Engr., San Francisco, Calif.

† *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 258.

‡ Such as Poisson's ratio, water-soaking, shrinkage of concrete, changes in E with stress and time, effect of plasticity, yield of abutments, etc.

of the portions of the load carried by the arches and cantilevers in any given structure is still a matter of controversy. Several designers hold that in actual practice a structure should be so proportioned that the arches will be capable of carrying the entire water load without developing excessive stresses and that no dependence should be placed on cantilever action. If, however, a distribution of load between the arch and cantilever elements is assumed, the use of the curves will be limited to the determination of stresses due to the part of the load assumed to be carried by the arches; Mr. Noetzli's discussion has given in detail the method of use under such assumptions.

The writer is glad to note that Mr. Huber and Mr. Jorgensen, in their consulting practice, and Major Edgerton, as Chief Engineer of the Federal Power Commission, have found the curves of value in simplifying calculations for structures that they have had to analyze. The writer has received similar comments from other engineers to whom he has furnished sets of curves for trial use and comparison with extended computations. The consensus of opinion appears to be that curves for arches with "fixed ends, including the value of shear" (Figs. 10 to 13), are by far the most generally applicable, most nearly correct, and, therefore, the most valuable in their work. In response to many suggestions, these diagrams have been extended to include values of $\frac{t}{r}$ ranging from 0.02 to 0.10 and amplified to show interpolated curves in the ranges of $\frac{t}{r}$ from 0.10 to 1.00. The substitute curves are shown in Figs. 10 (*a*) to 13 (*d*). These were computed on the same basis as the original diagrams now superseded by them.*

Even a casual inspection of Figs. 10 to 13, will show in many instances a considerable latitude in the selection of the central angle and the value of $\frac{t}{r}$ when designing for a certain limiting stress, the particular combination finally adopted depending to a great extent on the economy in yardage. A set of diagrams similar to those given in Fig. 16 is, therefore, often found convenient in making approximate comparative computations that will give the most economic design. In Fig. 16 (*a*) are shown the quantities, in cubic yards per unit of radius squared, for an arch ring of uniform thickness, and 10-ft. vertical depth; Fig. 16 (*c*) gives similar quantities in terms of the square of the span (or width of the dam site at the given elevation), also for 10-ft. vertical depth. The central diagram, Fig. 16 (*b*), included merely for convenience, gives squares of span or radius for given values of W or r. A more accurate determination of these squares could be secured from a table.

If it is desired to find the yardage in a ring with a central angle of 100°; a radius, r, of 140 ft.; and a thickness of 42 ft. (or $\frac{t}{r} = 0.30$); entering Fig. 16 (*a*), the volume per unit of r^2 is found at the intersection of the vertical for

* In passing, it should be noted that new curves for $\frac{t}{r} = 0.10$ and 0.30 differ very slightly from the originals at certain points.

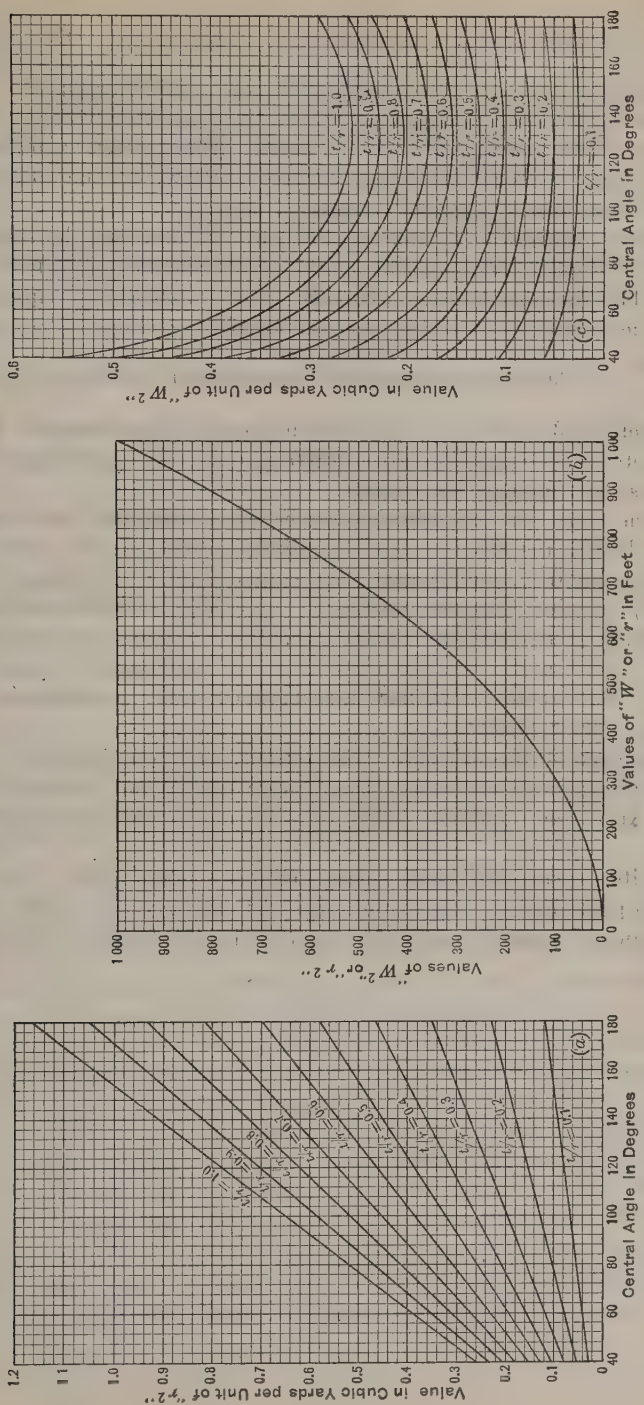

FIG. 16.—DIAGRAMS FOR COMPUTING APPROXIMATE YARDAGE IN ARCH RINGS IN TERMS OF SPAN OR RADIUS.

100° and the radial line for $\frac{t}{r} = 0.30$ to be 0.192 cu. yd. The square of r taken from Fig. 16 (*b*), or in this particular case as easily computed mentally, is 140×140, or 19 600. Multiplying by the constant, or $0.192 \times 19\,600$, gives 3 763 cu. yd. in the arch ring 10 ft. in depth. The yardage could have been (and in practice is more commonly) secured in terms of the span by using Fig. 16 (*c*) in an exactly similar manner.

A check of the results already obtained by use of r may be had by computation of the span corresponding to the given central angle, 100°, and the radius of 140 ft.; the solution gives W as 214 and W^2 as approximately 45 800. The intersection of the vertical at 100° in Fig. 16 (*c*), with the curve for $\frac{t}{r} = 0.30$, gives a yardage of approximately 0.083 per unit of W^2, or approximately 3 755 cu. yd. for the same arch ring in terms of W instead of r. A detailed computation gives 3 800 cu. yd.; the approximate method, therefore, is close enough for a guide.

After the data for the original curves were computed, the tabulations were furnished to the office of the Federal Power Commission in San Francisco, Calif., for trial, and through the courtesy of F. E. Bonner, M. Am. Soc. C. E., District Engineer of the U. S. Forest Service, and California Representative of the Federal Power Commission, curves were drafted on a co-operative basis under the direction of H. A. Sedelmeyer, Assoc. M. Am. Soc. C. E. This co-operation has since been extended as additional computations have been completed.

A large part of the original computations, and practically all those on which the interpolated curves are based, were carried out efficiently by Miss Winifred Kerr, and represent many days of most careful and painstaking work.

The writer wishes to thank those who have taken part in the discussion of this paper and to express the hope that the curves as finally developed may be found of value by engineers engaged in the design of arch dams.

Paper No. 1694

SIDE SPILLWAYS FOR REGULATING DIVERSION CANALS*

By W. H. R. Nimmo,† Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Edward S. Lindley, A. P. Flockart, George M. Bacon, and W. H. R. Nimmo.

Synopsis

In 1922, the Hydro-Electric Department of the Government of Tasmania completed a diversion channel of 450 sec-ft. capacity to convey water from the Upper Ouse River, at Liawenee, to the Great Lake storage. The intake of this channel is in a deep and narrow gorge where a low weir, only about 100 ft. long, suffices to divert the normal flow into a flume, ½ mile in length, built on a rock bench excavated along the wall of the gorge. From the outlet of the flume a canal, part of which is excavated in earth, conveys the water a farther distance of 5 miles where it is discharged into the Great Lake.

Within the catchment area are a large number of snow-fed lakes and lagoons and the stream is very flashy, the flow sometimes increasing from a few hundred to 12 000 sec-ft. within about 10 hours. The estimated maximum flood flow is 20 000 sec-ft. At present, the flow in the canal is controlled by a gate operated by a resident attendant but, as the country is inhabited only by a few shepherds in summer and is practically uninhabited in winter, it is desirable that some means of automatically regulating the flow in the canal should be devised. To be satisfactory in service any automatic arrangement must comply with the following conditions: (1) When the flow of the river does not exceed 450 sec-ft., all the flow must be allowed to pass into the concrete flume; and (2) when the total flow in the river exceeds 450 sec-ft., the flow in the concrete flume must not exceed 550 sec-ft. To meet the fore-

* Published in October, 1927, *Proceedings*.

† Chf. Draftsman, Main Roads Comm., Brisbane, Queensland, Australia.

going conditions several types of mechanically operated gates were considered, but those depending for their action on small differences of water pressures were discarded as they would fail to function during freezing weather. As the head-works are likely to become coated with ice for several weeks at a time, the forces applied to move the gate must be large, and for this reason gates operated by floats were found to be unsuitable. The writer then investigated the theory of flow in a side spilling channel with a view to devising a type of regulator without moving parts.

This paper presents the theory developed, describes the experiments carried out to test it, and the adaptation of the theory to the design of automatic head-works for the Ouse-Great Lake Canal.

Head-Works of the Ouse-Great Lake Canal

The head-works include a low concrete weir having a vertical up-stream face, a flat top, and a sloping down-stream face. At one end of the weir a converging channel, shown on Fig. 1, leads the water into the flume, this channel being bounded by the curved end of the weir on one side and by a concrete wall on the other. The crest of the weir is just high enough at all points to provide the necessary velocity head and entrance losses for the normal flow of 450 sec-ft. Down stream 184 ft. from the throat of the converging channel, is a head-gate 9 ft. wide, with vertical walls (visible in Fig. 5), which controls the entrance to the concrete flume. The outer guides of the gate are recessed so as to be flush with the walls of the flume and offer no obstruction, but the central guide consists of a 5 by 4½-in. by 18-lb., rolled steel joist.

Between the head-gate and the converging channel, there is a timber flume of trapezoidal section shown in plan, Fig. 1. Structural details of this flume are shown in Fig. 2, and Fig. 4 is a general view, looking up stream from the head-gate. Fig. 4 also shows the converging inlet and the weir, in which openings, now closed by stop-planks, have been left to carry the dry-weather flow during future alterations to the head-works. For a distance of 40 ft., up stream from the head-gate, the timber flume is on a curve of 198 ft. radius. The floor, which is flush with that of the concrete flume, has a normal width of 5 ft. 8 in. The side of the flume next to the river is intended to act as a spillway throughout the straight portion of its length, and the lip is 5 ft. above the floor, at which depth the water area is 45 sq. ft., being the same as that of the concrete flume, at its normal depth of 5 ft. The floors of both the timber and the concrete flumes are laid on a grade of 1 in 330. Along the entire side away from the river and on the curved portion of the side next the river, the wall of the flume is built 2 ft. above the lip of the spillway portion.

The throat of the converging channel has a width of 9 ft. and a depth of 5 ft., corresponding to the width and normal depth of flow in the concrete flume. At the down-stream end of the timber flume, a transition, 14 ft. long, connects the trapezoidal section to the rectangular section at the head-gate. In this transition the slope of the walls decreases uniformly and, consequently,

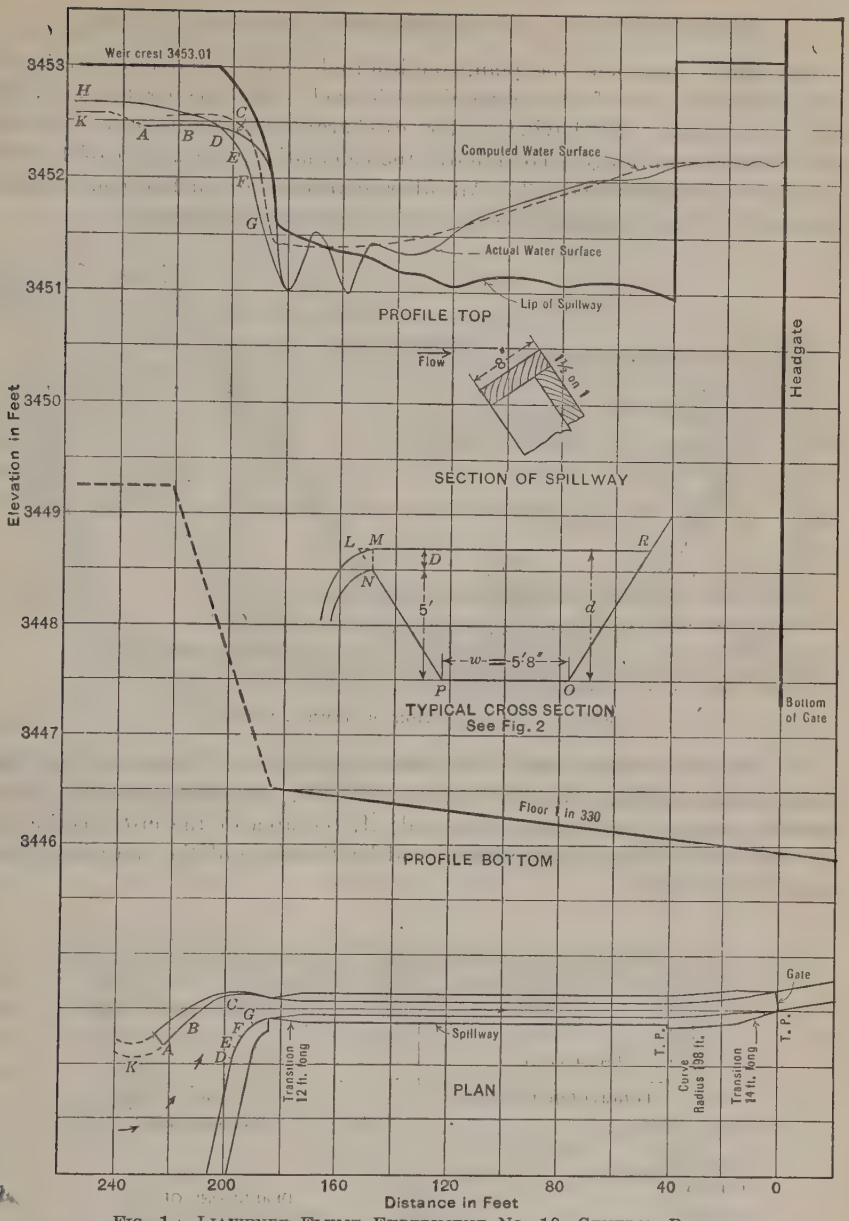

FIG. 1.—LIAWENEE FLUME EXPERIMENT NO. 19, GENERAL PLAN.

their surfaces are slightly warped. At the up-stream end of the timber flume a similar transition, 12 ft. long, connects with the throat of the converging channel. Figs. 5 and 9, which were taken when the head-gate was closed, show the whole flow of the river—approximately 400 sec-ft.—discharging over the side of the timber flume. The concrete flume is 6 ft. deep, the free-board being 1 ft. at the normal flow of 450 sec-ft.

Theory of Flow in Any Overflowing Trapezoidal Channel

Let Fig. 3 represent the plan, longitudinal section, and cross-section of a short length, Δx, of any trapezoidal channel, with varying bottom width and side slopes, and having water discharging outward over one side which acts as a spillway. To simplify the calculations the weight of 1 cu. ft. of water is assumed to be 1 lb. All other quantities are in foot-pound-second units and the flow is assumed to be in the direction of the arrow.

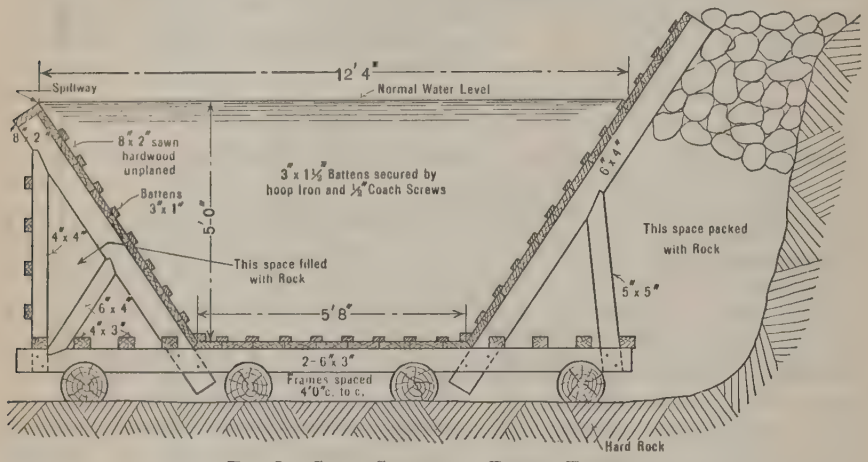

Fig. 2.—Cross-Section of Timber Flume.

At the down-stream end of the short section, let P represent the total static pressure acting over the cross-section; V, the mean velocity; Q, the quantity passing the section per second; A, the area of the cross-section; w, the width of the floor; d, the depth; and let the slope of the sides be n horizontal to l vertical.

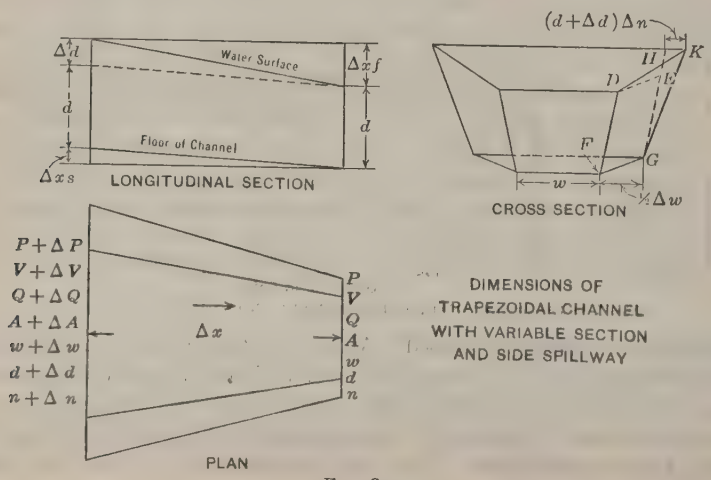

Fig. 3.

At the up-stream end of the section the corresponding quantities are to be denoted by $P + \Delta P$, $V + \Delta V$, $Q + \Delta Q$, $A + \Delta A$, $w + \Delta w$, $d + \Delta d$, and $n + \Delta n$, respectively. ΔQ, Δw, Δd, and Δn are positive, when Q, w, d, and n, respectively, are increasing up stream. Also, let f represent the loss of head per unit length due to friction and s, the slope of the floor per unit length, s being positive when the floor of the channel slopes down stream.

Then, ΔQ represents the quantity of water which is discharged over the side of the channel in the length, Δx, and, as it retains its momentum parallel to the channel, a certain amount of momentum is lost with it. The value of ΔQ is given by the usual equation

$$\Delta Q = c \, \Delta x \, D^{\frac{3}{2}} \quad \ldots\ldots (1)$$

in which, D is the head of water over the spillway lip, and c is the constant.

From the principle of conservation of momentum, the change of momentum in the length, Δx, less the momentum lost with the overflowing water, must equal the algebraic sum of the external forces. The external forces are:

(1) The static pressures on the end areas, given by,

$$P = \left(\frac{w\,d^2}{2} + \frac{n\,d^3}{3}\right) \quad \ldots\ldots (2)$$

and,

$$P + \Delta P = \left(\frac{(w + \Delta w)\,(d + \Delta d)^2}{2} + \frac{(n + \Delta n)\,(d + \Delta d)^3}{3}\right) \quad \ldots\ldots (3)$$

(2) The reaction from the projected area of the side-walls: The rectangle, $D\,E\,G\,F$, and the triangle, $H\,K\,G$, may be taken as closely representing the actual area, $D\,K\,G\,F$. The reaction for both sides of the channel is given by,

$$\frac{\Delta w\,d^2}{2} + \frac{\Delta n}{3}(d + \Delta d)^3 = \frac{\Delta w\,d^2}{2} + \frac{\Delta n}{3}(d^3 + 3\,d^2\,\Delta d + 3\,d\,\Delta d^2 + \Delta d^3). \quad (4)$$

Neglecting products and powers of Δ-quantities, Equation (4) becomes,

$$\frac{\Delta w\,d^2}{2} + \frac{\Delta n\,d^3}{3} \quad \ldots\ldots (5)$$

(3) The retardation due to friction: This is very nearly equal to $\Delta x\,f\,(A + \frac{1}{2}\,\Delta A)$, but for short sections of any channels met with in practice, $\Delta x\,f$ will be very small, and $(A + \frac{1}{2}\,\Delta A)$ will be nearly equal to A. The retardation therefore, may be represented with sufficient accuracy by the term, $\Delta x\,f\,A$.

(4) The force due to gravity which may be represented by the term, $\Delta x\,s$: The momentum lost with the overflowing water is very nearly equal to,

$$\frac{\Delta Q\,(V + \frac{1}{2}\,\Delta V)}{g} \quad \ldots\ldots (6)$$

in which, $V + \frac{1}{2}\,\Delta V$ is the average mean velocity in the length, Δx.

Equation (7) can now be written:

$$\frac{Q\,V}{g} + \frac{\Delta Q\,(V + \frac{1}{2}\,\Delta V)}{g} - \frac{(Q + \Delta Q)\,(V + \Delta V)}{g}$$
$$= \left\{\frac{(w + \Delta w)\,(d + \Delta d)^2}{2} + \frac{(n + \Delta n)\,(d + \Delta d)^3}{3}\right\} - \left(\frac{w\,d^2}{2} + \frac{n\,d^3}{3}\right)$$
$$- \frac{\Delta w\,d^2}{2} - \frac{\Delta n\,d^3}{3} - \Delta x\,(f - s)\,A \quad \ldots\ldots (7)$$

Putting $V = \frac{Q}{A}$ and $V + \Delta V = \frac{Q + \Delta Q}{A + \Delta A}$ and rejecting products of Δ-quantities,

$$\frac{Q^2}{g A} + \frac{Q \Delta Q}{g A} - \frac{(Q + \Delta Q)^2}{g (A + \Delta A)} = \left\{ \frac{(w + \Delta w)(d^2 + 2 d \Delta d)}{2} + \frac{(n + \Delta n)(d^3 + 3 d^2 \Delta d)}{3} \right\} - \frac{w d^2}{2} - \frac{n d^3}{3} - \frac{\Delta w d^2}{2} - \frac{\Delta n d^3}{3} - \Delta x (f - s)(w d + n d^2) \quad \ldots\ldots\ldots\ldots (8)$$

from which,

$$Q^2 w \Delta d + Q^2 \Delta w d + 2 Q^2 n d \Delta d + Q^2 \Delta n d^2 - Q \Delta Q w d - Q \Delta Q n d^2 = g \left\{ (w d + n d^2) + (w + 2 n d) \Delta d + \Delta w d + \Delta n d^2 \right\} (w d + n d^2) - (w d + n d^2) \Delta d - \Delta x (f - s)(w d + n d^2)$$

rejecting Δ-terms in the denominator, this reduces to,

$$\frac{\Delta d}{\Delta x} = \frac{(f - s) - \frac{Q}{g} \times \frac{1}{(w d + n d^2)^2} \times \frac{\Delta Q}{\Delta x} + \frac{Q^2}{g} \times \frac{d}{(w d + n d^2)^3} \times \frac{\Delta w}{\Delta x} + \frac{Q^2}{g} \times \frac{d^2}{(w d + n d^2)^3} \times \frac{\Delta n}{\Delta x}}{1 - \frac{Q^2}{g} \times \frac{w + 2 n d}{(w d + n d^2)^3}} \quad \ldots\ldots (9)$$

In Equation (9), if the channel is not acting as a spillway, then ΔQ vanishes and the second term of the numerator vanishes. If w be constant, the third term vanishes, and, if n be constant, the fourth term vanishes. The equation then reduces to:

$$\frac{\Delta d}{\Delta x} = \frac{f - s}{1 - \frac{Q^2}{g} \times \frac{w + 2 n d}{(w d + n d^2)^3}} \quad \ldots\ldots\ldots\ldots (10)$$

For a rectangular channel, $n = 0$, and the equation further reduces to:

$$\frac{\Delta d}{\Delta x} = \frac{f - s}{1 - \frac{Q^2}{g} \times \frac{w}{w^3 d^3}} = \frac{f - s}{1 - \frac{Q^2}{g A^2 d}} = \frac{f - s}{1 - \frac{V^2}{g d}} \quad \ldots\ldots\ldots (11)$$

Also, if the slope of the bed of the channel is just sufficient to overcome the resistance due to friction, then $f = s$, and Δd vanishes, or, in other words, the depth becomes constant which is the condition of normal flow in a uniform channel.

Again, when,

$$\frac{Q^2}{g} \frac{w + 2 n d}{(w d + n d^2)^3} = \frac{Q^2}{g A^2} \frac{w + 2 n d}{w d + n d^2} = \frac{V^2}{g} \frac{w + 2 n d}{w d + n d^2} = 1 \quad \ldots\ldots (12)$$

that is, when,

$$\frac{w d + n d^2}{w + 2 n d} = \frac{V^2}{g} = \text{twice the velocity head} \quad \ldots\ldots\ldots (13)$$

the denominator vanishes, and the ratio, $\frac{\Delta d}{\Delta x}$, becomes infinite in the limit, or, in other words, the water surface becomes vertical. This can only occur when passing through the critical depth. For a rectangular channel, as n is then zero, the critical depth occurs where the depth is twice the velocity head, or,

$$d = \frac{V^2}{g} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

For a channel, such as the spillway, into which water flows from the reservoir, the water enters at right angles to the axis of the channel and introduces no additional momentum corresponding to the loss of momentum which takes place when water flows outward from the channel.

The equation of flow for this condition is given by Equation (7) if the term, $\frac{\Delta Q\,(V + \frac{1}{2}\Delta V)}{g}$, is omitted, and a new equation corresponding to Equation (9) is then obtained:

$$\frac{\Delta d}{\Delta x} = \frac{(f - s) - \frac{2Q}{g}\frac{1}{(w\,d + n\,d^2)^2}\frac{\Delta Q}{\Delta x} + \frac{Q^2}{g}\frac{d}{(w\,d + n\,d^2)^3}\frac{\Delta w}{\Delta x} + \frac{Q^2}{g}\frac{d^2}{(w\,d + n\,d^2)^3}\frac{\Delta n}{\Delta x}}{1 - \frac{Q^2}{g}\frac{w + 2\,n\,d}{(w\,d + n\,d^2)^3}} \quad \ldots\ldots\ldots (15)$$

By writing $y - xs$ for d, and bx for Q, and omitting the friction term, f, it can be shown that Equation (15) is another form of the equation,

$$\frac{d\,y}{d\,x} = \frac{V}{g}\frac{d\,V}{d\,x} + \frac{b\,V^2}{Q\,g} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

which is given by Julian Hinds, M. Am. Soc. C. E., in his paper on "Side Channel Spillways".*

Flume Experiments†

Equations (9) and (15) are only strictly correct when the average velocity is equal to the mean velocity, that is when,

$$\frac{1}{2}\,M\,V^2 = \frac{1}{2}\,\Sigma\,m\,v^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

in which, for any elementary stream tube, m represents the mass passing the section per second, and v the velocity. This condition is never quite satisfied in any ordinary stream owing to the irregular distribution of velocity over the cross-section. In the case of a channel discharging a large quantity of water over the side, it was thought that the disturbance set up by eddies might be

* *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 881.

† The Liawenee experiments were carried out in November, 1922, and January, 1923. A full description of these experiments and the theory of flow in an overflowing channel are contained in an unpublished thesis presented by the writer to the University of Melbourne early in 1924.

sufficient to vitiate entirely the results obtained from Equation (9) and, therefore, it was considered necessary to make a large scale experiment before applying the equation to the design of new head-works.

Fortunately, the timber flume made it possible to carry out an experiment—known as Liawenee Flume Experiment No. 19—the results of which are shown in Fig. 1 and Table 1. The lip of the spillway was slightly irregular owing to warping of the timber, and the profile of it, shown by the heavier full line in Fig. 1, was obtained by spirit leveling. The observed water surface, shown by the thinner full line in Fig. 1, was also obtained by spirit leveling, the staff being held close to the wall of the channel on the side opposite the spillway and it is, therefore, probably slightly higher than the mean level of the water surface.

Owing to the centrifugal effect in the curved converging inlet and the fact that the velocity of approach in the river above the weir slightly heaps up the water at the point marked, *H*, in Fig. 1, the water level on the two sides of the channel differs considerably. The points lettered on the longitudinal section correspond with those on the plan. The grade of the floor in the converging inlet had not been accurately determined and, for that reason, it is shown dotted in Fig. 1. The walls of the inlet are cement, but the floor is rough and the value of Kutter's n has been taken as 0.020. In the computations in Table 1, Kutter's n for the timber flume was taken as 0.015, although it was later found to be 0.017, but the effect of the friction term is so small that the level of the computed water surface is not appreciably affected thereby.

The flow in the flume was determined by current meter at a permanent gauging station on a uniform section of the canal a few hundred feet down stream from the outlet of the concrete flume. In this experiment, the total flow entering the timber flume was 360 sec-ft., of which quantity, 235 sec-ft. were discharged over the spillway, the remaining 125 sec-ft. passing under the head-gate, the lower edge of which was 1.37 ft. above the floor of the flume. It should be noted that spilling over the edge of the flume commenced 40 ft. up stream from the gate and ceased at 172 ft. and, therefore, was confined to a straight length of flume of normal cross-section, having a bed width of 5 ft. 8 in. and side slopes of $\frac{2}{3}$ horizontal to 1 vertical.

The water surface, shown by the dotted line in Fig. 1, was computed by Equation (9), the calculations being presented in Table 1. In order to find values of ΔQ for use in Table 1, it was necessary to determine the value of the coefficient for the spillway lip, a detailed cross-section of which is shown in Fig. 1. The mean value of the head, D, on the spillway was determined for each 4-ft. length, and the value of the coefficient, c, was found to be 3.57 from Equation (18):

$$\Sigma \Delta Q = c \Sigma (\Delta x D^{\frac{3}{2}}) = c \Sigma (4 D^{\frac{3}{2}}) = 235 \ldots\ldots\ldots\ldots (18)$$

In Equation (9), the expression, $(w d + n d^2)$, represents the complete trapezoid, *L R O P* (see cross-section, Fig. 1), but, in the computation in Table 1, the area, *M R O P N*, was utilized as more nearly representing the

actual cross-section of the water area. This procedure resulted in more labor in calculation than would have been involved if the complete trapezoidal area had been adopted and as the maximum area of the triangle, $L\,M\,N$, is only 0.006 of the area, $L\,R\,O\,P$, no appreciable error would have resulted if the area, $L\,R\,O\,P$, had been adopted instead of the area, $M\,R\,O\,P\,N$.

The actual water-surface level at a point 30 ft. up stream from the gate was adopted as a starting point from which to obtain the computed water-surface curve (dotted line, Fig. 1) which, in general, agrees closely with the actual water surface. From the head-gate to Station 40, the flume is curved and the centrifugal effect here would be to lower the actual water surface along the side of the flume opposite the spillway and this is probably the explanation of the divergence between the actual and computed water surfaces between Stations 30 and 60. The critical depth for the flume for a flow of 360 sec-ft. is 4.22 ft. and as the waves, which occur at the up-stream end of the flume, do not extend down to the critical depth, they are not hydraulic jumps. The water issues from the curved inlet at a velocity of 8.27 ft. per sec. and, as the upper portion of the walls of the timber transition flare outward from the end of the concrete inlet, the rapidly moving stream cannot immediately accommodate itself to the changed direction of the walls, and, consequently, a partial vacuum occurs against the upper portion of the walls, and is marked by a small area of turbulence which can be seen at the extreme left in Fig. 5. Equation (9) is based on the assumption that the water exerts a pressure against the walls at all points equal to the full static pressure due to the depth, and the waves are due to the fact that this condition does not hold just at the entrance to the transition. Up stream from the throat the computed water surface agrees fairly well with the mean of the observed water surfaces in the curved inlet. The computed total discharge of 370 sec-ft. (see Table 1) agrees well with the measured discharge of 360 sec-ft.

Proposed Design for New Head-Works for Ouse-Great Lake Canal

As the foregoing experiment showed that Equation (9) could be satisfactorily applied in practice on a comparatively large scale, it was decided to make a new design for the head-works of the canal based on the theory just developed. A diagrammatic longitudinal section of the proposed head-works is shown in Fig. 6. The existing curved inlet, shown in Fig. 1, from Station 184 up stream will be retained. At Station 184 a square-edged concrete baffle-wall will be constructed above the throat of the inlet and will extend across to the wall of the gorge so that water can enter the flume only by means of the orifice, 5 ft. high by 9 ft. wide, under the baffle. No gate is required at this point, but provision for stop-planks will be made. A second orifice, 5 ft. high, will be formed by a square-edged concrete head-wall in the position occupied by the existing head-gate, and a sector gate having the full width of the concrete flume will be provided for closing this orifice when it is desired to prevent water from entering the canal.

Between Stations 0 and 184, the existing timber flume will be replaced by a rectangular concrete flume, 9 ft. wide, designed to act as a spillway between

Stations 30 and 152. It will be noted that, between Stations 10 and 174, the floor of the flume is lowered about 5 ft. below the normal grade line of 1 in 330 to form a deep pool throughout the spillway portion of the flume. In the actual design the sharp changes of grade shown in Fig. 6 at Stations 10, 30, 152, and 174, will be rounded, but the hydraulic computations are simplified by considering them as being sharp and this assumption has no appreciable effect on the results.

Before investigating the behavior of the proposed head-works in detail, it is necessary to decide on suitable values for the coefficient of roughness of the concrete flume and the coefficients of discharge of the spillway and the orifice at the inlet and head-gate.

Coefficient of Roughness of Flume.—Gaugings taken in the existing concrete flume show that the value of Kutter's n varies from 0.014 in summer to 0.015 in winter, owing to the fact that a growth appears on the walls and floor during the high-water period when the flume is continuously filled. This growth dies again if the flow ceases frequently. The value of 0.015 was adopted for Kutter's n, but the shape of the water-surface curves shown in Fig. 6 would be very slightly affected by a considerable error in the value of n.

Coefficient of Discharge for Spillway.—A cross-section of the crest of the proposed spillway is shown in Fig. 6. For a triangular weir, sharp crest, up-stream face vertical, top sloping 2 horizontal to 1 vertical, the value of c in Equation (1):

$$\Delta Q = c \Delta x D^{\frac{3}{2}}$$

for a head of 1 ft. on the crest is given by King* as 3.50. Bazin's experiments on wide crested weirs showed an increase of 9% in the value of c when the up-stream edge was rounded to a radius of 4 in. Assuming the same increase for the spillway, the value of c would become 3.82. A value of 3.80 was adopted for the spillway.

Coefficient of Discharge of Orifices.—At both the inlet and head-gate orifices, the floor and the two walls of the flume are continuous so that contraction is entirely suppressed on these three sides, but the top of the orifice is sharp-edged and the velocity of approach is usually considerable. No published experiments dealing with orifices of this nature could be found and, therefore, some experiments (referred to as the "baffle experiments") were carried out in January, 1923, by placing a timber baffle in a straight portion of the existing concrete flume. The data obtained from Experiments B2-6 and the profiles of the water surface are shown in Table 2 and Fig. 7 which is self-explanatory. The bottom of the baffle in all experiments was sharp-edged and was located at Distance 0; in Experiment 3 the baffle was inclined 45° up stream. The depth, d_1, was measured 5 ft. up stream from the baffle. The floor of the flume had a grade of 1 in 330. In Experiment B-1 the water backed up and overflowed the wall of the flume, therefore, the results have been discarded. The water-surface profiles were obtained by measuring downward, with a rod graduated in inches, from points on the wall of the flume, the elevations of which had been determined with an engineer's level. As the result of these experiments, 0.58 was adopted as the value of c for the inlet and head-gate.

In Fig. 6 are shown the water surface curves which will result from various conditions of flow, and these curves will now be discussed in detail separately.

Curve C.—This curve represents the conditions which will occur when the river is rising and the discharge has just reached 450 sec-ft., but the water surface has not made contact with the under side of the baffle-wall at the inlet. Since the grade of 1 in 4 entering the spillway pool is sufficient to maintain a velocity much greater than the critical velocity, it follows that the water surface must cross the critical depth, and it will do so at the change of grade at Station 174. A known point on a back-water curve has now been obtained and, in most cases, the form of the curve could be computed, in either the up-stream or down-stream direction, by Equation (9).

It has been previously shown that theoretically the water surface becomes vertical when passing through the critical depth and although in practice it does not become actually vertical, it does assume a very steep slope, and to this portion of the curve Equation (9) cannot be applied directly. Up stream from Station 174, Curve C will take a form approximating to the dotted line on Fig. 6. The energy ordinate, E, that is, the vertical height of the energy line above the floor of the channel, is given by,

$$E = d + \frac{V^2}{2\,g} \qquad (19)$$

At Station 174, the value of E is 6.41 and the energy curve is, therefore, at Elevation 3 452.73, so that, in order to provide for the friction loss occurring between the pond and Station 174, the pond level behind the weir must be somewhat above Elevation 3 452.73. The exact shape of the dotted portion of Curve C is of no importance in connection with the problem under consideration.

As regards the portion of the curve, C, down stream from Station 174, it is known that the value of E at Station 174 is 6.41. As the floor slopes 0.25 ft. in the next foot, and the friction loss in that short length is very small, the value of E at Station 173 may be taken as 6.66. Solving the energy equation, the depth at Station 173 is found to be 3.54 ft. From Station 173 down

stream, Curve C has been computed by Equation (9) in a manner exactly similar to that used in computing the water surface in Experiment No. 19 (Fig. 1), as shown in detail in Table 1, except that, for Curve C, ΔQ, ΔW, and Δn are all zero, and the calculation is thereby simplified.

Curve D.—The normal depth for 450 sec-ft. in the concrete flume being 5.0 ft., therefore, if the water surface is not touching the under side of the head-gate, a depth of 5 ft. at Station 0 may be adopted as a starting point from which Curve D can be computed up stream by Equation (9).

In applying Equation (9) to those portions of the curve between Stations 10 and 30 and Stations 152 and 172.5, where the slope of the water surface is changing rapidly, it is necessary to take extremely small steps in making the calculations, but, owing to the great depth, the energy lost in friction in each of these portions does not exceed about 0.01 ft., and, therefore, no appreciable error is introduced by considering the energy line to be at the same elevation throughout these portions of the flume. The value of d can then be determined by solving the energy equation,

$$E = d + \frac{V^2}{2g} = d + \frac{Q^2}{2g\,w^2\,d^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (20)$$

This method of dealing with the steeper portions of the curves avoids the great amount of labor involved in applying Equation (9) and has been adopted in determining such portions of all curves shown in Fig. 6. Between Stations 30 and 152, Curve D has been computed by Equation (9).

Curves C and D.—The water entering under the baffle cannot continue to follow Curve C indefinitely as the bottom of the flume is level, and energy is being absorbed by friction. In order to pass under the head-gate, the water must change by some means from Curve C to Curve D and, as this involves crossing the critical depth, the change can only take place through an hydraulic jump. An hydraulic jump between any two curves can only take place at a point where the value of the momentum,

$$M = \frac{A\,d}{2} + \frac{Q\,V}{g} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

is the same for both curves.

The curves in Fig. 8 show the value of M at various points on the correspondingly lettered curves in Fig. 6. Referring to Curves C and D in Fig. 8, it is seen that they intersect at Station 170 and, therefore, the water surface must jump from Curve C to Curve D (Fig. 6) at that point.

Curve A.—This curve represents the conditions which will occur with a falling stage of the river when the flow is 450 sec-ft. and the water is in contact with the under side of the baffle. From the formula,

$$Q = A\,c\,\sqrt{2\,g\,h} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

it is found that the head, h, over the center of gravity of the orifice is 4.65 ft. The crest of the weir, therefore, must be 7.15 ft. above the bottom of the orifice, that is, at Elevation 3 453.46, in order that no water shall be wasted over the weir until the flume is receiving 450 sec-ft.

The value of E on the up-stream side of the baffle is 7.15 and Baffle Experiments No. B-2 to B-4 (Table 2 and Fig. 7) show that a loss of about 4% of the energy occurs in passing the baffle. Therefore, on the down-stream side of the baffle, the value of E will be about 6.86, from which it is found that the depth at about 6 ft. on the down-stream side of the baffle will be 3.33 ft. From Station 178 down stream, Curve A has been computed by Equation (9) and merges into Curve C.

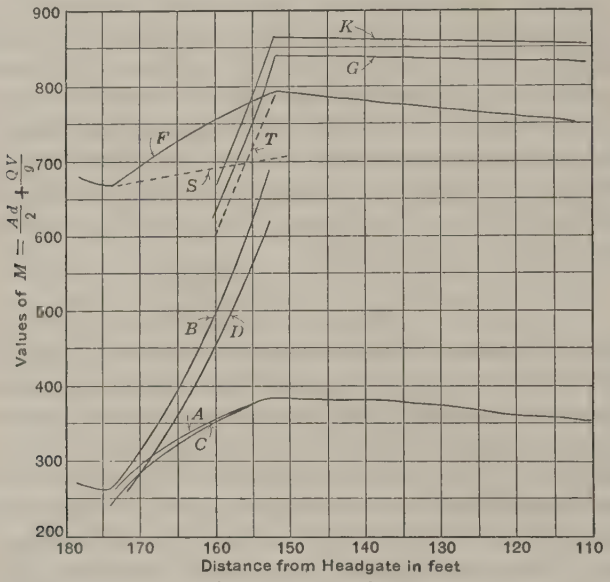

FIG. 8.—MOMENTUM CURVES.

Curve B.—This curve represents the conditions occurring with a falling stage of the river when the flow is 450 sec-ft. and the water touches the underside of the head-gate. From the formula, $Q = A\ c\ \sqrt{2\ g\ h}$,

$$h = d + \frac{V^2}{2\ g} - 2.5 = 6.92 \text{ ft.}$$

from which, for the up-stream side of the head-gate, d, by trial, equals 8.64 ft.

Curve B is then computed from the head-gate up stream in exactly the same manner as has been described in the case of Curve D. Curve B fixes the lowest level at which the spillway can be placed without losing water when the total flow in the river does not exceed the normal canal capacity of 450 sec-ft. To provide some margin for error in the calculations, the spillway has been placed slightly above Curve B, being horizontal and exactly 12.0 ft. above the floor of the channel.

Curves A and B.—The water, entering under the baffle and flowing along Curve A, must jump to Curve B in order to pass the head-gate. Reference to Fig. 8 shows that the momentum Curves A and B intersect at Station 173.5 and at this point the jump must take place.

Curve F.—This curve represents the surface curve that will be assumed by the water passing under the baffle during the maximum flood which is estimated to rise to a height of 8 ft. above the crest of the weir, that is, to a height of 15.15 ft. above the bottom of the orifice. Therefore, $h = 12.65$ ft., and,

$$Q = A\ c\ \sqrt{2\ g\ h} = 743 \text{ sec-ft.}$$

As the velocity head at the up-stream side of the baffle is negligible, the energy ordinate, E, at this point is equal to the depth, d_1, that is, 15.15 ft. Allowing 4% loss of energy in passing the baffle the energy ordinate on the down-stream side, E_2, becomes 14.55 ft., from which, $d_2 = 3.04$ ft. is obtained by trial. This depth will occur about 6 ft. down stream from the baffle, that is, at Station 178. From Station 178 down stream, Curve F has been computed by Equation (9).

The critical depth, d_c, for 743 sec-ft. is given by,

$$d_c = \sqrt[3]{\frac{Q^2}{g\ w^2}} = 5.97 \text{ ft} \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

and it is obvious that the water cannot pass through the head-gate without first jumping across the critical depth to some curve, such as G or K, and while flowing along such a curve a large quantity of water will be discharged over the spillway, although the flow under the head-gate will also be somewhat in excess of the normal canal capacity of 450 sec-ft.

For the flow to take place along any curve, such as G or K, two conditions must be satisfied: (1) That the value of M on the given curve, at the point where the jump takes place, must be equal to the value of M for Curve F at the corresponding point; and (2) the sum of the discharges over the spillway and under the head-gate must be 743 sec-ft. The curve which will satisfy these conditions can be found by trial as explained subsequently.

Curve G.—Let it be assumed that the quantity of water passing under the head-gate is 490 sec-ft., then, in the same manner as has been explained in regard to Curve B, it is found that the depth, d_1, against the up-stream side of the gate is 7.07 ft. From Station 0 to Station 30 and from Station 152 to Station 160, Curve G has been computed by the energy equation as previously explained for Curve D. Throughout the length of the spillway, that is, between Stations 30 and 152, Curve G has been computed by Equation (9), and the computation is shown in Table 3.

Referring to the momentum curves in Fig. 8, it will be seen that Curves F and G intersect at Station 154, and, therefore, at this point the water can jump from Curve F to Curve G. On referring to Table 3, it is noted that the value of Q increases from 490 sec-ft. at the down-stream end of the spillway (Station 30) to 712 sec-ft. at the up-stream end (Station 152), but this latter value should be 743 sec-ft. in order to satisfy Condition (2) as stated. The water surface, therefore, must take up some position above Curve G.

Curve K.—Assuming that the quantity of water passing under the head-gate is 495 sec-ft., it is found that the depth, d_1, against the head-gate is 7.20 ft., and from this point Curve K is computed in exactly the same manner as Curve G. In Fig. 8, it is seen that the momentum curves, F and K, intersect

FIG. 9.—VIEW OF TIMBER FLUME, UP STREAM FROM THE HEAD-GATE, SHOWING HYDRAULIC JUMP.

FIG. 10.—VIEW OF TIMBER FLUME UNDER NORMAL CONDITIONS.

at Station 155, which is the only possible position for the jump. Table 3, however, shows that the value of Q increases from 495 sec-ft. at Station 30 to 761 sec-ft. at Station 152, but, as in order to satisfy the conditions the latter value should be 743 sec-ft., it follows that the water surface must take up some position below Curve K and, therefore, it must occupy some position between Curves G and K.

It is necessary to consider to what extent the degree of regulation will be affected by errors in the adopted values for Kutter's n and the coefficients of discharge of the baffle and head-gate and of the spillway. Table 3 shows that the friction term in the numerator of Equation (9) is very small compared with the term in ΔQ and, therefore, variation in the value of n will not appreciably affect the water surface opposite the spillway. The coefficient adopted for the baffle and head-gate is based on actual experiments made under conditions exactly similar to those that will obtain at the baffle and head-gate, and it is not likely therefore to be seriously in error.

Assuming, however, that the true value of the coefficient is 5% greater than the adopted value, the discharge under the baffle would be increased by 37 sec-ft. and the discharge under the head-gate by about 24 sec-ft. The increase in the discharge of the spillway would be only about 13 sec-ft. and the level of the water surface would be very slightly changed. An increase of 5% in the value of the coefficient, therefore, would increase the excess in the canal to about 15% of the normal flow. A small decrease in the value of the coefficient, of course, will improve the regulation, but will raise the level of Curve B to some extent, for which reason the spillway crest has been placed a little higher than Curve B.

The coefficient for the spillway is the factor which is most likely to be in error, but Curves G and K (Table 3) show that a variation of 44 sec-ft., or 20% of the total discharge over the spillway, only causes a variation of 5 sec-ft. in the discharge under the head-gate, so that the value of the coefficient for the spillway may be considerably in error without appreciably affecting the regulation of the canal.

The proposed design for the head-works, therefore, will probably prevent the normal capacity of the canal being exceeded by more than 10% and will certainly prevent it being exceeded by more than 15% which is equivalent to 70 sec-ft. Since the canal is provided with spillways where it crosses natural drainage channels and can be operated for a reasonable period under an overload of 100 sec-ft., the proposed design which involves no moving parts and is, therefore, "fool-proof" and frost proof, will provide satisfactory regulation.

If the floor of the spillway portion of the channel were not lowered, but were constructed to the dotted line, L, in Fig. 6, the momentum, M_L, of the water leaving the baffle orifice at the lower stage, would exceed the momentum, M_U, for the upper stage, which would be the normal depth. If a jump is to occur, the value of M_L must be decreased until it equals the value of M_U. As friction would be the only force tending to decrease the value of M_L, the high velocity stage might persist to a point beyond the head-gate. Therefore, in order

to make the spillway effective, some means must be adopted to ensure that a jump will occur at some definite point close to the baffle. Similar conditions were met in the experiments of the Miami Conservancy District* in the design of outlets from its flood-detention reservoirs. In that case the reaction of a submerged obstruction was used to decrease the value of M_L, but in order to avoid raising the water level too high in passing over the obstruction, the obstruction was placed below the normal floor of the channel and the water led to it down an incline which had the effect of first raising the value of M_L.

In the proposed head-works design shown in Fig. 6, a definite location for the jump is secured in a different manner. The function of the deep pool is to make the value of M_U greater than that of M_L. Instead of decreasing M_L, it is necessary, therefore, either to increase M_L or to decrease M_U, or to do both. The curves in Fig. 8 show clearly that the steep grade of the floor in Fig. 6 does both increase M_L and decrease M_U, causing the curves to intersect at a decided angle and thereby definitely locating the jump within the limits of the steep grade.

The view, Fig. 9, looking up stream from the head-gate during a moderate flood in the river, shows a good example of an hydraulic jump occurring at about the center of the timber flume. The jump is due to the fact that the head-gate was partly closed, thus backing up the water in the flume. In comparison, Fig. 10 shows the flume under more normal conditions.

For the particular head-works under discussion, the very narrow space available at the side of the gorge renders the method of obtaining regulation by lowering the floor very suitable. It is not the only possible method, however, and similar results could be achieved by widening the channel behind the baffle at the inlet and contracting it again at the head-gate. Thus, if the width of the floor be increased from 9 ft. at Station 174 (Fig. 6) to 40 ft. at Station 152, the dotted curve, S, in Fig. 8 shows the variation of M_L for a discharge of 743 sec-ft. The dotted curve, T, shows the approximate value of M_U, assuming a depth of 1 ft. of water over the spillway at Station 152. Although no incline is used, the intersection of Curves S and T (Fig. 8) shows that the jump will be just as definitely located in the transition in this instance as it is for the design shown in Fig. 6 and many cases might arise in practice where it is preferable to widen the channel rather than deepen it.

For the Ouse-Great Lake Canal, regulation of the flow within 15% of the normal is sufficient, but if closer regulation were desired it could be obtained by installing a second baffle, stilling pool, and spillway immediately down stream from Station 0 (Fig. 6) and moving the head-gate to the down-stream end of this second pool. If necessary, a series of stilling pools and spillways, separated by orifices, might be used.

The problem of regulating the flow in a diversion channel taking water from a river subject to rapid and considerable changes of level is one which must frequently be encountered, and where some type of automatic gate is not suitable, the principles of the design illustrated in Fig. 6 may find a practical application.

* Miami Conservancy District, Technical Reports, Pt. 3.

DISCUSSION

EDWARD S. LINDLEY,* M. AM. SOC. C. E. (by letter).—The author arrives at a coefficient of 3.82 for the spillway section shown on Fig. 6. This is probably about the maximum value of coefficient that it is possible to realize, as long as no negative pressures are induced at the control section; but tests made by the writer† indicate that that value is likely to be realized.

In the formulas and calculations of Table 2, the author measures the head causing velocity down to the center of the orifice. That is the textbook method for a small orifice the jet from which discharges freely into the air all round it; but a different solution applies when the height of orifice is not small relative to its submersion up stream, and when down-stream water is above its bottom. Where, as here, side and bottom contractions are completely suppressed, and the jet from the orifice is supported on the sides and bottom, Bernouilli's theorem gives a simple rational formula, so elementary that no demonstration is needed.

Following the author's notation, but splitting his coefficient of discharge into:

c_v = the coefficient of velocity;
c_c = the coefficient of top contraction; and

h_a = the head to be added to allow for velocity of approach $\left(\text{actually greater than } \frac{V^2}{2g}\right)$;

$$Q = c_v\, c_c\, d \sqrt{2\, g\, (d_1 + h_a - c_c\, d)}$$

The simplest case is that of a bellmouth orifice with c_c equal to unity. The writer has confirmed it in tests of a 6 by 3-in. orifice, under heads up to about 2.5 ft. Plotting the squares of discharges against the up-stream water level, the "curve" was a straight line which cut the axis of zero discharge at the level of the top of the orifice; the bellmouth used had a c_v of 0.975 over the range of heads tested.

In the sluices of the Assuan Dam‡ there is contraction, and c_c varies with the gate-opening, at any rate when the slightly belled tunnel opening comes into play with bigger openings. Discharge from the tunnels being freely into air, the head was measured to the center of the orifice, as in textbooks, and the resulting coefficient was found to vary with the head. At the writer's suggestion the rational formula was applied to the data, when the coefficient was found to be independent of the head, and the top contraction was calculated.

Where, as in the observations given by the author, the height of orifice is greater than the critical depth of flow, and probably also where it is only a little less than that depth, conditions are uncertain; they are even probably unstable, undergoing a slow pulsation.

† *Paper 97*, Panjab Eng. Congress, 1925.

‡ *Minutes of Proceedings*, Inst. C. E., Vol. CCXVI (1922-23), pp. 213 and 257.

The observations are too few for analysis; and it would seem that they are not full and certain enough to make analysis worth while. The author has measured his d_1 at the up-stream face of the gate, including banking up, and has still taken the whole velocity of approach into account. Velocities were so high that the difference between h_a and $\frac{V^2}{2g}$ would be appreciable.

A. P. FLOCKART,* ESQ. (by letter).—The structures described by Mr. Nimmo were designed and erected prior to the publication of information on hydraulic jump problems† by Julian Hinds, M. Am. Soc. C. E. It was intended that at full supply 450 cu. ft. per sec. should flow 5 ft. deep at 10 ft. per sec. through both wood and concrete flumes, no allowance being made for possible difference in hydraulic properties of the sections, nor for the obstruction caused by the gate stanchion. In operation, 410 cu. ft. per sec. ran 5 ft. deep in the wooden flume; it drew down through the transition to a depth of 3 ft. 6 in. just beyond the gate, and then gradually rose to normal depth some distance down the concrete flume. Experiments were then undertaken to determine what was causing the apparent throttling, with the result that the gate stanchion was ruled out, as also was the slight curve preceding the gate.

About 1920 the method of analysis by drawing the minimum energy line was introduced. This showed a hump at the end of the wooden flume section and also showed that the water levels down stream were not high enough to drown out this possible control, which, therefore, operated and caused a disturbance down stream. The throttling was thus caused solely by a change of shape of cross-section which has been avoided in the design for permanent works.

In Mr. Nimmo's proposed design, provision has been made for all the flow conditions that can be foreseen, and it is hoped that Equation (9) will prove to be accurate. There is a great need, however, for some simpler expression which will indicate the effect of altering the various factors without having to make a complete calculation. It would certainly be of interest to know the effect of sloping the floor of the pool from Station 150 to the outlet with the object of reducing the yardage of concrete.

The statement that the water surface becomes vertical when passing through the critical point is obviously not correct when, for instance, water passes over a broad-crested weir. An examination of Equation (11) shows that, at the critical point, not only does the value of $\frac{\Delta d}{\Delta x}$ take the values of plus and minus infinity, but that the equation itself becomes discontinuous. This would be illustrated if the equation could be integrated and a more general expression for the relation between d and x written.

It is possible, however, to integrate the expression graphically by plotting $\frac{\Delta x}{\Delta d}$ on d as abscissa, in which case the areas under the curve represent the

* Hydr. Engr., Hydro-Elec. Dept., Hobart, Tasmania.

† *Engineering News-Record*, 1920.

lengths of conduit between successive values of d, and so permit the surface curve to be drawn. This does away with the labor and uncertainty of "arithmetical integration", and permits both back-water curves and Equation (11) to be studied. The method is not applicable however, to Equation (9).

GEORGE M. BACON,* M. AM. SOC. C. E. (by letter).—This paper should command the interest of all engineers who have to deal with problems involving the distribution of water. All such engineers are constantly on the watch for, and seeking after, devices which shall be perfectly automatic in their action. In general, the big problem is to provide for the situation when everything is not going exactly as planned.

Past observations have long ago given the writer a definite suspicion that large volumes of flowing water fail to behave in accordance with any set of formulas. It would be interesting to see what results would be obtained from analyzing this problem on the basis of a thin sheet of water the lower surface of which was that bounded by horizontal lines extending across the flume from the lip of the spillway. This thin slab would naturally have the velocity of the water immediately below its lower bounding surface and the assumptions as to one would, in a measure, apply to the other. This slab could be considered as being acted upon by two forces, one representing the momentum of the water along the direction of the flume and the other a force represented by the slope, at right angles to the flume, which the upper surface of the slab must take in discharging water over the edge of the flume.

In Equation (1), how is the momentum that has just been mentioned taken care of? Independent of this case it is easy to see that this momentum might be sufficiently great to allow very little over-flow. A factor certainly should be taken into account covering the loss of momentum as the flow in the flume loses its velocity.

It is not entirely clear just how static pressures on the end areas can be compared, with no particular reference to the velocity involved or the force of gravity keeping up or modifying the velocity.

It would be extremely interesting to have the results of the experiment which the author states is fully described in his thesis presented to the University of Melbourne. These results would be extremely valuable if they indicated some definite relation between over-flow, capacity of flume, and length of over-flow, as calculated from the formula, and that found from actual experiment. It is obvious that if no particular limit is fixed for the length of the spillway all surplus water will be ultimately lost especially if reasonable provision can be had for a considerable length of flume in which the flow of water has a chance to become quite uniform and regular.

The results of experiments of this kind might have a distinct bearing on what could be considered the reverse of the present problem, namely, that of a spillway channel of a reservoir which was fed by the ordinary over-flow on a long crest, the channel being designed so as to carry away from the edge of this over-flow the water as fast as it is fed into the channel. This problem

* State Engr., Salt Lake City, Utah.

would not occur very often in actual practice as conditions usually admit of making such a channel sufficiently deep and steep so that the water in it will not become crowded and thus build up a back-water resistance.

W. H. R. Nimmo,* Assoc. M. Am. Soc. C. E. (by letter).—The writer is obliged to Mr. Lindley for drawing attention to the tests† which he has made and which apparently confirm the value of $c = 3.80$ for the weir shown in Fig. 6.

The equation given by Mr. Lindley is undoubtedly the rational form of expression for the discharge through an orifice of the type under consideration, but he is in error in stating that the writer measured his d_1 at the up-stream face of the gate, including banking up. The quantity, d_1, was measured 5 ft. up stream from the gate at a point where there was no visible banking up. As far as could be seen, banking up was confined to a small area of turbulence immediately against the gate. The writer did determine a coefficient from the formula,

$$Q = c_1 w d \sqrt{2 g \left(d_1 + \frac{V_1^2}{2 g} - d_2\right)}$$

and, if $h_a = \frac{V_1^2}{2 g}$ and $c_c = \frac{d_2}{d_1}$, then this formula is identical with that given by Mr. Lindley and $c_1 = c_v c_c$. For the four experiments with a vertical baffle (Table 2), the values of c_1 are 0.605, 0.597, 0.610, and 0.602, respectively. With the approximate methods of measurement adopted, it was not possible to determine the value of d_2 with great accuracy and, since the results of the experiments were to be applied directly to another orifice of the same type and dimensions, it was thought advisable to use the coefficient, c, which does not depend on the value of d_2. The measurements were not sufficiently precise to justify splitting the coefficient, c, into coefficients of velocity and contraction.

Mr. Flockart has described and explained the phenomena which take place at the existing gate at the entrance to the concrete flume. He is also correct in stating that the water surface does not actually become vertical when crossing the critical depth. Plotting $\frac{\Delta x}{\Delta d}$, as he proposes, provides a useful method of showing the water surface curve at points close to the critical depth, for which condition Equation (11) cannot be applied in practice.

Paper No. 1695

EMERGENCY DAM ON INNER NAVIGATION CANAL AT NEW ORLEANS, LOUISIANA*

By Henry Goldmark,† M. Am. Soc. C. E.

With Discussion by Messrs. F. R. Harris, R. H. Whitehead, R. O. Comer, W. J. Barden, Roger D. Black, Samuel McC. Young, T. B. Mönniche, and Henry Goldmark.

Synopsis

This paper is devoted primarily to a description of the so-called "emergency dam" in the Inner Navigation Canal at New Orleans, La., an important harbor work, completed in 1922. Such "emergency dams" are designed to shut off the flow of water through a lock, such as may occur when one of the lock-gates is struck by a vessel and seriously injured.

As the dam at New Orleans differs radically in its design from those previously built and has the merit of being lower in first cost and requiring a smaller operating force, a description of the work should be of interest to engineers. The paper first enumerates certain protective devices for preventing accidents to the gates, such as special guard gates, power capstans, and electric towing locomotives for controlling vessels in transit, and chain fenders for bringing them to a stop if improperly handled. A brief reference is then made to some emergency dams previously built, especially those in the Sault Ste. Marie and Panama Canals. Finally, a full description is given of the New Orleans Dam.

This design may be called the "stop-log" type, since the flow of water is checked by a number of transverse girders spanning the lock chamber, placed one above the other, like the stop-logs in hydraulic power plants. These gir-

* Presented at the meeting of December 7, 1927.
† Cons. Engr., New York, N. Y.

ders are lowered and raised by a hoisting engine carried on a revolving crane, similar in appearance to a railroad swing bridge. The several parts of the dam are described and illustrated.

Introduction

Although the risk of serious accidents in properly built and operated ship locks is very small, there are unquestionably certain dangers inherent in their use. Such accidents as do occur arise, in most cases, from injuries to the lock-gates when they are accidentally struck by vessels. Even if the damage to the gate is small, the repairs are difficult to make and certain to result in delays to traffic. If the gate is more seriously injured it is likely to be carried away by the rush of water; other gates may then be torn loose, and a heavy flow established from the upper to the lower pool.

Various safeguards are installed in locks to prevent vessels from striking the gates. The most common of these are duplicate lock-gates, the so-called "guard gates", placed above and below the ordinary operating gates to act as barriers to protect the latter from injury.

As a further measure of safety many large locks are fitted with power capstans for controlling vessels in transit. At Panama, however, all vessels are towed through the locks by special locomotives traveling on tracks laid on the lock walls. In this way the ships are kept under full control at all times.*

As an additional protection to the gates, heavy chain fenders stretched across the lock chambers have been installed in the approaches and upper chambers of the Panama Canal, and have also been in use for many years in a number of English harbors. When struck by a vessel, the chain pays off under a heavy braking strain, gradually bringing the ship to rest. At Panama, these fenders have proved their value in actual service.† In several instances, vessels, some of them of large size and moving at a fair rate of speed, were brought to a stop by the chain without injury to the vessel, fender, or lock-gate.

Besides such safeguards intended solely to prevent vessels from striking the gates, special devices have been installed in some locks for shutting off the flow of water if, in spite of these safeguards, one or more of the gates is seriously injured. However, such "emergency dams" are necessary only in exceptional cases. They are not required, for instance, in tidal locks, since in these there is slack-water at each period of high and low tide when the guard gates at the ends of the lock can be closed without trouble.

They are also superfluous where the pool above the lock is small, or where a series of locks is separated by short stretches of canal. In these cases the water above the lock can be readily drained off, so that a special dam is unnecessary.

When, however, the body of water above the lock is a large river or lake, unquestionably it should be possible to shut off the flow in case of an acci-

dent, to permit repairs to be made with reasonable promptness. In some cases it would be impracticable—in any event, very time-consuming—to improvise means for accomplishing this object after the accident had occurred.

Special "emergency" dams have been installed, therefore, in the canals at Sault Ste. Marie and Panama, and in some other waterways. The latest of such dams is that built in the Inner Navigation Canal, at New Orleans, which is the special subject of this paper. A brief reference to some of the older ones, however, may be of interest.

Early Emergency Dams

As far as is known to the writer the first "movable" or "emergency" dam installed in connection with a lock was designed by the late Alfred Noble, Past-President, Am. Soc. C. E., for the United States Canal at Sault Ste. Marie, Mich., about 1885. It was removed later when the canal was widened. Its general appearance was that of a railroad swing bridge revolving about a vertical pivot on the lock-wall. Along one of the arms a series of wicket girders was hinged by pins. After the dam had been turned across the lock, these girders were revolved in planes at right angles to the axis of the dam until their lower ends rested against a concrete sill. After the girders were thus put in place, the openings between them were successively closed by small wickets.

This gradual reduction in the cross-section of the flowing water is essential on account of the high velocity with which it moves. Such a principle is necessarily followed in all dams of whatever type.

At a later period, an emergency dam of quite similar design was built on the Canadian side of the St. Mary's River, also at Sault Ste. Marie. It is unique in having been actually tested under emergency conditions.

The accident, which occurred in June, 1909, was due to a vessel approaching the locks from below and striking the lower operating gates forcing them partly open and causing a heavy flow of water from the lock. At this time a vessel was in the lock and the upper gates were being closed. The heavy flow broke the fastenings of the upper and lower gates. Some of the leaves were torn entirely loose and others were badly damaged.

The vessel in the lock, the one in the lower approach, and a third one just above the lock were all carried away into the lower river, fortunately without loss of life. The flow of water was checked by closing the emergency dam, which was accomplished without serious difficulty. Figs. 1 to 4 show various phases of this accident.

In addition to these dams, which are all essentially of the same type, at least one other important structure of different design, but serving a similar purpose, should be mentioned. This is the "butterfly" dam on the Chicago Drainage Canal, which revolves about a vertical axis at one edge of the channel, the clear opening being 160 ft.

Panama Canal

When the plans for the Panama Canal were being matured, it was decided to adopt an emergency dam of the swing type with girders and wickets, quite

similar to the dams at the "Soo". This decision followed the recommendations of a Board of Army Engineers appointed some years before to study the general question of emergency dams.

The Panama dams,* six in all, are longer and heavier than any others. Great care was taken to make them perfect in all their details, so that their operation is smooth and rapid. The swing span is revolved and the girders and wickets are lowered and raised by separate electric motors.

New Orleans Inner Navigation Canal

This canal is situated in the lower part of the City of New Orleans and connects the Mississippi River and the tidal inlet known as Lake Pontchartrain.† Its primary purpose is to furnish an "inner harbor" of approximately constant depth, but it may ultimately provide an outlet to the Gulf of Mexico shorter and in other ways more desirable than the Lower Mississippi. The canal is 5 miles long, with a lock at its upper end close to the river in order to overcome the difference in elevation between the Mississippi and Lake Pontchartrain. Both sides of the canal between the lower end of the lock and the lake are to be lined with docks or piers, while it will also be possible to utilize the shores of Lake Pontchartrain for docking purposes. The canal has a bottom width of 150 ft. The lock is 75 ft. wide, with a depth of 30 ft. on the lock-sills and a maximum lift of 19 ft. (Fig. 5).

In case of serious accident to the lock-gates, a heavy flow of water would occur between the upper and lower levels, the maximum volume being computed to be in excess of 70 000 sec-ft.—about equal to one-third the total flow over the American and Canadian Falls, at Niagara. As a large part of the city below the lock, including important railroad yards, would be flooded in case of an accident, it was vital that the dam should be reliable beyond question and rapid in operation.

The emergency dams on the Panama Canal meet these requirements, but their cost was very high and a large number of attendants is required for their operation. It was thought possible that some other form of construction might be devised, which would be as efficient as the Panama dams but lower in first cost, and require a smaller operating force.

After several types had been considered, in addition to the standard swing-bridge design, it was suggested by Mr. R. O. Comer, Designing Engineer of the New Orleans Port Commission, that it might be possible to shut off the flow of water by a series of transverse girders, sliding in grooves in the side walls, like the "stop-logs" used in power plants. It would be necessary, of course, to provide suitable structural work and machinery for placing and removing the girders when operating the dam.

A careful study showed that a dam of this kind could be built—one that would be simple and reliable and cost decidedly less than the standard form used elsewhere. It was therefore adopted for construction (Fig. 6). At that

* The Panama dams are described in detail in a paper by their designer, T. B. Mönniche, M. Am. Soc. C. E., and published in *Transactions*, Inter. Eng. Cong., San Francisco, Calif., 1915 ("The Panama Canal"), Vol. II, No. 18.

† A brief description of the entire Inner Harbor Navigation Canal, by the writer, may be found in *Proceedings*, Brooklyn Engrs. Club, Vol. XXV, Pt. I (October, 1926), pp. 36–49.

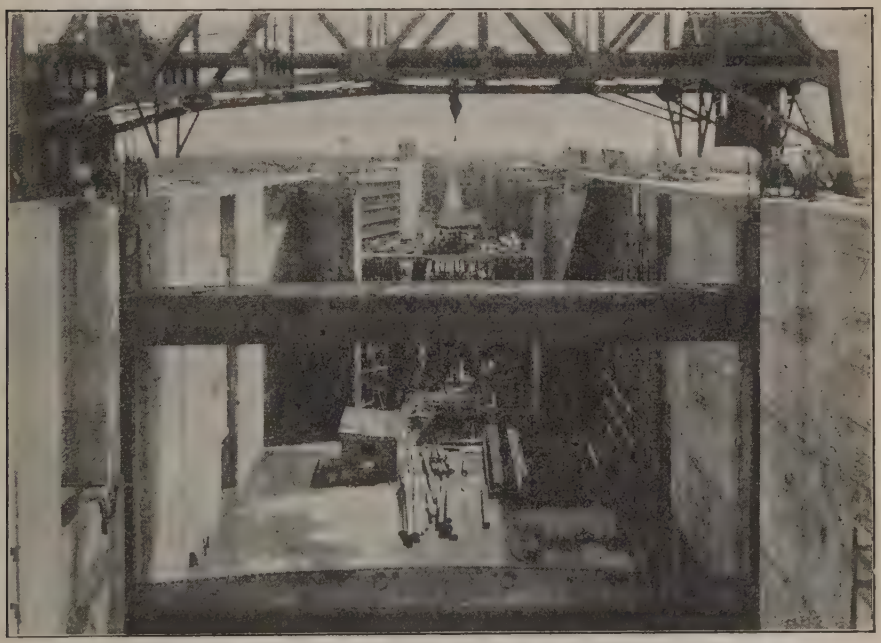

FIG. 6.—OPERATION OF EMERGENCY DAM, LOWERING STOP-LOG GIRDER FROM REVOLVING CRANE.

time the stop-log type of dam was believed to be entirely novel in lock construction, but it was afterward found that at least one dam of the kind had been built in Canada, on the Trent Canal, although on a much smaller scale, and with entirely different details.

General Features—New Orleans Dam

The general arrangement of the New Orleans Dam is given in Fig. 7, showing the ground plan, cross-sections, and end elevation. Various details of the structural work and mechanical parts are shown in other diagrams and photographs.

It will be seen that the stop-log girders are handled by a huge revolving crane or swing span, with its pivot on one of the lock-walls. Except when in use for closing the lock-opening, the girders rest on the top of the back-fill with their axes radial (Fig. 7). From these positions they are raised by the handling machinery, the swing span is revolved, and the girders are then placed one above the other, with their ends in the recesses in the side walls. This operation is reversed when they are being removed after they have served their purpose.

While the dam was built primarily for checking the flow of water in case of accident, the same girders are also used to form a coffer-dam at the upper or lower end of the lock when it is desired to pump it out completely and expose all the lock-gates for inspection, painting, and repair. When the girders are to be used at the lower end, they are lifted from their seats in the storage yard by the revolving crane and lowered into the water in the position indicated by the dotted outline in Fig. 7. They are then floated through the locks. Of course, it was necessary to add vertical seats for the girders at the lower end of the lock, and a simple form of hoist was also installed for raising and lowering them. These hoists are operated by two of the power capstans ordinarily used for handling vessels in transit. It will be seen that the additional expense entailed was quite moderate.

In order to give a clearer understanding of the construction and operation of the dam, it has seemed best to describe its various parts separately. They are:

I.—The Stop-Log Girders.
II.—The Swing Span, or Revolving Crane, with the Mechanism for Turning It.
III.—The Hoisting Machinery for Handling the Girders.

I.—The Stop-Log Girders

The girders are of box-form with plate-webs and side-plates (Fig. 8). There are eight girders in all. Six of them, which are used at the lower as well as the upper end of the lock, are designed so as to float when free from water. The other two are not adapted for floating. All the girders are 84 ft. long over-all, and 7 ft. 9⅛ in. wide horizontally at the center of the span. Their depth is about 6 ft. The weight of the heavy girders in the dry is

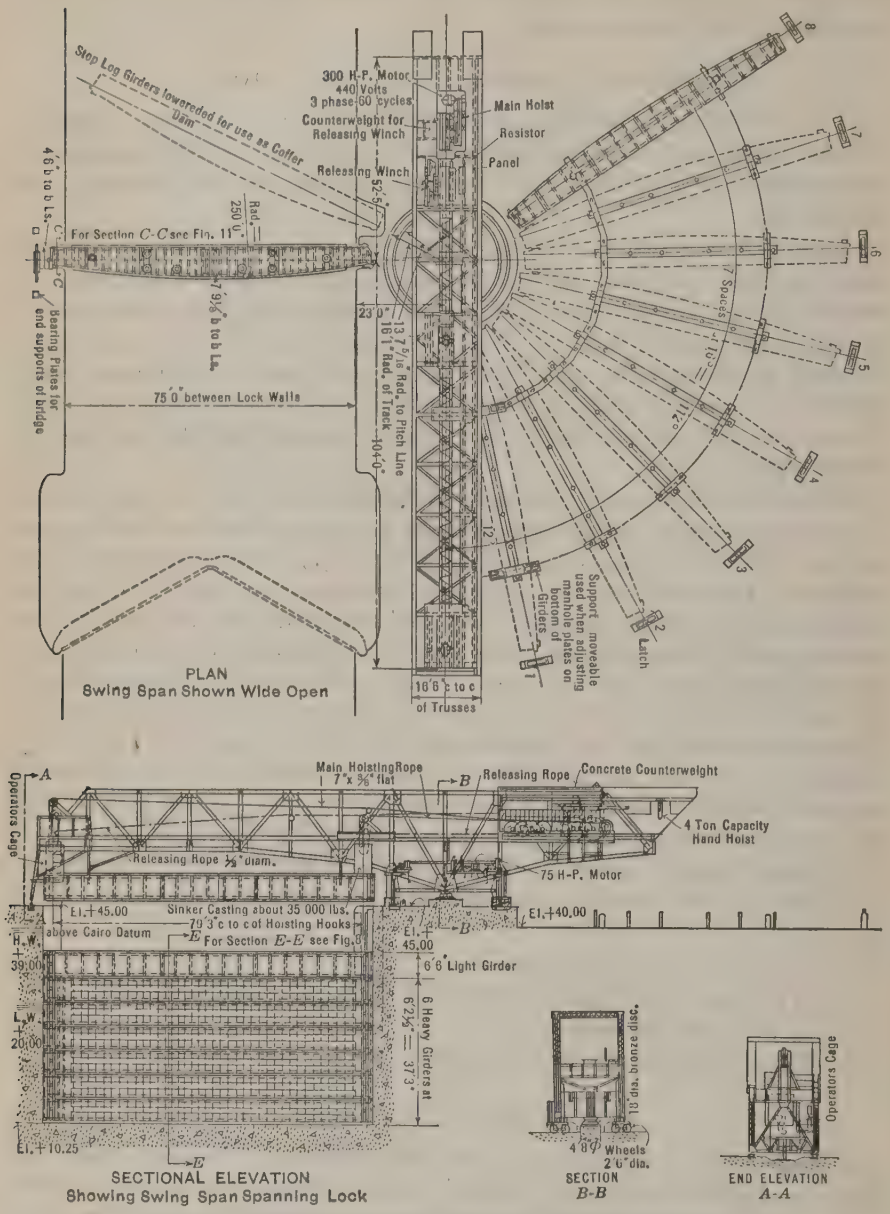

FIG. 7.—GENERAL PLAN, NEW ORLEANS EMERGENCY DAM.

174 000 lb. In these, both the web and side-plates are strengthened by closely spaced channel stiffeners.

When the lock is pumped out the girders are under maximum hydrostatic pressure, the water extending to the top on the upper face with no water on the lower side. While this maximum head will act only on the bottom girder, it was thought best to make all the "heavy" girders of identical construction to guard against errors in placing them.

When the girders are being lowered into place under emergency conditions —that is, when there is a flow of water through the lock—the horizontal pressures are a combination of the velocity head due to the flow and the static head at the various levels. The computation of the loads due to these conditions is quite involved. In this case, too, the worst possible conditions have been assumed.

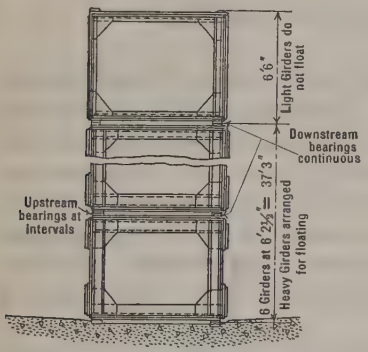

FIG. 8.—VERTICAL SECTION THROUGH STOP-LOG GIRDERS, SECTION *E-E* OF FIG. 7.

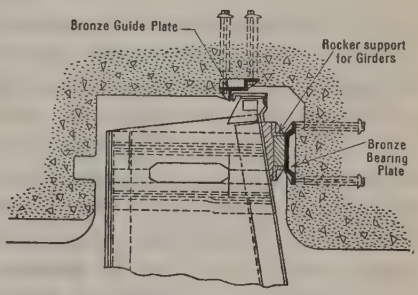

FIG. 9.—SECTION THROUGH SLOT IN WALL, SHOWING BEARING AND GUIDE-PLATES.

As noted, most of the girders are arranged for flotation, but when they are being lowered, they must be filled with water, to insure their sinking. This made it necessary to supply these girders with a sufficient number of openings fitted with adjustable covers. These openings also allow the water to flow out of the girders at a proper rate when they are being raised, thus guarding against an over-load in the hoisting machinery and excessive stresses in the stop-logs.

In operation, the heavy horizontal pressure exerted against the up-stream side of the girders produces frictional resistances between the bearings and the slots in the side walls. Much study was given to the proper design of these bearings, shown in Fig. 9. While roller bearings would have reduced the friction materially, it was thought best to avoid devices that were complicated and subject to corrosion in the brackish water of the lock. It would also have been necessary to provide separate means to insure water-tightness. The fixed bearings in the wall, therefore, were made continuous from top to bottom. They are of bronze at the upper, and of cast iron at the lower, end of the lock. The bearing plates on the several girders are of steel and are made as rockers revolving slightly about their vertical axes, to adjust themselves to

inequalities from errors in workmanship or from deflections of the girders under their loads. The fitting of these bearings has proved to be excellent; there is no leakage even when the lock is pumped out and the girder is under full hydrostatic head.

Water-tightness along the horizontal joints between the several girders and also between the lowest girder and the bottom of the lock chamber is insured by continuous metallic bearings along the down-stream flanges. These joints also have proved to be tight. At their ends, the girders are fitted with vertical steel channels. Similarly, continuous bronze guide-plates are fastened to the face of the concrete.

This description covers all parts of the stop-log girders, except some mechanical attachments, which may be described more properly in connection with the hoisting machinery.

II.—Swing Span, or Revolving Crane, with the Mechanism for Turning It

The structural work of the revolving crane has the general appearance of a railroad swing bridge with unequal arms. The longer arm is 104 ft. from the pivot to the end, the shorter, 52 ft. 5 in.; and the width between the centers of trusses is 16 ft. 6 in. All connections are riveted. There are the usual top and bottom lateral systems with transverse and diagonal members, besides the secondary structural parts that support the hoisting mechanism. At the end of the shorter arm is a heavy concrete counterweight. The span is carried in part on the central pivot and in part on wheels traveling on a circular track 32 ft. 2 in. in diameter.

The details of the pivot are shown in Fig. 10 and a diagrammatic view of the device for attaching the hoisting hooks in Fig. 11. The pivot has an upper disk of phosphor bronze, 18 in. in diameter, which turns with the span; and a lower disk of the same size made of forged steel, which is secured to a steel casting resting on the concrete (Fig. 10). The wheels that travel on the circular track are eight in number. Their diameters are 2 ft. 6 in. and the width of face is 5½ in. They have cast-steel centers and rolled-steel tires. The axles are 7 in. in diameter and turn in journals on four truck bodies of cast steel bolted to the lower side of the bridge truss.

The swing span is turned about the pivot by a system of gears operated by a 75 h. p., electric motor, the type of mechanism being that commonly used in draw-bridge machinery. The principal details are shown in Fig. 12.

Stresses in Truss Members and Reactions on Pivot and Truck Wheels.—The loads carried by the truss are: (1) The dead load, which consists of the structural steel, the machinery, the concrete counterweight, and various minor parts; and (2) the live load, that is, the heaviest stop-log girder.

The calculation of the stresses and reactions presented some interesting features differing from those met in similar structures. It was thought worth while, therefore, to include in this paper, a tabular statement of the stresses and reactions which occur under various cases of loading (Table 1) and a diagram (Fig. 13), giving an outline of the truss, together with the panel loads.

In Table 1 the make-up of the various members is given in Column (10). The size of the concrete counterweight (277 000 lb.) was computed to balance the whole dead load and one-half the live load so that the reaction against the truck at Panel Point 9 (Fig. 13) when the dead load alone is being carried should be exactly the same as the reaction at Panel Point 7 when the trusses also carry the live load. In the case under Column (5), Table 1, all

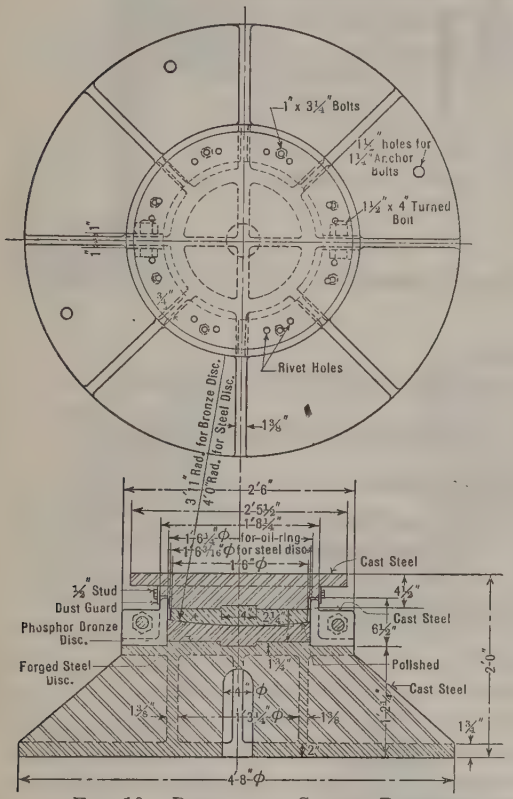

Fig. 10.—Details of Center Pivot.

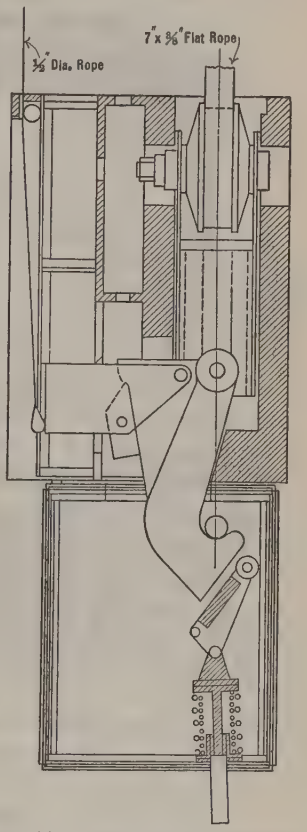

Fig. 11.—Sinker and Automatic Latch, Section *C-C* of Fig. 7.

the load ($D + \frac{1}{2} L$) is carried by the pivot, Panel Point 8. This condition prevails for an instant only while the girder (live load) is being picked up or set down by the hoisting machinery. The assumption in Columns (8) and (9), Table 1, corresponds to the girder containing 1.43 ft. of water, a condition that prevails for a few seconds when the girder is being drawn out of the water at a speed of 30 ft. per min. The details of the various loads carried by the trusses are given in Table 2.

In the computations, both arms of the truss were taken as cantilevers, as this condition will prevail practically at all times. It was deemed best, however, to fix the end of the long arm vertically when the truss has been swung

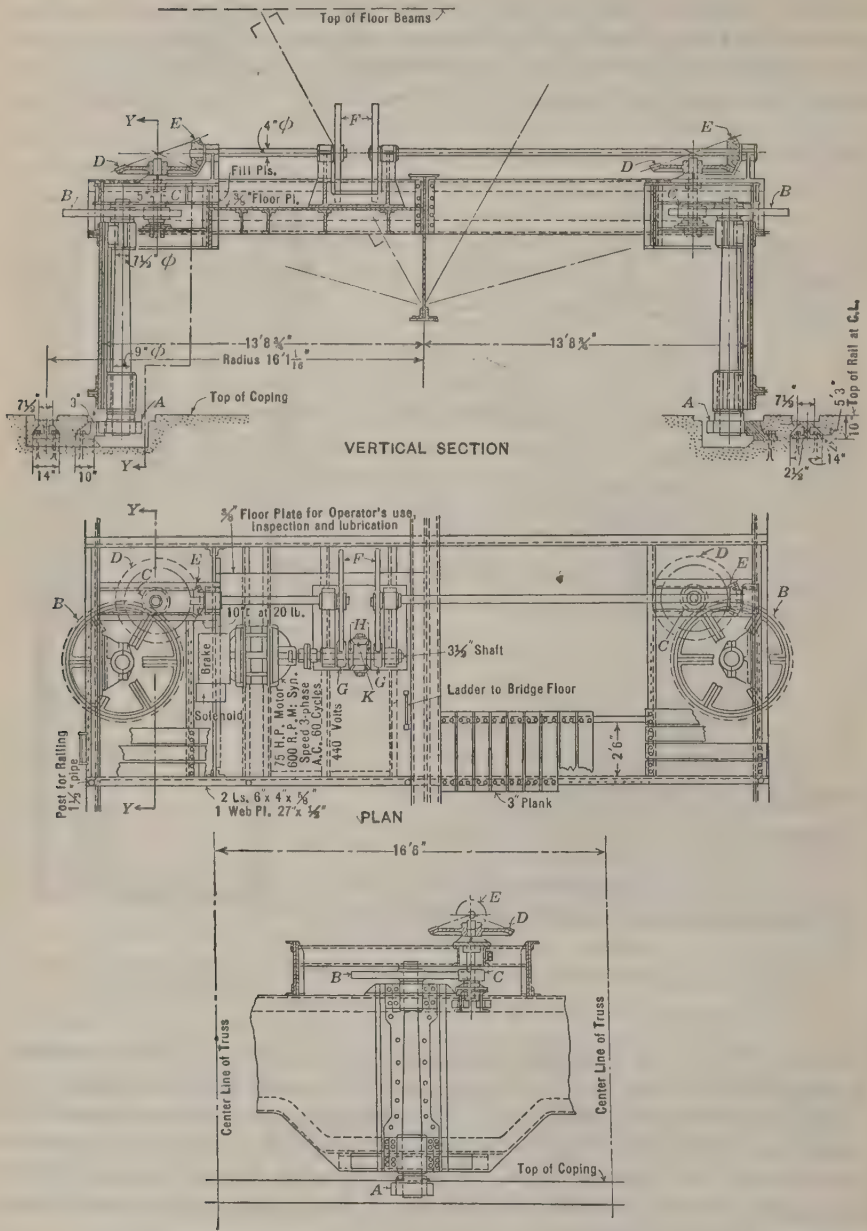

FIG. 12.—DETAILS OF MACHINERY FOR TURNING BRIDGE.

across the lock and the girders are being raised or lowered. A braced framework, therefore, was attached to the truss at Panel Point 0, so that the end of the truss can be slightly raised by a screw-jack attached to the framing. Under these conditions, a small part of the dead and live loads is supported by the side wall, but the stresses in the truss are only slightly changed (Fig. 7).

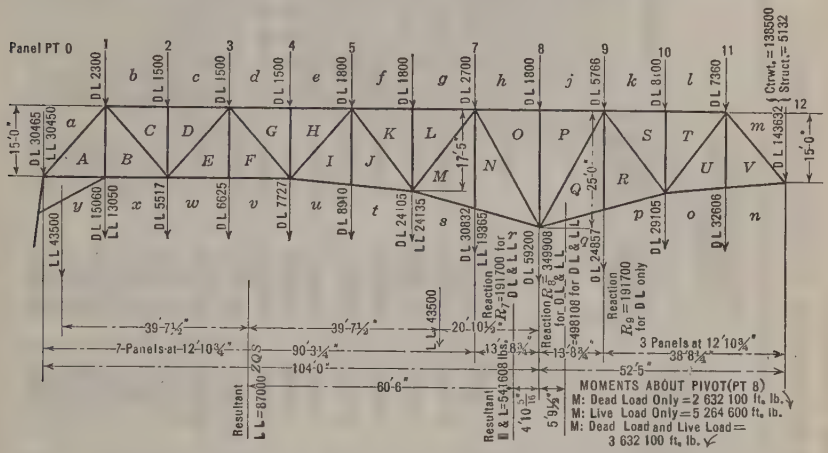

FIG. 13.—DIAGRAM OF TRUSS. GOVERNING STRESSES IN VARIOUS MEMBERS FOR ONE TRUSS ARE SHOWN IN TABLE 1.

III.—THE HOISTING MACHINERY FOR HANDLING THE GIRDERS

The hoisting machinery includes not only the hoisting engine proper, but also the cables with their sheaves, the so-called "sinker castings," the hooks for lifting the girders, and certain devices for detaching the hooks from the girders, after the latter have been lowered into place. These last devices are important features of the dam. Their design proved to be quite difficult.

The general arrangement of the machinery is given in Fig. 7, while Fig. 14 shows the hoisting engine on a larger scale, as well as an outline of the electric apparatus connected with it. It also shows a small hand-operated winding engine forming a part of the machinery used in detaching the hooks. The details of these two engines were developed by the contractor for the hoisting machinery.

The two main hoisting cables consist of 7-in. by ⅜-in., flat, steel ropes. One end of each rope is wound about a separate drum in the hoisting engine, the two drums being connected by gearing and driven by a single 300 h. p. electric motor. The other end of the rope passes around three 30-in. sheaves, multiplying the lifting power threefold, and connects with the massive hook from which one end of the girder is suspended. The journals for two of these sheaves, at each end of the truss, are bolted firmly to the structural work, while the third sheave moves up and down as the hook is raised or lowered. A bight of the flat rope makes a half-turn about this sheave, while the end of the rope is fastened to a clevis through which the axle of the sheave passes. From the same axle a riveted structural frame is hung, to which the hook for suspending the girders is connected. (See Figs. 11 and 15.)

Sinker Castings.—The "sinker castings" are two massive blocks of cast iron (each weighing about 35 000 lb.), which are suspended from the axles of the movable sheaves just mentioned. They are shown on a small scale in Figs. 7 and 11, and in greater detail in Fig. 15. They may also be observed in the photograph, Fig. 6.

TABLE 2.—Loads Carried by Trusses, in Pounds.

Loads.		Two trusses.	One truss.
Dead load:			
Structural steel		339 174	169 587
Castings and turning machinery		58 392	29 196
Concrete and windows in machinery room		50 200	25 100
Creosoted timber in footwalks, etc.		10 919	5 460
Hoisting machinery proper	75 450		
Sheaves and brackets	12 100	173 530	86 765
Sinkers and hooks	86 000		
		632 215	316 108
Concrete counterweight		277 000	138 500
Total dead load		909 215	454 608
Live load:			
One stop-log girder in dry		174 000	87 000
Total dead and live load		1 083 215	541 608

The purpose of the "sinker castings" is to increase the weight, thus tending to overcome the frictional resistances when the girders are being lowered in their recesses. This is of special importance in an emergency, when the flow of water through the lock produces lateral forces, increasing the friction. In order to utilize their extra weight, the sinkers, of course, must rest directly on the top of the girders when the latter are being lowered. This was insured (as may be seen in Figs. 11 and 15), by giving an oblong shape to the holes in the castings, through which the axles of the "movable sheaves" pass.

It will also be seen that the structural member from which the hook is suspended passes directly through the sinker casting, and that certain mechanical details, forming a part of the mechanism for detaching the hooks, are fastened to the sinkers.

Attaching of Hooks.—The hooks for supporting the girders when they are being raised or lowered (Fig. 15) are of forged nickel steel and are suspended from pins 5 in. in diameter in a riveted frame within the sinker casting. When carrying their load these hooks engage $6\frac{1}{2}$-in. pins fastened to the inside of the girders. The center lines of the upper and lower pins, when the hooks are attached, are in a vertical plane passing through the center of gravity of the girder, which therefore hangs vertically.

The hook is entered and withdrawn from the girder through a slot 7 in. wide and 2 ft. 3 in. long in the top plate of the girder. As may be seen from Fig. 16, the position of this slot and the shape of the hook are such that the

latter, when lowered, will be deflected sidewise and enter the slot. On being lowered farther inside the girder, the hook swings back to a vertical position, and then, upon being raised, engages the hoisting pin.

Detaching of Hooks.—In order to detach the hooks this process is reversed. They are first lowered slightly to clear the hoisting pin, then deflected sidewise, and, finally, raised through the slot in the top plate of the girder. A separate mechanism is required to give the lateral deflection to the hook.

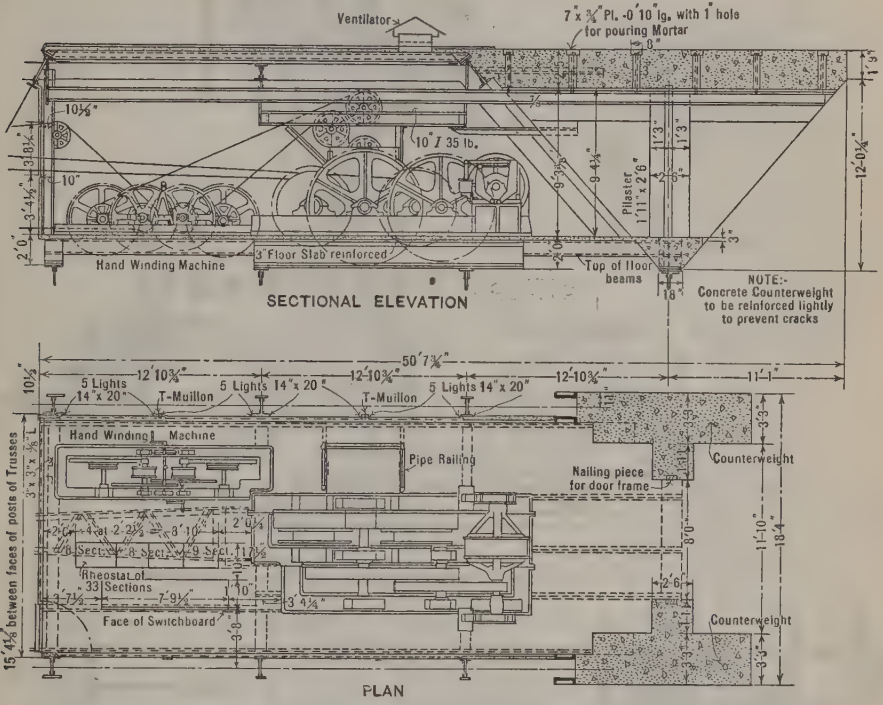

FIG. 14.—PLAN OF MACHINERY HOUSE AND COUNTERWEIGHT, EMERGENCY DAM, INNER HARBOR NAVIGATION CANAL.

Two devices are provided for this purpose. The first of these is the spring shown in detail in Fig. 16. It forms a permanent part of each girder. A stem projecting from the bottom plate near the end of the girder is forced upward when the girder becomes seated, compressing the spring, so that its thrust is transmitted through a bell-crank lever and the hook is pushed sidewise. This device, which operates automatically, comes into play after the girders have been deposited in the recesses in the side walls to shut off the flow of water through the lock or to permit its unwatering.

In this case, the ends of the girders come to a solid bearing on the floor, or on the girder next below, and the projecting stem is forced upward. The automatic spring device cannot be used when the girders are placed on their seats in the storage yard, since under these conditions the ends of the girders will project beyond the supports. Similarly, of course, it cannot be used when

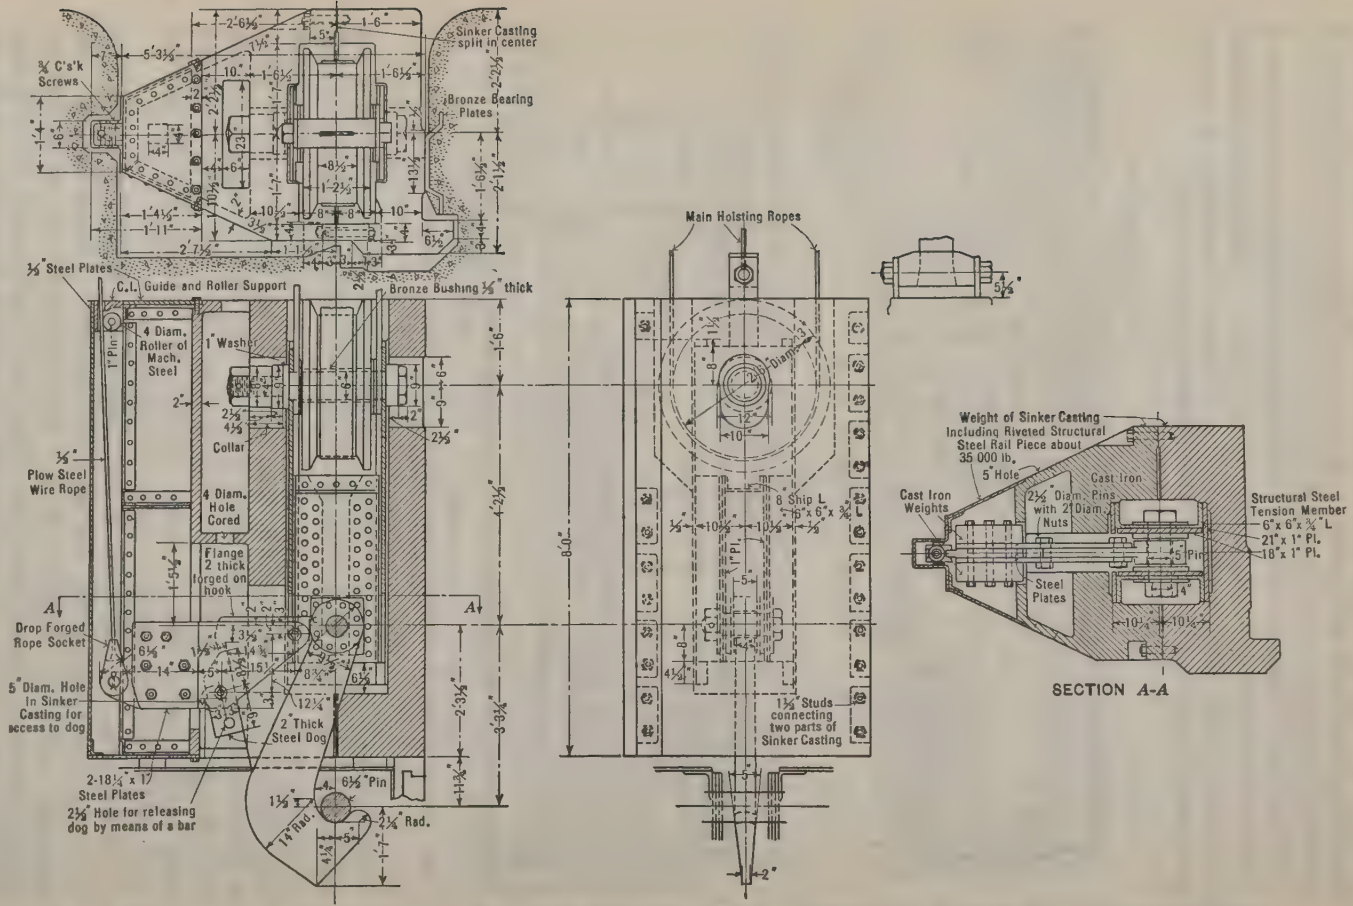

FIG. 15.—DETAILS OF SINKER CASTING, HOOK, AND RELEASING DEVICE, EMERGENCY DAM, INNER HARBOR NAVIGATION CANAL.

the girders are lowered into the water of the lock to be floated to the lower end for use as a coffer-dam. For service in the last two cases, a hand-operated mechanism has been provided. This device is shown in Figs. 11 and 15. Its essential feature is a lever hinged to the vertical flange on the hook and

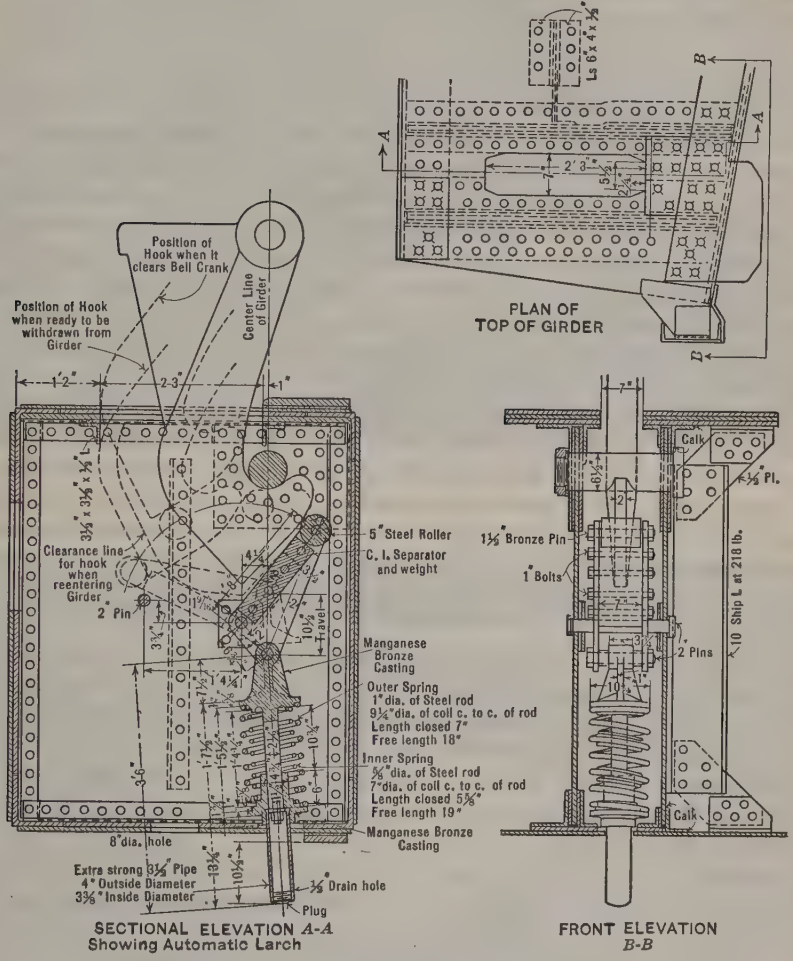

FIG. 16.—DETAILS OF AUTOMATIC LATCH.

operated by a ½-in. wire rope connected to the hand-winding machine on the short end of the truss (Fig. 14). This lever deflects the hook by bearing against its horizontal ribs so that it can be hoisted through the oblong hole in the top plate.

In order to prevent interference between the two devices for giving the horizontal displacement, and to guard against accidents in lowering the girder, the second device is designed so that it will operate only when a 2-in.

block of steel, called "the dog," is in place. When the spring mechanism is relied on to deflect the hook, this dog is released before attaching the hook to the girder, making the hand-operated device inoperative. If, now, in lowering the girder one end becomes wedged in the recess and, at the same time, the ½-in. rope breaks, there will be no danger of the hook becoming detached and allowing the girder to fall.

Operation of the Dam

The motors for revolving the draw-span and for raising and lowering the girders are operated from a small enclosed cab or platform suspended from the truss near the end of the long arm (Fig. 17). This position of the cab enables the attendant to get an unobstructed view of the storage yard and of the girders when they are being swung into position and lowered. All the principal operations are under the control of one man, although a few others are required in the storage yard and on the lock walls. However, this does not mean any addition to the ordinary lock force. Fig. 17 shows the completed draw from above, while Fig. 18 is a view of the dam from the lock floor below.

Experience has shown that it requires 7 min., on the average, to pick up a girder in the storage yard and lower it into the lock recesses, and 12 min. to raise it from the lock and replace it on the back-fill. For the complete set of eight girders these figures correspond to cycles of 1 hour and 1½ hours respectively, or about the same time in each case as that required for operating the Panama dams.

Comparative Costs

As already stated, the New Orleans Dam has the merit of being lower in first cost than structures serving the same purpose previously built. Comparisons of this kind are difficult, owing to differences in the dimensions of various works and the conditions under which they were built.

However, the depth is almost identical in the New Orleans Lock and several of those at Panama, so that it seems worth while to quote the cost of each from the records.

Panama Canal.—In the Gatun and Pedro Miguel Locks, in which the lock chamber is 54.7 ft. deep and 110 ft. wide, with a cross-section of 6 017 sq. ft., the costs were:

Total	$432 475.10
Per square foot	72.00

New Orleans Canal.—In this canal, the lock-chamber is 55 ft. deep and 75 ft. wide, with a cross-section of 4 125 sq. ft., and the costs were:

Total	$353 523.68
Per square foot	85.70

The Panama work was done about 1912, at which time the cost of structural steel was unusually low, while the New Orleans Dam was built under World War conditions, the labor and material at this site being fully twice

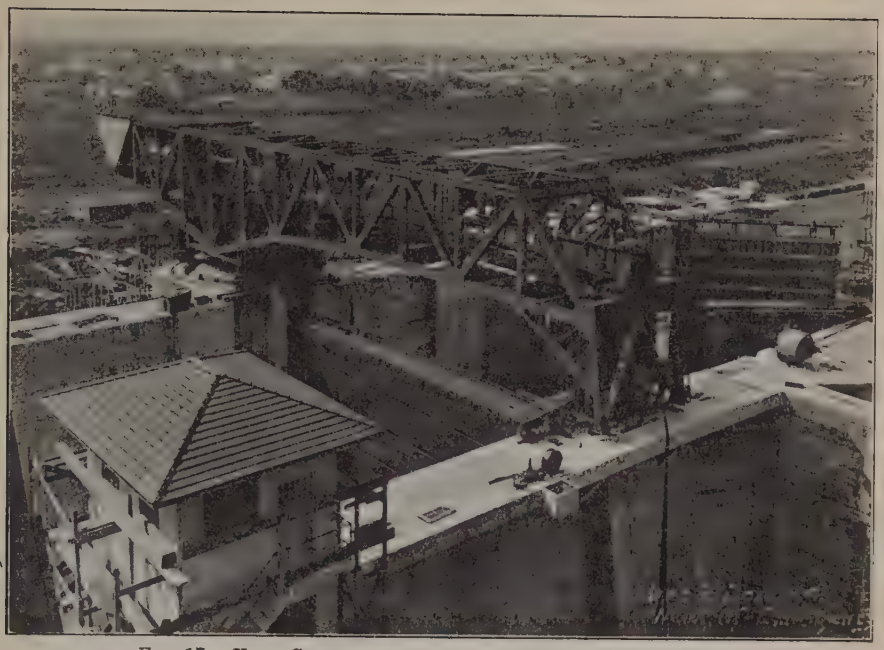

FIG. 17.—VIEW SHOWING EMERGENCY DAM IN TRIAL OPERATION.

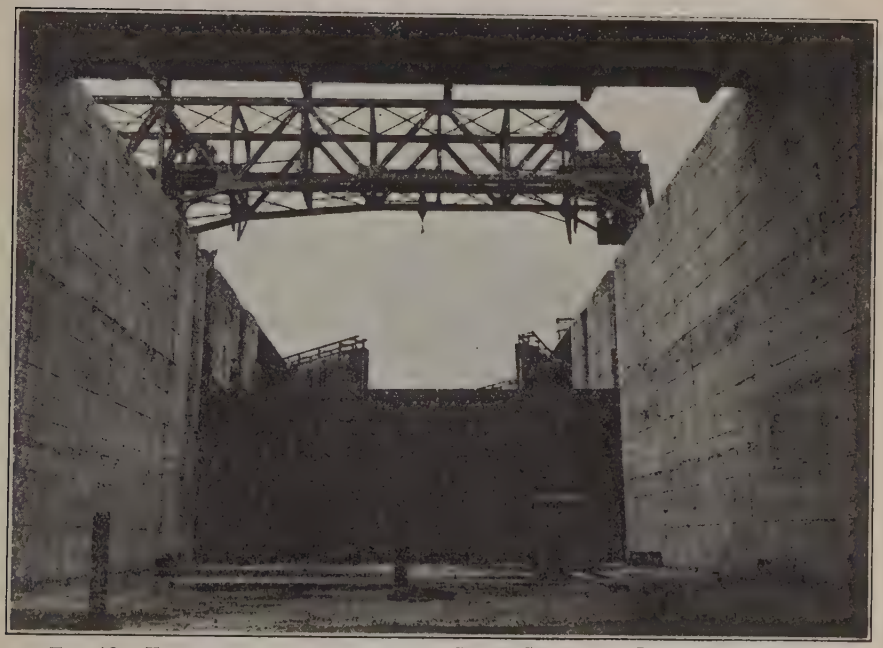

FIG. 18.—VIEW OF EMERGENCY DAM AND SWING SPAN FROM LOCK FLOOR BELOW.

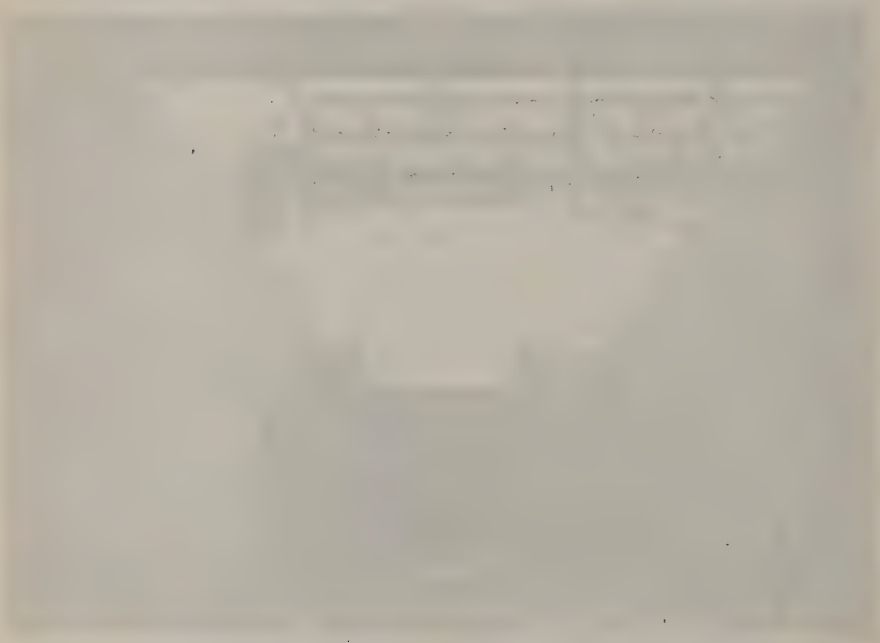

as high as at Panama in 1912. It seems reasonable, therefore, to ascribe the small increase (about 20%) in the cost per square foot of lock opening at New Orleans, mainly to the more economical type of design.

Contractors and Personnel

The material for the emergency dam, with the exception of the concrete counterweight and some minor parts, was furnished by the following contractors:

Swing span, including turning machinery.Bethlehem Steel Bridge Corporation
Stop-log girders.....McClintic-Marshall Company
Hoisting machinery.....Wellman-Seaver-Morgan Company

The structural work was divided between two firms in order to expedite the work which was begun during the World War, its speedy completion being important from a military standpoint.

The Consulting Engineers for the Inner Navigation Canal were George W. Goethals and Company, the writer being retained by the Commission of the Port of New Orleans to prepare the designs for the structural, mechanical, and electrical equipment of the lock. All plans for this part of the work were made in his office. Special credit should be given to F. E. Sterns, M. Am. Soc. C. E., his Principal Assistant.

DISCUSSION

F. R. Harris,* M. Am. Soc. C. E.—This is a very interesting contribution to the very little that has been written on this subject. Such structures are not only necessary and an insurance against possible very serious damage to locks, amounting in some cases even to their entire destruction, but they are an adjunct necessary to enable periodic unwatering and inspection, together with the necessary repair and maintenance work involved.

The stop-log emergency dam and canal lock is new to the speaker. Mr. Goldmark states that at an earlier period an emergency dam was built on the Canadian side of the St. Mary's River, and that it was actually tested under emergency conditions. The views, Figs. 1 and 2, of the accident are very interesting.

However, the feature of making steel girder stop-logs capable of being floated to any location is a novel one. The speaker is not sure that he entirely understands how water is admitted to them to overcome their buoyancy when lowered into position. That is, whether this is an automatic device or a special hand preparation. It would seem that when lifting them from the water, unless the openings are very large to permit the interior water to be discharged, great care would have to be exercised so as not to strain the lifting truss or the hoisting mechanism, unless, of course, the designer had provided for this by additional strength for the additional weight of water.

The speaker would anticipate some difficulty in securing and maintaining water-tightness of the box girders. He does not know whether these have been provided with caulking edges and caulked, or whether the water-tightness is dependent on gaskets. In either case, when these stop-logs have been subjected to load and consequent deflection, it would seem that the joints would start leaking. It would be interesting to know what experience had revealed in this line.

The author's hooking and unlatching device is very ingenious and would require careful attention so that corrosion may not occur and interfere with its operation. This apparatus, which is principally for emergency use, may lie unused for long periods, and the temptation is to neglect proper inspection and upkeep. When the emergency arises the apparatus is often not in proper condition. There is no way to overcome this except to insist on periodic use and placing of the apparatus for inspection purposes, whether it is or is not actually required. Unless something of this kind is done, it is either not on hand or not in usable condition when required.

The speaker has used similar stop-log dams, although of much smaller dimensions, in the discharge culverts of dry docks. Their purpose in this case is a somewhat similar one. They are provided for use in the event of the breakage of a sluice-gate or gate-valve, in order to prevent reverse flow of the water and back-race of pump impellers, together with the incident flooding when flooding is not desired. Also, they are used as an emergency dam to permit inspection and repair of discharge culverts and chambers. As

* Rear-Admiral, U. S. N. (*Retired*); Cons. Engr., New York, N. Y.

they are much smaller, with less head and span, they are much simpler and can be improvised. The speaker has had several experiences of deciding to use them and then, after specifying them, making the discovery that they could no longer be found. The Dock Master had gotten tired of seeing them lying around so long and not being used and had sent them to the scrap heap or had broken them up and used the material for other purposes.

It would be interesting to know something about the extent of leakage in horizontal joints between abutting girders or stop-logs. The leakage in this type of emergency dam cannot, presumably, be greater than that at Panama. On the other hand, when considering this type of dam as compared to the type of emergency dam at Panama, attention must be given to the greater span of the Panama locks and the consequent greater depth of girder (horizontally), greater bending moment, and consequent greater weight.

Considering the theoretical design of an emergency dam a series of horizontal beams, such as Mr. Goldmark has evolved, will have to be computed to take the entire water pressure. In general, the steel required and the cost would bear a direct relation to the width of the opening and the depth (horizontally) of the beams. In the case of the Panama emergency lock, there is one horizontal girder at the top having a span the full width of the opening. The sum of the reactions received by it from the vertical members, or beams, will equal one-third the water pressure, the remaining two-thirds being taken by the sill. Likewise, for the vertical beams, in turn, since the maximum moment will be at a point about one-third the distance from the bottom (all other factors being equal), the steel structure, on the basis of the Panama design, will have to take care of only two-thirds of the water pressure as compared with all the water pressure for a stop-log dam. It is, of course, very probable that the details in the Panama design, as compared to the relative simplicity in the stop-log design, might more than make up this difference, although in comparing costs with the New Orleans costs—attempting to equalize the difference on account of the conditions existing at the different times of construction—the greater depth and span, in the case of Panama, should generally result in higher cost.

It is difficult to compare the costs of a design completed before the World War, with one made under existing conditions, because the cost of labor and materials is so much higher.

Going back again to the question of water-tightness for flotation purposes, it has occurred to the speaker that in the long span of 75 ft. there would necessarily be some deflection due to water pressure. What effect would this have on water-tightness, especially after continued repetition of deflections? The matter of water-tightness is of considerable importance in considering the stability of these box girders because they are at times a floating structure, and it is evident that, when so floating, the center of gravity is above the center of buoyancy, giving a type of stability dependent entirely on the righting effect, which is computable in terms of moment of inertia of the water plane of flotation. Any water in the girder, due to leakage, for example, would cause it to careen, with consequent instability and a tendency to

roll over on the side. If this does occur, and it will occur with leakage, there will be some difficulty in attaching the lifting hooks. The speaker would like to inquire if anything like this happened.

The paper was also not very clear as to whether the process of flooding the gates and making them water-tight was automatic or whether it was a hand operation. At one time it is stated that they are arranged so as to freely take water in order that they can be lowered and at another time that they must be water-tight.

As an alternate suggestion to prevent leakage in horizontal joints, the speaker recommends making the meeting surfaces of a soft wood, such as white pine. The Federal Government has been very successful in using that material instead of rubber gaskets for meeting surfaces of gates.

R. H. WHITEHEAD,* ESQ. (by letter).—The Panama Canal type of dam is an emergency dam, pure and simple. The stop-log type described by Mr. Goldmark has the merit of not only being ready as an emergency dam, but the girders used take the place of the very expensive floating caisson of the Panama Canal. If the latter type of emergency dam had been used in the Inner Navigation Canal at New Orleans, it would have been necessary to supplement it with a floating caisson for overhauling the lock-gates at the upper and lower ends of the locks, assuming that the operating policy was to guard the equipment against deterioration. From the standpoint of simplicity, there is no doubt that the stop-log type is simpler than the Panama type; but the writer does not regard this of very great importance, because it is the business of the operating force in charge to master any details of operation and to be ready to respond with efficiency to any emergency. However, when it comes to maintenance, the Panama Canal type requires more careful maintenance to keep it in a high state of efficiency, and this is expensive and demands close supervision.

The choice of types of dams, either the stop-log or the Panama Canal type, depends on the size of the opening to be closed. The writer does not believe that the stop-log type, while it seems to be a very good type for New Orleans, would be the correct type to use at Panama. The importance of the Panama route makes expense secondary and of minor importance, and speed of operation in an emergency of major importance.

Mr. Goldmark states that it requires 1 hour to put the Panama Canal in position. On the contrary, from the time the emergency occurs it requires, at a maximum, only ½ hour. It takes an hour to put the smaller New Orleans Dam in position, and it is evident by considering the designs that, basically, the Panama Canal type is a faster one to operate. It is true that it was originally expected that an hour would be required to put the Panama Canal Dam in position, but the operating force, by the proper indexing of the clutches required for handling the gates in storage, and by proper training, has reduced this time by half.

The Panama Canal type of dam is safer for Panama than the stop-log type, because the area is blocked off by separate independent units in a vertical plane rather than separate dependent units in a horizontal plane.

* Vice-Pres. and Gen. Mgr., The New Haven Clock Co., New Haven, Conn.

In regard to Mr. Goldmark's method of calculating the cost on a square-foot basis and comparing the two types, it would probably be a better comparison if the two dams were calculated on a tonnage basis, because after all is said and done, if the New Orleans type of dam, which is 75 ft. wide, was built to cover a width of 110 ft., such as in Panama, the cost per square foot would mount up much more rapidly than in direct proportion to the relative areas. In calculating on a pound basis, it would be found on certain sizes of openings that the Panama Canal dam, considered simply as a dam, is cheaper when the area becomes sufficiently large, than the stop-log type, and *vice versa.* As the area becomes smaller from a critical amount, the stop-log type will show more and more economy. There appears little doubt but that the stop-log type is the correct one for New Orleans and that the Panama Canal type is the best for locks of their size.

The writer wishes to pay tribute to the author. The operating force of the Panama Canal has always looked on the lock-gates that Mr. Goldmark designed and that the McClintic-Marshall Company built as the greatest single engineering achievement of the Panama Canal.

R. O. Comer,* Esq. (by letter).—The author has presented an interesting and valuable summation of the efforts that have been made to devise machinery to check the uncontrolled flow of water in locks and other large channels. Furthermore, he has given a specific and accurate description of how this has been done in a relatively cheap, simple, and effective way.

Devices of this kind are few in number and the cases are fewer still where these devices have been put to use under emergency conditions. The time is probably quite remote when any considerable amount of data will be derived from lock accidents. The designer in this problem is obliged, therefore, to visualize every possible mechanical weakness or defect and to provide against an extended chain of events in a calamity which he, in all probability, will never see.

In comparing the stop-log type of dam and the wicket-girder type, the writer's remarks are based on observations made on the Panama dams and the New Orleans Dam in each case. The stop-log type of dam is favored over the wicket type, under the conditions ordinarily met with in lock design, for the following reasons:

1.—The bridge, in the general design and in the details, is simpler. The hoisting machinery is likewise more simple. On the other hand, the wicket girder dam is a very complicated machine both structurally and mechanically.

2.—The cost, as shown by Mr. Goldmark, is less.

3.—The time necessary for planning, fabrication, and erection, is less.

4.—The maintenance should be less. There are relatively few parts in the stop-log girder type of dam to get out of order. The details are generally simple and rugged and, with few exceptions, all parts are readily accessible for painting, inspection, and repair. However, as far as accessibility is concerned, there is little choice between the two types.

5.—The number of men required for operation is less. The stop-log girder dam is a one-man operated machine in the emergency case. No great amount

* Syracuse, N. Y.

of skill is required. On the other hand, the wicket-girder dam seems to require a crew of about fourteen or fifteen well-trained men for good results.

6.—The stop-log girders can be adopted for use as a lock caisson with small extra expense.

7.—The weight of the loaded bridge under the same conditions will no doubt be less, since only a part of the dam proper is carried at one time. This was no small advantage at New Orleans because of the low bearing value of the soil and because of the fact that the dam and its foundation necessarily formed an unfavorably located concentrated load on one wall of the lock.

8.—The leakage rate is a great deal less. At the time of the test at New Orleans, full head was artificially created on the up-stream face by pumping the forebay full of water to approximately the 1922 high-water mark. The entire down-stream face was bared by pumping. Under these conditions, the leakage was so small that no one thought it worth while to go to the trouble of measuring it. It was thought at the time that between 100 and 200 gal. per min. would account for all of it. The leakage was confined almost entirely to a number of open spaces in the steel horizontal sealing strips between the upper girders. The strips of the lower girders appeared absolutely tight, very likely because of the superimposed weight of the upper girders. The vertical seals in the lock walls were likewise quite tight, not only because of good workmanship, but because of the large unit pressures on the sealing surfaces. Before the test, when the girders were piled up across the lock in the dry, the joints were inspected for tightness by noting the amount of light coming through and testing the openings with strips of thin flat steel. There were only a very few places that showed more than 0.02-in. opening. It is recalled that perhaps 50 or 60% of the length of the seals showed no light coming through at all. Under the heat of the sun, the upper girders would be bowed up so that they had a bearing only at the ends.

The steel sealing strips were made in short sections to conform with the down-stream curved outlines of the girders. The strips were fitted with adjusting or leveling screws and were backed up with Babbitt metal. Obviously, this construction made for accuracy.

It can be readily appreciated that the workmanship in lining up the sealing strips was unusually good. The records show that the leakage under a similar test at Panama was 950 cu. ft. per sec. This can be regarded as a practicable minimum for the wicket-girder type of dam. No particular effort was made at the time of the New Orleans test to treat the sealing surfaces. There was the usual coat of slush oil on them which had been applied some weeks previously. The girders for the purposes intended can be pronounced tight. It seems that the degree of tightness stated is about the best it is practicable to secure using sealing strips of steel. If in future work a greater degree of tightness is desired, the design of the seals very likely can be changed. However, some sacrifice in durability would no doubt have to be made.

9.—It is obvious that the most essential requirement of an emergency dam is certainty of action. In the wicket-girder type the multiplicity of relatively small leaves with numerous sliding surfaces offer an opportunity for jamming. The leaves at Panama jammed on some occasions during rou-

tine drills, at least in the earlier days of operation. The one instance of emergency operation, cited by Mr. Goldmark, at Sault Ste. Marie, was not an unqualified success, since it is understood that improvised wood closures had to be made, because some of the leaves had failed to go down. The degree of closure, even then, was not sufficient to admit closing a pair of gates on the leakage current without danger.

The dam at New Orleans was placed in service after remarkably few adjustments. It has been operated once each month, as a matter of routine, since 1923. There is no knowledge of any failure to function. The great weight and strength of the vital parts should be much in its favor in an emergency. The chances for sticking have been reduced to the simplest number of surfaces, namely, two. Jamming, due to "drawer action", has been eliminated by the design. The operation of the New Orleans Dam is more largely automatic than is the case at Panama. The personal factors affecting the emergency operation have been reduced by having only one operator.

The duties of the operator are simply the ordinary duties of a crane man. The principal thing to look out for is to see that, after landing the girders below water, he slacks off on the hoist far enough to allow the unlatching mechanism at both ends to function. There is a possibility that if this is not done, he may have released one end of the girder and not the other. If, under these conditions, the girder is hoisted, it may be swept out of the slots on the lock walls and defeat the purpose of the entire investment. The hoist is so powerful that an inexperienced operator, during routine operation, has some difficulty in sensing whether he has only the sinker casting or the sinker casting plus one end of the girder on a hook. The water has a high turbidity and nothing can be seen below the surface.

The New Orleans dam cannot be operated by hand. It is, therefore, exposed to the danger of an interruption in the power supply. The stop-log girders were shop-fabricated at Pottstown, Pa., and were sent completely assembled to New Orleans by rail.

W. J. Barden,* M. Am. Soc. C. E.—As stated by Mr. Goldmark, the risk of serious accidents to properly constructed and operated locks is in general small, but there is always the inherent danger of a ship striking and injuring the gates with consequent serious damage. Provisions against such accidents are all matters of insurance and, like any other insurance, cost money and are, therefore, used to such extent only as the circumstances in each case appear to justify.

Emergency dams, as Mr. Goldmark states, are not essentially protective devices, but a means by which damage done by the breakage of lock-gates and the consequent flow of water through the lock may be minimized by stopping the flow more quickly than could otherwise be done. The emergency dam designed by him and constructed at the New Orleans Inner Navigation Canal is a new application, on a much larger scale than had ever before been undertaken, of the simple stop-log method of closing water openings.

* Col., Corps of Engrs., U. S. A., New York, N. Y.

At the Lake Washington Ship Canal locks, the condition existed under which emergency dams are indicated as desirable, namely, a large body of water above the lock which would be drained were the flow not stopped in a reasonable time. There, the damage would not be done below the lock, as in the case of New Orleans, but above it. Mr. Goldmark estimates the discharge that would take place at New Orleans as 70 000 sec-ft. As a comparison that computed for the Lake Washington lock would be about 58 000.

The type of dam adopted for the latter lock was an adaptation of the balanced cantilever turn-table bridge type used at Sault St. Marie, Mich., and at Panama, and designed to decrease the cost at the expense of some speed in placing.* All parts are stored on the lock wall and placed in position by a stiff-leg derrick, first the bridge supporting the upper end of the six wicket girders, next the operating bridge placed up stream and carrying the machinery for lowering the girders after they have been attached to the main bridge, and then the gates, twenty-four in number.

This dam has been placed in slightly more than 4 hours against as much head as could be secured by opening the culvert valves to full capacity. The lowering of the lakes, the area of which is about 26 000 acres, in that or even somewhat longer time, would probably not be sufficient to cause any very material damage.

The lock is 80 ft. wide, with a draft of 36 ft. over the upper miter-sill. The cross-section of the opening is, therefore, a little more than 3 000 sq. ft., as compared with 4 125 sq. ft., for the New Orleans lock. The total cost, the work having been completed about 1924, was approximately $175 000, or somewhat less than one-half that at New Orleans.

At the small lock, which is 30 ft. wide, with about 17 ft. on the upper sill, the emergency dam consists of five rolling girders or "stop-logs" which are lowered into recesses in the lock walls by a hand-operated stiff-leg derrick.

The author states, that the time required for placing the dam at New Orleans is about the same as that at Panama, namely, 1 hour. It would be interesting to know whether this is in still water, and what experience, if any, has been had in placing it under conditions as nearly similar as practicable to those in time of emergency.

Roger D. Black,† M. Am. Soc. C. E.—Mr. Goldmark's excellent paper and the discussion which has followed it bring sharply to mind certain extremely interesting conditions surrounding the general subject. One is the paucity of actual experience in the operation of these dams under the situation of extreme emergency which they are designed to meet; another is the grave seriousness of the results in the event that one of them fails to function when the emergency occurs. A third condition is that a service test of an emergency dam must always be difficult and dangerous and is often found to be impracticable. From these three conditions it is apparent that the design must be based almost entirely upon the correct application of sound theory and

* For more detailed description of this dam, see the paper by the writer and A. W. Sargent, M. Am. Soc. C. E., entitled "The Lake Washington Ship Canal," p. 1001.

† (Leaycraft & Black, Associated), New York, N. Y.

yet must produce a structure which can be depended upon in the emergency. Obviously, the problem is one of the most serious and difficult which arises in engineering practice.

Mr. Goldmark's paper is particularly interesting in that the dam which he describes is almost unique and a radical departure from the general type which for many years might have been looked upon as almost standard for major locks in the United States—the type which was adopted for the Panama Canal locks and the great lock at Seattle described by Colonel Barden, and the only type which in a serious practical emergency is known to the speaker to have functioned successfully, namely, in the accident at the Canadian Sault Ste. Marie.

It will be recalled that the stop-log principle, as against the Panama Canal type, was adopted at New Orleans on the score of economy in first cost. As this consideration may lead to its further adoption which, in turn, would undoubtedly follow a careful re-study of all existing emergency dams, it seems manifestly proper to invite attention to another emergency dam—a dam differing materially from either of those mentioned and one which was designed after giving full consideration to the Panama and other then existing types. This is the emergency dam* protecting the lock in the concrete dam crossing the Hudson River at Troy, N. Y., which was built by the Federal Government between 1910 and 1915 to replace the old State dam at that point.

The State dam, a stone-filled timber-crib structure, was erected in the early part of the Nineteenth Century, partly for power purposes and partly to create a pool above Troy with adequate depth for the traffic of the Erie and Champlain Canals.

The Federal Government's project of 1910 for the improvement of the Upper Hudson River was undertaken with the particular purpose of providing adequate channel accommodation for the traffic to be expected from the new Barge Canals. Below the State dam at Troy the elevation of the rock underlying the channel bed and the bank conditions were such as to permit open-channel improvement by dredging, rock excavation, and regulation, but the conditions above Troy (including the elevation given the miter-sills of the lowest locks of the Barge Canals) were such that, coupled with the possibility and desirability of utilizing power, replacement of the State dam was decided upon.

The transverse dimensions of the new lock conform to Barge Canal standards, that is, a width of 45 ft. with a depth over the miter-sills at the established low water of 14 ft., to ensure under all possible changes in the regimen of the river a navigable depth of 12½ ft. To provide adequately for the combined traffic of the Champlain and the Erie Branches of the Barge Canal System, the lock (Fig. 19) was made approximately one and one-half times the length of the standard Barge Canal locks and given three sets of miter-gates, dividing it into two chambers, one equal in length to the standard of the Barge Canal, the other one-half that length. Using the smaller chamber

* Described by Frank P. Fifer, M. Am. Soc. C. E., in *Professional Memoirs*, Corps of Engrs., U. S. Army, and Engr. Dept. at Large, Vol. 10, No. 53, September-October, 1918.

alone, economy in the use of water is effected in locking the large portion of Barge Canal traffic which moves in boats less than 150 ft. in length. The longer chamber alone will obviously take any craft that the Barge Canal can pass, and with the center gates open the two chambers in combination materially increase the lockage capacity over that of a standard Barge Canal lock. In addition, the culverts and river wall were so designed as to permit the construction in the future of a duplicate lock at a minimum cost.

The head on the dam at low stages, such as 5 000 cu. ft. per sec., is approximately 14 ft., which decreases as the discharge increases until it practically disappears. For example, in the great flood of 1913, with a discharge computed in excess of 200 000 cu. ft. per sec., the slope at the dam was less than that induced by bank contraction at various points in the river below it, the depth on the dam being about 13 ft.

It is obvious that the volume of water and the conditions of flow in the pool above the lock are such as to make it highly desirable to be able to stop flowage through the lock in the event of the destruction of the miter-gates. The importance of having a simple and dependable emergency dam, however, was greatly enhanced by the position of this lock as the gateway to two great canals, and by the responsibility of the Federal Government to limit interruption of their traffic to the absolute minimum.

The Barge Canal System itself is without emergency dams in its locks for the reason that the pool levels and the flow of water to the locks are otherwise subject to control; for example, by the regulating dams along the Mohawk which apply the principle of the Panama Canal type of emergency dam, except that the supporting structures are in the form of fixed bridges instead of swing draws.

The design of the emergency dam adopted for the Troy lock was derived in part by the application of principles used in the movable dams on Western rivers. Economy in first cost and in maintenance was, of course, a consideration; but the governing consideration was dependability in operation, in turn to be derived mainly from simplicity.

The essential elements of the dam are three trestle bents, a service bridge deck, and a set of roller wickets, each wicket being made up of a steel frame about 11 by 5 ft. over all and supporting six buckle-plates. When not in use the trestles nest one on the other in the bottom of the lock chamber (Fig. 20) behind, and protected by, a heavy concrete sill; and the bridge deck and wickets are stored on shore. To erect the dam the trestle bents are revolved 90° in a direction at right angles to the current, thus placing them in a vertical position (Fig. 21); their tops are then secured to each other and to the lock-walls by the service bridge deck, and the wickets are lowered into position one by one in front of and against the trestles, thus shutting off the flow gradually until closure is completed.

The three trestle bents are spaced 11 ft. 3 in. on centers, and the center line of the easterly trestle is the same distance from the face of the land lock-wall. When nested, the upper parts of the bents revolve into a recess in the river wall (Fig. 20). The rollers on the outer ends of the outer sets of

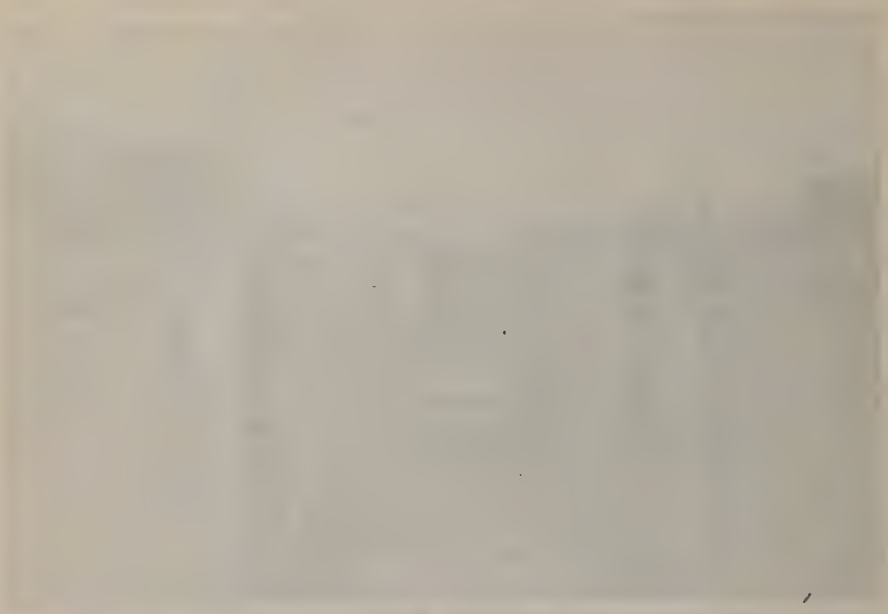

FIG. 21.—EMERGENCY DAM UNDER CONSTRUCTION. TRESTLE BENTS IN SERVICE POSITION AND CONNECTED BY STRINGERS OF SERVICE BRIDGE DECK.

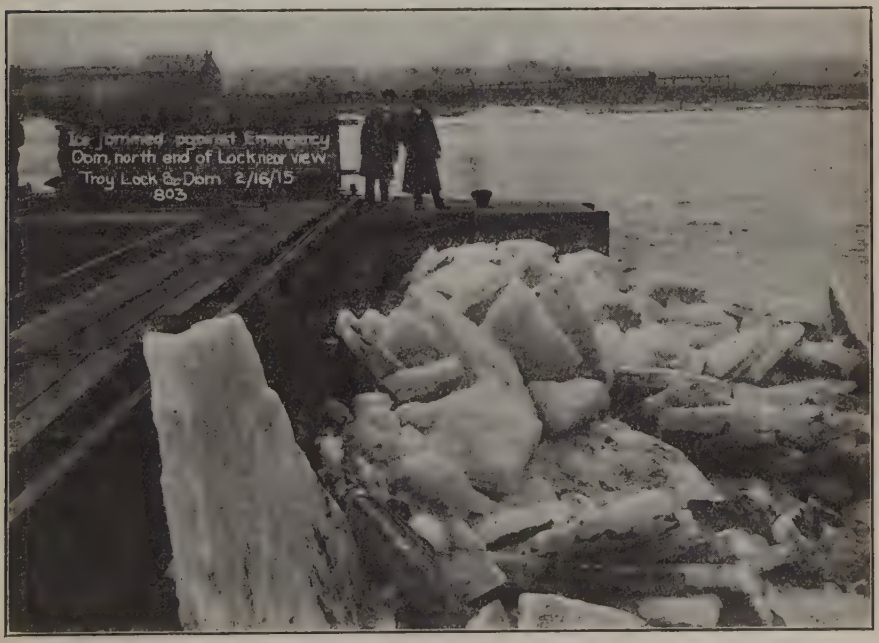

FIG. 22.—EMERGENCY DAM IN SERVICE.

wickets bear on steel castings set in recesses in the lock-walls. All intermediate wicket rollers bear directly on the faces of the up-stream trestle legs. The bearing face of the casting in the land wall is in line with the up-stream faces of the trestles, but the similar recess in the river wall (Fig. 22) is advanced up stream sufficiently to clear the trestle recess, so that the westerly set of wickets rests at a slight angle up stream from the others.

The entire structure is designed to resist a hydrostatic head of 26 ft. plus a velocity head of 11 ft. per sec. The three trestle bents, which are identical, are designed to function in the vertical position as cantilevers, transmitting the portion of the load brought to them by the wickets, to anchorages in the lock floor (Fig. 20), through the bearings on which the trestle legs rest and about which they revolve.

Each trestle bent consists of a vertical front, or up-stream, leg, and an inclined back leg, connected by a horizontal member at the top supporting the service bridge deck, and by three inclined and one horizontal web members. There is no member connecting the feet of the trestle legs, but the web members are so arranged (Figs. 20 and 21), as to carry the entire horizontal component of the load to the down-stream bearing. There it is adequately cared for by inclined anchor-rods leading from the shoe of the bearing up stream and downward to a suitable anchorage buried in the lock floor. The up-stream bearing is likewise anchored, but only to resist the upward reaction.

Each up-stream vertical leg is divided by the web members into three panels. In the lowest panel it acts as a cantilever (extending downward) and in the upper panels as a continuous girder, thus carrying the horizontal load to the web members, and relieving the up-stream bearing of all horizontal thrust. The panel points are so spaced that, under this horizontal loading and the tension due to the vertical reactions, a uniform section is used in the front leg with practically uniform unit stresses throughout its length.

The interesting advantage gained in concentrating the entire horizontal thrust at the down-stream bearing, is that all uncertainty is removed as to its distribution between the two bearings under unequal wear or faulty setting of their surfaces, and that the anchorage can be designed accordingly with precision.

The tops of the trestle bents are connected by a heavy chain which, when they are nested, lies on them and leads across the lock to the land wall where it reaches the surface through a vertical recess. To raise the bents this chain is hauled in by a winch bringing them into a vertical position successively. As they reach the vertical position their tops are connected by light channels which hold them in place and become the stringers on which the service bridge deck is laid. From this service bridge the wickets are lowered by chains and if necessary forced down, shutting off the flow bit by bit. The lowest roller wickets in the erected position rest on the concrete sill previously mentioned. Leakage is controlled by timber stops bolted to the wickets, and can be prevented entirely by simple caulking after the dam is erected.

This emergency dam performed an important function during the construction of the lock. As soon as the up-stream sections of the lock-walls were

completed, the dam was erected. This permitted the removal of the northerly end of the steel sheet-pile coffer-dam which was re-erected near the southerly end of the lock. For a period of two years the emergency dam thus acted as a coffer-dam (Fig. 19) and incidentally withstood exceptional pressure from ice and the ravaging effect of several periods of high water. It has since been erected almost annually to permit complete unwatering of the lock and inspection of itself as well as of the upper miter-gates.

In a report* submitted by the Albany Office of the United States Engineer Department on May 14, 1919, the cost of the emergency dam at Troy is given as "cost in place, 93 398 lb. @ \$0.05¾, \$5 360.53".

The width of the lock is 45 ft. and the depth on the miter-sills, 14 ft. This gives a cross-section protected by the dam of 630 sq. ft. at a cost of \$8.50 per sq. ft., a figure which it is interesting to compare with the data given by Mr. Goldmark for the Panama Canal and the lock at New Orleans.

When in charge of the construction of the lock in 1913-14 the speaker cherished a desire to give this emergency dam a service test under full head. It is believed that one of the best features of the design is the ease and comparative safety with which such a test could be made. Obviously, the dam would be erected in still water with the upper miter-gates closed. The miter-gates could then be opened and the roller wickets of the emergency dam removed one at a time until the desired flow to give a proper service test and all measurements connected therewith had been produced. During this operation precautions could be taken and tested out to make absolutely sure that the gates could be replaced under full flow. It is doubtful whether the Panama Canal type, or the stop-log type at New Orleans, is susceptible of such a practical test with so little real danger.

In considering this problem probably the most serious uncertainty has always been as to whether under service conditions the friction in the roller bearings of the wickets would be so great as to neutralize their effectiveness, but even if this were the case it is believed that little difficulty would be had in forcing these wickets down with jacks operating from the service bridge; or, if necessary, from a heavy girder placed across the top of the bridge to take the vertical thrust.

Whatever may be said of other designs, it is true that the emergency dam in the lock at Troy was designed and erected with the primary object of dependability in operation, but nevertheless the suggestion is made that its effectiveness can never be completely proved until it is tried under emergency conditions. In view of the importance of this lock and the waterways to which it is an outlet, would it not be interesting for the Society to arrange with the Federal Government for a service test?

Samuel McC. Young,† M. Am. Soc. C. E. (by letter).—In reading this interesting paper, one is impressed with the simplicity and the economy of the design. At the same time, an examination of the diagrams for the sinker

* Loaned by courtesy of Col. R. R. Ralston, Corps of Engrs., U. S. Army, Dist. Engr., 1st N. Y. Dist., U. S. Engr. Dept.

† Chf. Engr., Board of Commrs., Port of New Orleans, La.

castings (Fig. 15) and the automatic latch mechanism (Fig. 16) will reveal the results of careful thought and considerable ingenuity.

This equipment has been operated, for testing only, about once a month since its installation in 1922, and no serious difficulty has developed in this respect. However, due in part to local conditions, certain little operating kinks, here and there, have been discovered as a result of experience. For example, an accumulation of silt on the floor of the lock when the Emergency Dam is being placed may interfere with the proper operation of the spring device which should release the hooks. In that case, it becomes necessary to use the hand-operated mechanism provided for releasing the hooks when placing the girders in the storage yard.

Another detail, which may not have been thought of in the preparation of plans, but which is more or less important, is the use of tell-tale ropes or cords for determining when both hooks have become engaged or released, as the case may be. When an Emergency Dam girder is being placed in, or is being removed from, the dam, suitable weights, with ropes attached, are placed one on each end of the girder, and two men, standing on the lock-walls opposite the ends of the girder, hold these ropes with their hands, keeping them taut. Then, should only one hook be engaged when the lifting mechanism is being operated, one rope will remain taut while the other will begin to be slack. This condition will indicate that only one hook is engaged and that only one end of the girder is being raised. The lifting mechanism, which is being handled very carefully at this stage of the operation, is stopped at once, or else the girder might become jammed between the lock-walls. It is then necessary to go through the process again of engaging the loose hook or of disengaging the other, depending on what is being done with the girder. It may be more convenient, when lowering the girders into the lock chamber, to attach the tell-tale ropes directly to the girders in a manner in which they may be easily released after the hooks are disengaged.

A few minor modifications of the original design were made in the field. These had to do principally with the latching mechanism and the sinker castings. In order to detach the hooks when the girders are to be floated to the north end of the lock, it is necessary to take the weight of the sinker castings off the girder, as the girders have not sufficient buoyancy to carry the sinkers. This is accomplished by inserting in the oblong holes of the castings 2 by 2 by 6-in. steel blocks which transfer the weight of the sinker castings to the axles of the movable sheaves.

Even the weight of the hooks is sufficient to overcome the buoyancy of a floating girder, and, consequently, in order to re-engage the hooks, it is necessary to hold them back with the dogs to permit the latching mechanism to be lowered to a position where the hooks will engage. In this position, the dogs are tripped and the hooks take hold. To facilitate the proper alignment of the sinker castings and latching devices in picking up a girder, two cone-shaped steel dowels, $4\frac{1}{2}$ in. in diameter by 2 in. high, have been attached to the bottom of each sinker casting, and corresponding holes were drilled in the tops of the girders. To prevent these castings from swinging about their supports, suitable guides and braces have been attached to the crane structure.

The counterweights, which were attached to the hooks, were found to be unnecessary, and their removal has facilitated the detaching of the hooks.

While this Emergency Dam has not been tested under the actual conditions for which it was designed, there is every reason to believe that it would be equal to such a test.

T. B. MÖNNICHE,* M. AM. SOC. C. E. (by letter).—This paper is of great interest to the profession. It describes a novel structure, and, as the literature on emergency dams is very meager, any addition to this subject should be of value. The problems involved in the design of an emergency dam are far more complex than one would imagine.

The author claims that the New Orleans Dam is as reliable in operation as the Panama Canal dams; that it requires a smaller operating force; and that it has the merit of being lower in cost than any emergency dam previously built. The writer is of a different opinion. He also believes that it would have been entirely infeasible to construct a dam of the "stop-log" type for the Panama Canal, whereas the type adopted there could have been used to great advantage at New Orleans.

When the writer began designing the Panama Canal dams, no emergency dam had ever been tested under actual emergency conditions, so that there were no practical results to follow. Calculations were made of the flow of water that would occur at each site of the dams in case of an emergency. The most serious condition was found to be at Gatun (see Fig. 23), where there is a double flight of three locks, each 110 ft. wide and about 1 000 ft. long. The depth of water at the upper lock-sill is 49¾ ft. and the difference in elevation of the water at the top lock and the bottom lock is 88 ft. The computed result was a discharge of 95 000 cu. ft. per sec., with a velocity of 24.1 ft. per sec. It became apparent at once that, in trying to stop a flow of such magnitude, it would be practically impossible to do so simply by enlarging upon the dams already constructed at Sault Ste. Marie. The wicket girders became so long that, in order to counterbalance their weight, the horizontal truss had to be placed on the down-stream side of the down-stream vertical truss, instead of, as at the "Soo", between the two vertical trusses; and the rolling gates could not be made (as at the "Soo") in one length, but had to be made in sections and hung up under the floor so as to clear the flow of water. This is shown in Figs. 23 and 24.

The principal point considered in the design of the wicket girders and gates was to construct them so as to make their lowering in the swift current as reliable as possible. The possibility of the wicket girders meeting obstructions at the sill was guarded against by placing large concrete pockets, 32 ft. wide and 14 ft. deep, in front of the sill. These would have to be filled before any obstruction could settle on the sill. Furthermore, the shape of the sill was made such that any obstruction which might settle would be washed away by a current of 24 ft. per sec. If some obstruction should be caught between the sill and the wicket girders just as the latter are approaching the sill, the hoisting machines have been made so powerful that these

* Boquete, Panama.

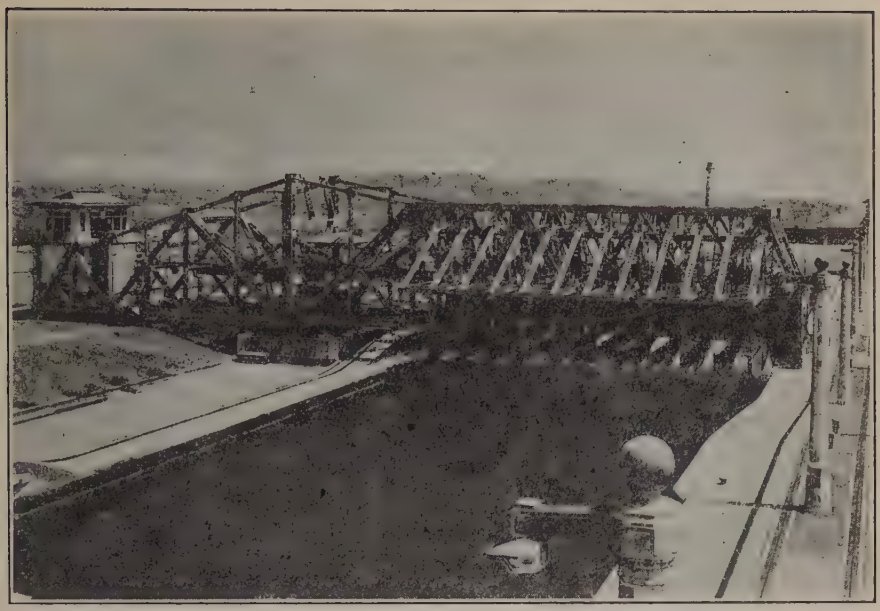

FIG. 23.—VIEW SHOWING WEST EMERGENCY DAM IN POSITION ACROSS LOCK CHAMBER, GATUN LOCKS, PANAMA CANAL.

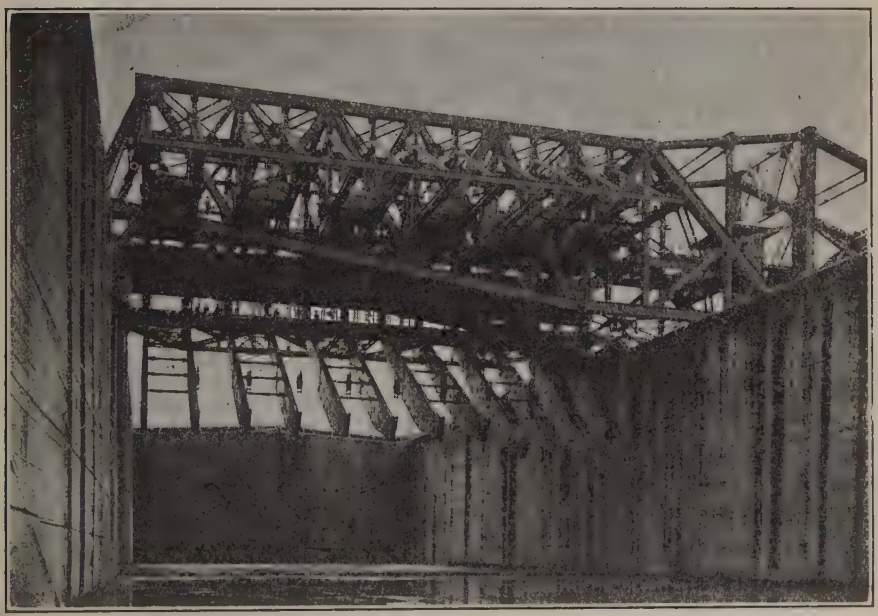

FIG. 24.—PANAMA CANAL EMERGENCY DAMS, PEDRO MIGUEL LOCKS, VIEW SHOWING LOWERING OF WICKET GIRDERS.

girders may be raised against the current so as to allow the obstruction to pass. In lowering the gates in the current they are subjected to pressure caused by the static head and the kinetic energy of the water. In order to ascertain what the friction would be for each set of gates during lowering, tests were made on full-sized gates. These tests showed that the average load required to overcome the friction due to the loads produced by the current, was 3.2% of the weight of the gates.

Only a few months after the plans of the wicket girders and gates for the Panama Canal had been made, the accident at the "Soo" occurred. This was the first time an emergency dam had been brought into actual use and its successful operation proved its feasibility. The most serious mishap that occurred was that, in lowering one pair of wicket girders, they struck some obstruction, so that they did not get properly seated and were warped into a twisted mass. However, the principal framework of the dam was intact and the opening was later closed by provisional means. The gates, which were provided with wheels (but without roller bearings), failed to function, so they had to be jacked down into place. It was a satisfaction for the writer thus to obtain an actual proof of the importance of those points on which he had laid so much stress in his design.

The lock force on the Panama Canal is given a routine drill once a month in operating the emergency dams. The force which usually operates the dams at the Atlantic locks consists of ten "gold" and twenty "silver" employees, which is approximately 14% of the "gold" and 10% of the "silver" force. During the six months from August, 1927, to January, 1928, the average time for closing one dam, either day or night, was 25 min., the maximum time was 26 min., and the minimum time, 24 min. The force used in drilling during the same months at the Pacific locks consisted of eight "gold" and twelve "silver" employees. This represents, at Pedro Miguel, 16% of the "gold" and 12% of the "silver" force. The average time for closing was 29 min. for Pedro Miguel, and 24 min. for Miraflores. These forces are not the minimum required, as some of the men are oilers and stand-by men.

The lockmaster swings the dam and is in charge of the drill. As each pair of wicket girders is provided with a separate hoisting machine and limit switch, the lockmaster alone can start the lowering of each pair of wicket girders one after the other. The switches automatically cut off the current for each machine when the wicket girders reach the bottom sill. In a similar manner each horizontal set of gates may also be lowered. In lowering the gates, however, two additional men would be required to ascertain that the hooks for the gates are not interfering with the gates properly engaging the rails of the wicket girders. Thus, the dams for the Panama Canal may, if necessary, be operated with a minimum force of three or four men. The time for closing the dam in this manner would be increased to about double the present time.

The author states that the principal operations of the New Orleans Dam are under the control of one man, although a few others are required in the

storage yard and on the walls, and that "this does not mean any addition to the ordinary lock force." He also states that a "large number of attendants" is required for the operating of the Panama Canal dams. As no addition to the ordinary lock force is required for operating the New Orleans Dam, and as only 14 to 16% of the lock force is ordinarily used for operating the Panama Canal dams, it seems to the writer more probable that it takes a larger force to operate the New Orleans Dam than those of the Panama Canal. It would be interesting to know the exact number of men required for operating the New Orleans Dam, and the recorded time used during the day and night, including that lost between each operation. The Panama Canal dams have to resist forces, and to check the kinetic energy of water, of about twice the magnitude of the New Orleans Dam and, according to the available figures, this is done in less than one-half the time.

The author's statement that the New Orleans Dam is as reliable as those of the Panama Canal does not seems to the writer to be quite correct. The experience gained by the accident at the "Soo" shows the importance of guarding against improper seating of girders due to meeting obstructions. Possibly this point has been given little consideration by the author in his design, one of the principal features of which is the use of releasing hooks with which large box girders spanning the width of the lock chamber are lowered into place. The releasing of these hooks depends on the proper seating of each box girder. The chances for one of these box girders meeting obstructions while being lowered in a swift current are far greater than for all the wicket girders at the "Soo" or at the Panama Canal, because these box girders are to be seated across the entire width of the lock chamber, and as there are eight of them, the chances are still further multiplied.

No provision has been made for raising the box girders to allow obstructions to pass. With this type of emergency dam it would be practically impossible to do so on account of the enormous loads to which the hoisting machine would be subjected. It might happen, therefore, that the first girder to be lowered would meet an obstruction, so that the releasing hooks would not function and thus would put the dam entirely out of commission. A catastrophe of this kind could not occur at the Panama Canal. If a pair of wicket girders should not get properly seated, so that a set of gates could not be lowered, the principal structural framework of the dam would remain intact and the small opening in the dam could be closed later by some provisional means, as was actually done at the "Soo".

Unfortunately, the author has not given the hydraulic conditions for the New Orleans Dam. He simply states that the computed volume of the flow of water will be "in excess of 70 000 sec-ft.", without giving the velocity. From this figure the writer has computed the entrance head to be about 16 ft.; and the entrance velocity, about 28 ft. per sec.

In computing the flow for the Panama Canal the surface drop at the end of the three flights of locks was not taken into consideration either, as it would only have complicated the problem and have had little effect on the final result, because this drop occurs about 88 ft. below the upper

level. At New Orleans, however, the conditions are such that the surface drop at the end of the lock will greatly affect the computations. The writer, therefore, has made approximate calculations, the result of which is a discharge of 50 000 sec-ft., and a velocity of 16.5 ft. per sec. During the lowering of the stop-log girders at New Orleans the maximum static head imposed on them is estimated by the writer to be about 9 ft., whereas at the Panama Canal the maximum static head during the lowering of the gates is 24 ft.

The author ascribes the low cost per square foot of lock opening at New Orleans mainly to the more economical type of design. The writer believes it is uneconomical, because it is subjected to the full static head, whereas at the Panama Canal two-thirds of the reaction of the static head is carried by the sill and only one-third by the dam itself.

In the author's comparison of the cost of the New Orleans Dam with the Panama Canal dams, no account is taken of increased moments due to longer spans, nor to increased loads due to greater volume of flow, velocity head, and static head. This comparison is identical to estimating the weight of two bridges by simply calculating their weights in straight proportion to their respective spans without considering the different loads to which they are subjected. Evidently, in comparing costs it should be kept in mind that the moments vary in proportion to the square of the span; that the kinetic energy of the flow of water varies in proportion to the cross-section of the flow multiplied by the square of the velocity; and that the horse-power required and the weight of the machinery and its supports vary in inverse proportion to the time required for closing. In this connection it should be remembered that an emergency dam is practically nothing but one huge machine. The Panama Canal dams are subjected to:

Moment due to span..... $= \left(\frac{110}{75}\right)^2 = 2.15$ times New Orleans Dam.

Kinetic energy of flow $= \frac{4\,000}{3\,050} \times \left(\frac{24.1}{16.5}\right)^2 = 2.8$ " " " " "

Machinery and supports..... $= \frac{60}{25} = 2.4$ " " " " "

If proper allowance is made for these factors, the cost of each emergency dam for the Panama Canal ($432 000) compares very favorably with the cost of the New Orleans Dam ($353 000).

The greater reliability in the operation of the Panama Canal dams should also be taken into account. The use of releasing hooks was at first considered for the Panama Canal dams. A preliminary design was published in the Annual Report of the Isthmian Canal Commission for 1908. The principal feature in the operation of this dam was identical with that of the New Orleans Dam, because the whole operation of the dam was to be performed from a central power plant and releasing hooks were to be used. This design was abandoned because releasing hooks were considered unreliable on account of the possibility that they might not release if the wicket girders or the gates

should meet an obstruction at their lower ends. The design was low in cost. Its estimated weight was 1 870 000 lb., whereas the dams constructed weigh 6 700 000 lb. each. Thus, the estimated weight of each emergency dam for the Panama Canal as originally designed with releasing hooks amounted to only 28% of the weight of each of the present dams. This large increase in weight was caused not only by abandoning the use of releasing hooks and substituting separate hoisting units, but also by enlarging the size of the gates, thus reducing the time of closing; by furnishing the gates with roller bearings; and by providing the hoisting machines with sufficient power to raise the wicket girders against the current. The increased cost due to this increase in weight was of minor importance on the Panama Canal where reliability was given first consideration.

If it is desired to make a comparison between the "stop-log" type of emergency dam as used at New Orleans with the wicket-girder type as used at the Panama Canal, it should be made with the original design for the Panama Canal, using releasing hooks. The result of such a comparison, making proper allowance for the different spans, loads, and time required for closing, will show that the stop-log type as built at New Orleans is several times as expensive as the wicket-girder type with releasing hooks would have been if built in its stead. The writer believes that the New Orleans Dam, instead of having "the merit of being lower in first cost" than any emergency dam previously built, has the defects of being higher in cost and less reliable.

All the merits claimed by the author in favor of the New Orleans Dam as compared with the Panama Canal dams are lost, when it is considered that the stop-log type used at New Orleans would not be feasible for use at the Panama Canal. Following the author's design the stop-log girders, if used for the Panama Canal would have the following dimensions: Length, out to out, 120 ft.; horizontal depth at ends, 6 ft. 6 in., and at the middle section, 11 ft.; and vertical depth, 6 ft. 2 in. The horizontal area of each girder, A_h, would be 1 000 sq. ft. and the vertical area, A_v, would be 745 sq. ft. As the spans at the Panama Canal and New Orleans are 100 ft. and 75 ft., respectively, and as the static head, when the locks are empty, is practically the same at both places, the weight of the stop-log girders for the Panama Canal would be $\left(\frac{110}{75}\right)^3 = 2.15$, say, twice the weight of those for the New Orleans Dam. The sinker castings might be proportioned accordingly, and thus the weight of one stop-log girder with sinker castings for the Panama Canal would be $D = 2 \times 244\,000$ lb. $= 488\,000$ lb.

A study of the hydraulic conditions for the Panama Canal dams, during and after the lowering of each gate has been published by the writer.* In order to calculate the loads on the stop-log girders, if used for the Panama Canal, the writer has, for the sake of convenience, assumed that the upper edge of each stop-log girder will be lowered to the same depth as the upper edge of each tier of gates of the Panama Canal dams. In this manner the

* *Transactions*, Inter. Eng. Congress, San Francisco, Calif, 1915, "The Panama Canal", Vol. II, No. 18.

complicated computations made for these dams may be utilized for calculating the loads. The data thus utilized are given in Table 3, Columns (1), (4), (6), and (8). Fig. 25 illustrates the hydraulic conditions just before a stop-log girder reaches its final position, when its upper edge is at the same elevation as the upper edge of Gates No. 3 of the Panama Canal dams.

TABLE 3.

UP STREAM.

Gate No.	Horizontal pressure, p, in pounds per square foot. (1)	Horizontal load, $H = p \times A_v$, in pounds. (2)	Friction, $F = 0.2 \times H$, in pounds. (3)	Static head, H_d, in feet. (4)	Vertical load. $V = H_d \times A_h \times 62.5$, in pounds. (5)
1	1 120	835 000	±166 000	39.0	2 450 000
2	1 400	1 040 000	±208 000	32.5	2 030 000
3	1 375	1 020 000	±204 000	24.8	1 540 000
4	790	588 000	±117 000	15.5	970 000
5	190	141 000	± 28 200	4.8	0

DOWN STREAM.

Gate No.	Velocity, v, in feet per second. (6)	Velocity head, $h = \frac{v^2}{2g}$, in feet. (7)	Static head, H_d, in feet. (8)	Uplift, $U = (H_d + h) \times A_h \times 62.5$, in pounds. (9)	Lowering, $V + U + D - F$, in pounds. (10)	Raising, $V + U + D + F$, in pounds. (11)
1	22.9	8.2	—24.6	—1 020 000	1 752 000	2 084 000
2	21.4	7.1	—12.3	— 325 000	1 985 000	2 401 000
3	18.0	5.0	— 1.3	0	1 824 000	2 232 000
4	8.8	....	.....	0	1 341 000	1 575 000
5	0	....	.....	0	460 000	516 000

It may be seen that when the water rushes between the stop-log girders, a contraction will take place due to the sharp corners, and that a partial vacuum will be created on the under-side and down-stream side of the stop-log girders (shown at (*a*), Fig. 25). These girders are filled with water while being lowered; during the lowering, they will also be subjected to the load of water flowing over them. These loads are given in Table 3, Column (5). No account has been taken of the loads produced by the partial vacuum. The uplift in the girders caused by the down-stream pressure is given in Column (9). The load carried by the hoisting machinery, while lowering the stop-log girders, is equal to the loads given in Column (5), minus the loads given in Column (9), and minus the friction produced at the ends of the girders given in Column (3). While raising the girders the load carried by the hoisting machinery is equal to the loads given in Table 3, Column (5) minus the loads given in Column (9) plus the friction, Column (3). The resultant loads to be carried by the hoisting machinery when raising and lowering the girders are given in Columns (10) and (11), respectively.

It may be noted that the loads to be carried by the hoisting machinery when the stop-log girders have been lowered to the same elevation as Gate No. 2 will be, for lowering, 1 985 000 lb., and for raising, 2 401 000 lb., or in other words, more than the total estimated weight of each emergency dam for the Panama Canal as originally designed with releasing hooks. These figures should be sufficient to show the infeasibility of using the stop-log type of emergency dam for the Panama Canal.

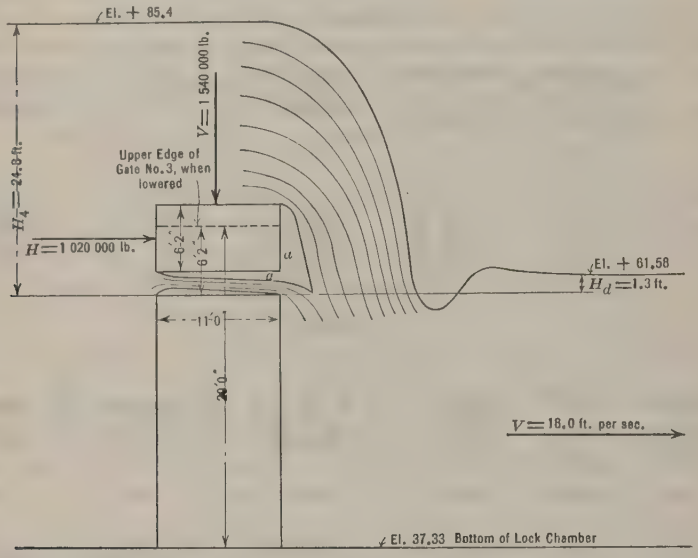

FIG. 25.—HYDRAULIC CONDITIONS FOR THE PANAMA CANAL IF STOP-LOGS WERE TO BE USED.

On the other hand, the stop-log type may be feasible for the New Orleans Dam, but it is difficult to form a definite opinion as to this because the hydraulic conditions while lowering the stop-log girders are not given. The author merely states:

"When the girders are being lowered into place under emergency conditions * * * the horizontal pressures are a combination of the velocity head due to the flow and the static head at the various levels. The computation of the loads due to these conditions is quite involved. In this case, too, the worst possible conditions have been assumed."

The author mentions nothing about the vertical loads imposed upon the girders by the flow of water. For the Panama Canal these vertical loads, as may be seen from Table 3, are about twice as large as the horizontal loads. It would be interesting to know the magnitude of the vertical loads for the New Orleans Dam under emergency conditions. It would be especially so because it is due to these loads that an emergency dam of the stop-log type is infeasible for the Panama Canal.

The author states that while lowering the girders they are filled with water, but while raising them, at a rate of 30 ft. per min., the water is allowed

to flow out at the proper rate, so that the girders will contain, for a few minutes only, 1.43 ft. of water, thus guarding against an overload in the hoisting machinery and excessive stresses in the girders. It appears to the writer, that the critical condition for the hoisting machinery and the girders is not during the raising of the girders in still water, but during the lowering of them under emergency conditions, when they are filled with water and also have to carry a large volume of water flowing over them. The vertical loads thus carried by the stop-logs would be the equivalent of a head of several feet for a considerable period of time, instead of 1.43 ft. for a few minutes. The writer, therefore, fears that under emergency conditions excessive stresses may be produced in the hoisting machinery as well as in the stop-log girders of the New Orleans Dam.

Henry Goldmark,* M. Am. Soc. C. E. (by letter).—The writer wishes to express his appreciation of the discussions contributed by several members. Replying to Admiral Harris' questions on the subject of water-tightness, it should be explained that this term refers to two different things: First, the tightness of the several stop-logs when empty and immersed in the canal; and, second, the leakage through the horizontal joints between the several logs when the water is pumped from the lock and through the vertical joints between the ends of the logs and the sidewalls. In both these respects an extreme degree of water-tightness was obtained, as stated by Mr. Comer.

The openings for admitting and discharging water are closed by square sliding covers operated by hand. Their size, as explained on page 1603, is large enough to be safe under the maximum load to be lifted.

Because of the extreme water-tightness of the box girders, no instability is experienced when the openings are closed and the stop-logs are floating.

Mr. Whitehead believes that perhaps the principal merit of the stop-log type of dam is that it can serve for closing the end of the lock-chamber when it is to be pumped out for inspection, thus making unnecessary an expensive caisson as used at Panama and elsewhere. His experience in operating the Pacific locks for several years after the opening of the Panama Canal makes his opinion of great value.

The greater simplicity of the stop-log design Mr. Whitehead does not consider of vast importance. While the writer cannot agree with him on this point, he is pleased that Mr. Whitehead agrees as to the merits (for that location) of the design adopted at New Orleans.

With regard to the times of operation, it should be borne in mind that at New Orleans, when the girders have been lowered into place, the dam is absolutely tight so that the uninjured mitering lock-gates below can be closed without delay.

On the other hand, in dams of the wicket type, there is considerable leakage through the vertical joints between adjacent panels. Hence, special closing pieces are necessary, and these are inserted after the wickets and gates have been lowered.

* Cons. Engr., New York, N. Y.

On the Canadian side at Sault Ste. Marie, no such closing pieces were provided. After the accident there in 1909, the flow, even after all the wickets and gates had been lowered, was very considerable. It proved very difficult to close the mitering gates. They were deformed; that is, bent out of shape by the flow of the water, and it was only because they were of wood that they escaped injury. At least, this was the view expressed to the writer by one of the principal Canadian engineers in charge, soon after the accident. This official was satisfied that steel miter gates could not have withstood the deformation caused by the flow of water and could not have been safely closed.

It appears no more than reasonable, therefore, to include the additional time required for placing the closing pieces in wicket dams, when comparing them as to speed of operation with other designs. If this is done, there will be little difference between the Panama and New Orleans dams, even if the wickets and gates in the former are placed more rapidly than in the early tests witnessed by the writer.

Mr. Comer's discussion is of special value as he was closely connected with the dam from its inception until it was completely erected, and witnessed its operation from the beginning. Mr. Comer explains nearly all points raised in other discussions, besides giving many additional facts which throw light on the design. There is no one whose opinion is of more value.

Colonel Barden's description of the dam in the Lake Washington Ship Canal is very interesting, although the conditions under which it works are different from those in most other places. Its low cost is a matter of interest. This is explained, in part, by the fact that it requires a relatively long time to operate. As stated by Colonel Barden, this slow operation is not of special importance at Lake Washington.

The emergency dam in the Hudson River near Troy, N. Y., described by Colonel Black, is another interesting structure, although it is of relatively small size. As this lock is practically a part of the Barge Canal System, its proper functioning is most important and it is interesting to note that notwithstanding its very low cost it seems to meet satisfactorily the conditions prevailing at the site.

Mr. Young's discussion is based on his experience as Chief Engineer of the New Orleans Port Commission for a term of years during which he has been in charge of the canal operation. His favorable opinion of the dam is, therefore, of much significance. Some minor modifications made by him in the method of handling the girders, etc., are very interesting.

Mr. Mönniche describes certain features of the Panama dams, designed by him, and claims for them various advantages over other designs, especially the stop-log type. It was by no means the writer's purpose to assert that the latter type is the most suitable one for all widths and depths of the lock-chamber. It is clear that the choice of type must depend on local conditions, as well as on the functions which the dam is to fulfill. The stop-log type was chosen for New Orleans largely on account of its economy because, aside from serving to stop the flow of water in case of accident, these dams can also be used as coffer-dams to close the ends of the lock-chamber when unwatering it.

Apart from its greater economy, however, the writer believes that the stop-log design is better, in this location, because the girders and the machinery are simpler than the more numerous and complex parts required in other types. The massive horizontal girders, securely guided in wall recesses, are less liable to injury, when being lowered or raised, than pairs of wicket frames hinged at the top and connected by rather light bracing. Each such pair is comparatively weak and subject to damage if the current makes an angle with the axis of the lock.

It was the belief of at least one competent observer that the difficulty in closing certain panels after the accident in the "Soo" was due to such a current, which swayed one of the structural frames so as to hold it up against the adjoining one, injuring one or both frames.* The horizontal stop-logs are also almost absolutely water-tight, when lowered into place, without additional closing pieces. The mechanism for handling the girders is also much simpler than that used in other types.

Mr. Mönniche's argument to show that the operating force at Panama is really smaller than that used at New Orleans is not convincing. As well stated by Mr. Comer, it is unquestioned that the satisfactory operation of the New Orleans Dam—including both the revolving of the swing-span, the attachment and release of the separate girders, as well as the operations of raising and lowering—is, at all times, done by a single operator stationed in a cage near the end of the swing-span.

Mr. Mönniche criticizes the value (70 000 sec-ft.) given by the writer (page 1636) as the flow of water at New Orleans when the lock-gates are carried away, the river level being + 39 and the lake level + 20. Mr. Mönniche finds that this value is only 50 000 and suggests that the writer has omitted the "surface drop" at "the end of the lock" from his calculations. Presumably he refers to the lower end of the lock. The writer used the standard method of computation employed when two bodies of water at different elevations are connected by an open conduit. A number of different values are assumed for the flow, and, for each of these values, the elevations of the water surface at various points from one end of the conduit to the other are computed, until the correct value is found. This value will be the one for which the sum of the hydraulic heads, due to the change in potential energy and to frictional resistances, is exactly equal to the difference in elevation of the two bodies of water connected by the conduit.

The conditions prevailing in the New Orleans Canal are shown in Figs. 25 and 26. Fig. 25 gives the plan of the canal and lock, with cross-sections, and Fig. 26 shows the elevations of the water surface at various points. As there is no sudden drop in the bottom of the lock and hence no weir effect on the flow, there can be no surface drop at the lower end of the lock, as claimed by Mr. Mönniche. It will be noted that the bottom of the canal below the lock is taken at Elevation — 8.25, while the lock bottom is at Elevation — 10. The canal, at some later time, will be deepened to Elevation — 10. This, of course, will make a change, although probably a slight one, in the results of the calculation.

* Letter to the writer, dated September 22, 1909, from M. J. Butler, M. Am Soc. C. E., then Deputy Minister and Chief Engineer, Department of Railways and Canals, Canada.

The writer is satisfied that the results obtained by his computations, as shown in Fig. 26, are reasonably correct, the only uncertain quantities being the coefficients of friction in the lock chamber and in the canal channel. He feels the greater confidence in their correctness since he applied the same method in the case of the accident on the Canadian side at Sault Ste. Marie in 1909. In this case, there was a quite close agreement between the calculated results and the actual measurements made by the engineers on the ground and furnished to the writer at the time.

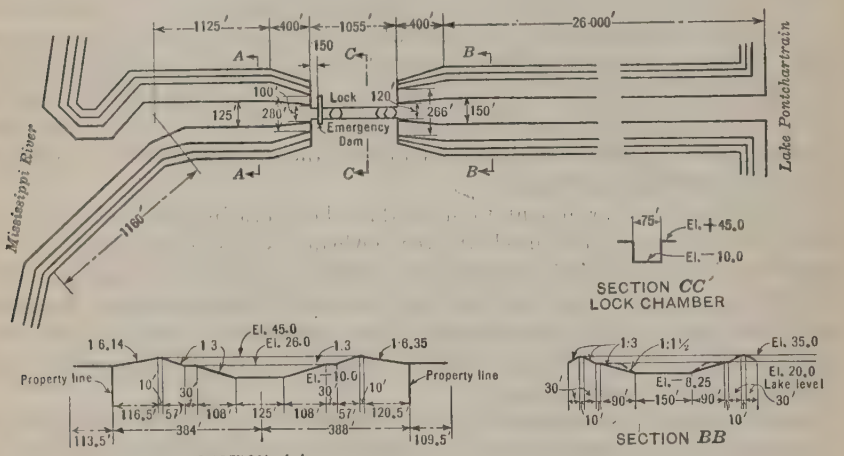

Fig. 25.—Plan and Typical Sections, Inner Navigation Canal.

In the paper the total costs of the New Orleans Dam and one of those at Panama are given and also their costs per square foot of lock section. Making allowance for the increase in the unit price of steel (about 2.4 to 1) the cost per square foot at Panama would be $180 as against $85.70 at New Orleans. The width of the Panama locks is only about one and one-half times as great as that at New Orleans, while the depth is the same. The weight of the Panama dams as built was three times as great and their cost per square foot two and one-tenth times as great. These figures seem disproportionately large as compared with the increase in the lock width.

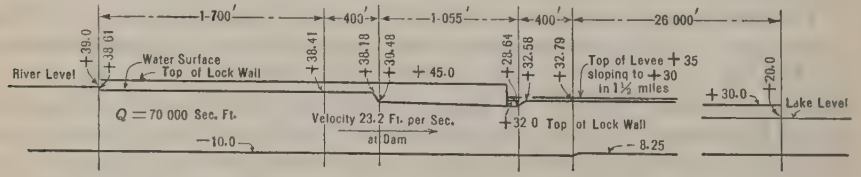

Fig. 26.—Profile, Inner Navigation Canal.

However, apart from any comparison with other locations, the great economy of the dam at New Orleans can be clearly shown by its double function as an emergency dam as well as a coffer-dam for shutting off the lock at either end

when it is to be unwatered for periodic inspection. If the dam were not able to fulfill this last function it would have to be supplemented by a separate floating caisson at a greatly increased cost. This is the case, although in order to use the stop-logs at the lower end of the lock they were arranged so as to float, making them much heavier, while their weight was still further increased by making them all identical and strong enough to withstand the full static head at the bottom when the lock is empty. Even with this increase in weight and cost the combined function of the New Orleans dam saves a great deal of money when compared to the cost of two separate structures.

The Panama caisson, which was built about 1912, cost approximately $350 000. It is 114 ft. long and 65 ft. high. A caisson in the New Orleans lock would be about 80 ft. long and 65 ft. high. Considering its smaller size, but also the increased present-day cost of material, the cost of a caisson may be safely estimated at from $300 000 to $350 000. The great economy obtained by using a stop-log dam, at a cost of $350 000, needs no further argument.

Paper No. 1696

BUILDERS, DEFENDERS, AND POLITICAL DESPOILERS OF OUR COUNTRY

ADDRESS AT THE ANNUAL CONVENTION AT BUFFALO, N. Y., JULY 18, 1928

By Lincoln Bush,* President, Am. Soc. C. E.

The progress of humanity has always depended on two things: First, on the strength of the natural instinct; and, second, on those necessities which a Mother Nature has sternly although kindly imposed upon her children. These two conditions have been the great drive wheels of the human engine, while the human mind—the reasoning power—has been the potent lever which for good or for ill, depending on the skill, the courage, the power, and the inspirations of the engineer, has commanded and controlled the whole machine.

Builders of Our Country

The laws of progress are but a compilation of the unwritten statutes of the Creator. Clearly discernible among these may be noticed the motives, the inspirations, the incentives, and the impelling forces, prompting through all life and ages to beneficence and accomplishment. This is exemplified by our former member, James B. Eads, in the dedication of soul and self to the construction of the Mississippi River jetties in these words,

"I therefore undertake the work with a faith based upon the ever-constant Ordinances of God, Himself, and so certainly as He spare my life and faculties for two years more, I will give to the Mississippi through His Grace and by the application of His Laws, a deep, open, safe, and permanent outlet to the Seas."

Forty-nine years have since passed and there now remains a clear channel of 40 ft. in depth, at the South Pass Jetties, and Eads' memory is enshrined in the Hall of Fame.

* Cons. Engr., East Orange, N. J.

The learned explorations, the scientific discoveries, and the mental developments of each succeeding generation are but the outgrowth of a clearer and a fuller understanding of these laws. What a beneficent creation! With delight we pursue; with gratification, possess. There are no limitations of the materials with which to work; no end of new truths, new laws, and new relations, which intelligent thought and energy cannot develop and grasp. Have you not heard of the new one-span structure reaching from Rocky Point to Rugby, 3 200 miles across the Atlantic? Invisible and intangible, its chords and web members were assembled on the evening and the morning of the Second Day, fifty-nine centuries ago; and engineering science, invention, and research are only now sending the first message across this vibrant mystery. Diamonds at our feet and world without end!

Undaunted by the failure of France, after thirty years of effort and the expenditure of $200 000 000 to build the Panama Canal, our engineers have said to the United States Government, "This is a practicable and a feasible proposition; we can build this great waterway". And within a decade we gave to the world that of which it had dreamed for 400 years, making New York from the Philippines only 9 600 miles instead of 13 600 miles, and the Golden Gate from Liverpool only 8 000 miles instead of 13 800 miles, and we now challenge the world for the billions of commerce of the East and West and for the inter-coastal trade of the two Americas. Conquests of the Civil and Sanitary Engineers: Wallace, Stevens, Goethals, and Gorgas!

The following record of our War Department was made only a few years before the last spike was driven in our first great transcontinental railroad in 1869; a record made by men who believed they were correctly forecasting the future of our present Great West beyond the Missouri and Mississippi Rivers, which reads as follows:

"From these vast prairies will be derived one of the great advantages to the United States, namely, the restriction of her population to some central limits and thereby a continuation of the Union. They [meaning the people] will be constrained to limit themselves to the borders of the Missouri and Mississippi, while they leave the prairies beyond, incapable of cultivation, to the wandering and uncivilized Aborigines of our Country".

Across these arid plains and tables of our Great West, we see in the sands and sage-brush the stakes and footprints of the Civil Engineer; and, following in his wake, we find the storage reservoirs, the irrigating channels, the shimmering fields of golden grain, and the Great American Desert is no more.

Instead of these vast prairies, declared incapable of cultivation, we have on this same territory to-day, the largest flouring mills, the greatest stock ranges, the largest granaries, and many of the richest ore mines of the world. Instead of these wandering and uncivilized aborigines we have to the west of the Mississippi River, the homes and firesides of 36 000 000 of our most intelligent people, the backbone of your own and New England's best stock, and heirs of the blood and courage of the pioneer. Instead of the aborigine's tepee, we have, to the west of this great river, 284 universities and colleges, a wealth represented by $102 000 000 000 of tangible property, and the emigrants' trail

of '49 has been buried under 127 000 miles of the most modern and well equipped railroad of our Country.

What a marvelous development in our great transportation systems, with only 23 miles of railroad in the United States in 1830 and 250 000 miles of railroad in the United States in 1925! They have stretched out over mountain and plain, up and over the great Rocky Ranges of our West and Northwest into that land of sunshine and flowers, and still on to the Yukon and Circle City, into a country with a coast line of 8 000 miles, of which the half has never been told, with 1 mile of rail for every 470 of our people against 1 mile of railroad for every 2 050 of Continental Europe, without which our great West, beyond the "Father of Waters," never could have been and the Louisiana Purchase would have been of little comparative value—a vast empire of 875 000 sq. miles, stretching west from the Mississippi to the Great Continental Divide and north from the Gulf to the Canadian Border. This acquisition barred forever the erection of a hostile or foreign State, made inevitable the annexation of Texas, New Mexico, California, and Oregon, and gave birth to a new nation of continental proportions and world influence.

Some one will say, "capital and labor have done these great and wonderful things", and they have done their part; but the inspired, scientific minds which conceived these great things and the constructive, courageous minds which executed these great things are superior to those instruments which they have employed.

What an epic of engineering and human progress has made possible our civilization and our Country with greater liberty, greater opportunity, and greater happiness to a greater number than has come anywhere at any time in the World's history.

Defenders of Our Country

Then came the World War with its years of bloodshed and sacrifice. Our civilization had been established and it must be defended. Mindful of the past and thoughtful of our future, we went forth, to protect and preserve our Country, its ideals and institutions, wrought from a wilderness after 140 years of superhuman effort by a great, a courageous, a patriotic, and a noble people, and we went forth to protect and preserve a world from chaos.

The Founder Societies, Engineering Council, National Research Council, civilian and commissioned engineers in all branches of transportation and industry, rendered indispensable service in the World War, but their activities were too diversified to be treated separately here. I shall speak of the Construction Division of the Army, which was a great human institution having only six Regular Army men in its entire organization and functioning under the single idea of emergency construction for war purposes; an assemblage of engineering and business skill of unusual and extraordinary capacities, consisting of chief engineers, consulting engineers, assistant engineers, water and sewerage experts, construction superintendents, and business men, supported by the War Industries Board with the vast resources at its command and ably led by Brigadier-Generals Littell and Marshall.

The Committee on Emergency Construction and Engineering of the War Industries Board, with only advisory powers, was formed in early May, 1917,* and its immediate problem was the housing of 1 344 000 men by September of that year. Before contracting any project, the General Staff requested and recommended it, the Emergency Construction Committee of the War Industries Board recommended it and recommended a contractor with an alternate. The Director of Purchases approved the recommendation, and the Construction Division, if it concurred, had to obtain the Secretary of War's approval of the project and the contractor and obtain his authority to proceed with the construction. Under such regulations and restrictions, the possibility of favoritism in the selection of the best, available, qualified contractor and the possibility or probability of collusion or conspiracy between five independent Departments and Bureaus, to defraud our Government in the great crisis, is too remote for an informed or a straight-thinking mind to believe and as an Officer in the Construction Division of the Army, I was in an advantageous position to know.

The Construction Division of the Army, with its 1 429 commissioned officers in charge of 30 000 clerical employees and a maximum of 427 000 laborers and mechanics, was an independent Staff Corps, without relation to the Quartermaster's Corps or to the Corps of Engineers. Prior to the World War, with three officers and thirty civilians, Colonel I. W. Littell was in charge of the construction and repair work at the Regular Army Posts, which quartered 100 000 men. Upon his retirement as Brigadier General in 1917, after having worn himself out leading his organization through the successful completion of the first cantonment program, he was superseded by Brigadier-General R. C. Marshall, Jr., M. Am. Soc. C. E.

On April 6, 1917, war was declared and on April 12, 1917, the Secretary of War declared that an emergency existed within the meaning of the "Revised Statutes and other Statutes", which exempted war emergency expenditures from the necessity of advertising for bids, and the Secretary ordered that until further instructed such contracts would be so made. The immediate problem confronting the Government was the construction of sixteen National Army Camps within a period of three months for the housing and training of 660 000 men. Before the construction of these sixteen camps was well under way, the Division was directed to construct within two months sixteen additional tent camps for the National Guard with a capacity for 684 000 men, and to be ready for the first contingent in two weeks. The civilian engineers and construction leaders of the country realized that a staggering program confronted the Nation for the housing and training of men and for the construction of innumerable other war projects on which the destinies of the overseas forces must depend.

In addition to the construction of the thirty-two National Army and National Guard Camps, this vast building program involved the construction

* This Committee consisted of William A. Starrett, M. Am. Soc. C. E., *Chairman*, M. C. Tuttle, transferred to the Emergency Fleet Corporation in 1918 and replaced by Major Clair Foster, C. W. Lundoff, Assoc. M. Am. Soc. C. E., Frederick Law Olmstead, and William Kelly, Major, Corps of Engineers, U. S. A., M. Am. Soc. C. E., later transferred overseas and replaced by John Donlin, representing the American Federation of Labor, with the late Leonard Metcalf and George W. Fuller, Members, Am. Soc. C. E., constituting the Sub-Committee on Engineering.

of hospitals with 121 000 beds; of terminal ports requiring roads, railroads, docks, wharves, and piers; of interior storage warehouses at industrial centers; of proving grounds, arsenals, and plants for the manufacture and storage of powder, high explosives, acids, and gases; of flying fields for the Signal Corps and Division of Military Aeronautics; of mechanical repair shops for assembling and repairing of automobiles and trucks in connection with the mobile artillery for the Motor Transport Corps; and of embarkation facilities for the Transport Service; with numerous other projects of lesser magnitude.

The camp and building sites for these projects had not been selected, the topography of the ground was not known, the extent of the projects had not been determined. Sewerage, drainage, and water supply had to be provided and typical buildings had to be designed that could be adapted to the sites when selected. It was at once evident to the War Industries Board that a form of contract must be devised that would expedite construction and safeguard the Government's interest; that a supervisory, administrative Governmental organization must be set up; and that a nation-wide survey of the construction industry must be made in order to obtain the most competent organizations in the construction fields, as no department of the Government had any adequate, up-to-date information on the construction industry.

Within two weeks the War Industries Board had secured reliable information on 1 500 contracting companies in the United States, based on information from engineers, architects, and the contractors themselves, and nationally known civilian engineers and experienced men were summoned by wire to fill the important posts in the Emergency Organization.

Under the emergency form of contract, the Government was enabled to proceed with its building program before details were completed, to push the work at any speed desired on any project great or small, to change the plan or scope of the work at will, and to get it done for such a reasonable fee as to be beyond the criticism of any informed individual.

After the thirty-two camps and cantonments had been completed and the advisability of concentrating construction work under a single head had been demonstrated, the Secretary of War on October 5, 1917, ordered that all construction for every Bureau and Division of the War Department within the United States, would be done by the Construction Division. This involved a total cost of $1 200 000 000 for 581 separate projects, located in every State of the Union except Arizona. It was made possible by an emergency construction program based on three considerations—the emergency form of contract that protected the Government's interest and was fair; the Construction Division organization that acted as administrators; and the competent, experienced contracting organizations that served as executors.

Under the emergency form of contract the contractor was allowed the actual cost at the site of the project with no "overhead", to which was added a sliding scale fee, depending on the magnitude of the job. On a contract estimated at $100 000, or less, the fee was based on 10% of the estimated cost, the maximum upset fee in all cases being fixed in advance by the contract. On a project estimated at $10 000 000 his fee was based on 2½% of the estimated cost, and on a project estimated at $25 000 000 (of which there were several),

his fee was based on 1% of the estimated cost, with a maximum upset fee fixed in advance by the contract.

In March, 1918, the Secretary of War appointed a Committee* to report on the methods of executing emergency work being done under the Construction Division. After careful consideration of the purchase and hire method, the lump sum contract, and the agency form of contract, the Committee reported unanimously in favor of the contract known as "cost of the work plus a sliding scale percentage with a maximum up-set fee" and further recommended that existing construction organizations be used for executing the work.

The complications in the construction industry arising from war conditions cannot be better illustrated than in the unfortunate experiences of the subway contractors of New York City. In the years 1914 to 1916, inclusive, 31 subway contracts were awarded on a unit price basis totaling $125 000 000. When war was declared, there remained $40 000 000 of unfinished work on these contracts. Nine suits for increased war costs on these contracts have been sustained and settlements have been made for $5 100 000, and six other suits are now pending (July, 1928). Out of twenty of these subway contractors who became heavily involved in losses incident to the war, eight are still engaged in construction work, seven have never recovered from their financial losses, and the other five have gone out of business.

It must be evident from such a record of losses and failures on these unit price subway contracts, due to increased war costs, that either the Construction Industry would have been wrecked or the Government would have been compelled to pay prices out of all reason had unit price contracts been adopted for the war emergency construction.

Each camp was a self-contained community with every modern facility for the comfort and health of the men and Camp Grant, at Rockford, Ill., costing $11 000 000 was typical. It had 1 600 separate buildings for quartering 43 000 men and 12 000 animals, with a hospital for 1 000 beds, and was ready to receive the incoming draft forces within 2⅓ months after construction was started. As fast as these camp facilities were completed, the Utilities Section of the Construction Division took charge of the upkeep and operation of the heating and lighting plants, the sewer and water systems, and the roads. Thus, the Army entered and occupied a completed city in working order, with an adequate fire protection system.

Provisions were made for supplying each of our men with 50 gal. of water per day and the animals with 15 gal., which exceeded the British, Belgian, Canadian, French, and German supplies by 80 per cent. The greatest care and sanitary precautions were exercised in the disposal of sewage and wastes by modern methods, so that not a single case of typhoid fever or other waterborne disease was traced by the Medical Corps to impurities of the camp water

* This Committee consisted of: A. N. Talbot, *Chairman*, then President, Am. Soc. C. E.; Charles T. Main, President, Am. Soc. Mech. Engrs.; E. W. Rice, President, Am. Inst. E. E.; John Laurence Mauran, President, Am. Inst. of Archts.; R. G. Rhett, President, Chamber of Commerce of the United States; Frederick L. Cranford, President, Associated Gen. Contrs. of America, Inc.; John R. Alpine, Representative, Am. Federation of Labor; and Oscar A. Reum, Representative, Bldg. Constr. Employers Assoc.

supplies. As evidence of the efficient measures taken for proper drainage, comfortable housing, adequate hospitals, mosquito control, sewage disposal, and pure water, it is noted in the Mexican War that the deaths from disease amounted to 110 per thousand men; in our Civil War, to 65 per thousand; and in the Spanish-American War to 26 per thousand. In July and August, 1918, when the camps and cantonments were in full operation, the death rate from disease was 2.8 per thousand, which was one-fortieth that of the Mexican War, less than one-twentieth that of the Civil War, one-tenth that of the Spanish-American War, and less than one-half the death rate for men of military age in civilian life. This was a remarkable record of splendid service by our sanitary and water supply engineers in the greatest emergency this country has ever known.

Hospitals to the number of 294 were provided at a cost of $128 000 000, with accommodations for 121 000 patients, 12 000 nurses, 4 000 doctors, and 34 000 enlisted men. For the Ordnance Department, 60 projects costing $175 000 000 were constructed, consisting of arsenals, ammunition storage plants, gas plants, industrial plants, and proving grounds. At Aberdeen, Md., the proving grounds had a plant for assembling gun carriages and artillery and the largest machine shop in the United States. The reservation contained 35 000 acres, with facilities for every conceivable test for guns and munitions; a bombing field; and a field of 4 000 acres with equipment and plant for the manufacture and testing of gas shells, which was known as the Edgewood Arsenal and cost $30 000 000. There were quarters at this plant for 12 000 men, with a gas-filling plant having a capacity of 120 000 loaded shells per day and facilities for the production of caustic soda, mustard gas, phosgene, and picric acid, on an enormous scale.

Among the larger projects built by the Construction Division and representing the best types of terminal port facilities, were the seven Army Supply Bases at Boston, Mass., Brooklyn, N. Y., Port Newark, N. J., Philadelphia, Pa., Norfolk, Va., Charleston, S. C., and New Orleans, La., at which were collected the vast stores for overseas shipment. They were connected by rail to the fourteen interior warehouses at industrial centers, such as Philadelphia, Pa., Baltimore, Md., New Cumberland, Pa., Pittsburgh, Pa., Schenectady, N. Y., Columbus, Ohio, Chicago, Ill., St. Louis, Mo., and Jeffersonville, Ind.

These Army Supply Bases were combinations of railroad terminal facilities, storehouses, and piers for transhipment by ocean-going vessels. The Brooklyn Army Base, of the multiple-story type and the largest one built, has three 8-story concrete warehouses connected with one open dock and three double deck piers, which provide loading or unloading berths for twelve 8 000-ton ships at a time, with the necessary railroad tracks and yards to facilitate operations. This project was completed in fifteen months at a cost of $30 000 000, and has a total net floor area of 113 acres. These seven Terminal Ports and fourteen interior warehouses have a combined storage floor space of 631 acres with an additional open-shed area of 50 acres. The docking space at the seven Terminal Ports is sufficient to berth 65 ships of 8 000-ton capacity at one time. Eight hundred and forty-four miles of railroad tracks and 1 061 miles of concrete roads serve these 21 projects, the total cost of which was $234 000 000.

In July, 1918, the War Department appointed a "Board of Review of Construction"* to advise on the methods and procedure for carrying on the war construction program and to investigate and report on the work which had already been done by the Construction Division and by all other Bureaus of the War Department. The Board worked for more than a year with its own engineers and assistants, had free access to Government and contractors' records, and visited personally more than fifty construction projects. It reported as follows:

"The Board finds that the use of this form of contract, as finally developed, was well justified and contributed to the success of the emergency program; that by its use, speed was obtained in war construction projects; and that it is probable that such work could not have been performed in the time available without it or its equivalent.

"The Board of Review endorses and commends the action of the War Department in placing its construction work under one Bureau, entirely separated from the combatant units of the army, conducted with a minimum of military control, according to modern business methods. The Board is of the opinion that such construction so placed was done with a remarkable speed, was superior in quality, was characterized by economy of design, and was as economically performed as the requirements of speed and other war conditions permitted. The facts ascertained and given in the accompanying report indicate that such construction performance contributed materially to the success of the army operations."

How well these engineers and constructors carried out a great emergency construction program, is set forth in the following extracts from the Secretary of War's Reports of November and December, 1917 and 1918, to the President of the United States:

"The assembling of an organization and the planning and execution of the work was undertaken with a view of accomplishing all that human ingenuity, engineering and construction skill could devise in the brief time available and involved construction work which was in itself, in view of the time limitation, an almost staggering task."

* * * * * * * * * *

"The preparation of places for the training of the recruits thus brought into the service, was a task of unparalleled magnitude."

* * * * * * * * * *

"In spite of the stupendous difficulties involved, the entire housing enterprise was completed on schedule time, consisting of one of the most remarkable accomplishments of the war."

Despoilers of Our Country

After all this the heart of our nation was saddened and our thoughts were mingled with hatred at the excesses and the indecencies of some of our politicians, the greatest menace to our Country and the most destructive agencies of our institutions.

It became politically expedient to discredit the War Administration, so Congress appointed the Graham Committee to investigate war expenditures. Three thousand pages of *ex parte* testimony were exhibited for public consump-

* This Board consisted of Francis G. Blossom, M. Am. Soc. C. E., of Sanderson and Porter, W. Saunders Davies, President, Am. Inst. of Accountants, and Charles A. Morse, M. Am. Soc. C. E., President, Am. Ry. Eng. Assoc., and Chf. Engr., C., R. I. & P. Ry.

tion at the October Criminal Term of the Supreme Court of the District of Columbia in 1922, and the Assistant Secretary of War, with the Chairman and five members of the Committee on Emergency Construction and Engineering, were indicted for conspiracy to defraud our Country in carrying out its war construction program. To quote in part from the Jury findings:

"* * * said conspirators procured said work to be done at great expense to the United States by civilian engineers and their assistants, and consulting engineers and town planners, selected by said conspirators at large fees and great expenditure of the public funds of the United States, the aggregate amount thereof to the grand jurors unknown, but which they charge was in excess of one million dollars."

Relating to the findings of the Talbot Committee:

"* * * At Washington, D. C., in said District, in aid of inducing and procuring the continuance of the system of cost-plus contracts, awarded without competitive bidding, said Defendant, William A. Starrett, about March 12, 1918, named and procured to be appointed by Defendant Benedict Crowell, as Acting Secretary of War, a committee, of which committee, certain members were interested in such contracts and system, ostensibly to investigate and report on the merits of said plan and system, which committee assembled on March 14, 1918, and reported on March 15, 1918, by adopting substantially as their report extended written statements and arguments made to them by said Defendant William A. Starrett and one Richard C. Marshall, Jr., then at the head of the Construction Division of the Army; to which report, as though it were a report of a thorough and impartial investigation, wide publicity was given."

Relating to the report of the Board of Review of Construction:

"* * * At Washington, D. C., in said District, about June 24, 1918, regardless of the interests of the United States, and in aid of procuring the indefinite continuance of the use of the cost-plus system of contracts without competitive bidding, said Defendants William A. Starrett and Clair Foster named and procured to be appointed by Defendant Benedict Crowell, as Assistant Secretary of War, a second committee composed of persons interested in said plan and system, ostensibly to investigate and report on said plan and system, and said conspirators then procured wide publicity to be given to such committee's report, as though said report was that of a disinterested and impartial investigation."

The Defendants entered demurrers to these criminal indictments and were sustained by Justice Hoehling, of the Supreme Court of the District of Columbia, in the following ruling:

"Accordingly, the Court is of the opinion, and so orders, that the demurrers filed herein be, and the same hereby severally are, sustained."

Civil suits amounting to $55 000 000 were brought against eleven of these cantonment contractors in 1922 by the Attorney General and, later, an additional suit was instituted, all charging a waste of public funds with the result that the men who built these cantonments, were without justification virtually and publicly branded as traitors. Many technical societies and similar organizations followed the lead of our Society and passed resolutions demanding of the Attorney General that he prove his allegations.

Primed with political chicanery and lacking in bills of particulars attempting to show how public funds had been squandered, only one of these suits ever

reached a jury. Within 3 min. after the Court's charges were concluded, the Jury returned a verdict for the Defendant. The Attorney General did not subpœna the former responsible officers of the Government in his attempt to prove his charges, and the following former officers appeared for the Defendant: The Secretary of War; the Chief of the Construction Division of the Army; the Chairman and Consulting Engineer of the Committee on Emergency Construction and Engineering, and the Construction Quartermaster; the Supervising Engineer and the Supervising Auditor on the job.

Yet it was ten years after the cantonments were completed and five years after these suits were instituted when the administrator of the Department of Justice finally took action to dismiss the remaining eleven suits.

The criminal indictments of the Assistant Secretary of War and of the Committee on Emergency Construction and Engineering, the clearly implied charges of conspiracy against our outstanding and nationally known engineers, and the suits instituted against twelve of our competent cantonment contractors, indispensable in turning the tide of war, were brazen exhibits of political indecency and a slander on the patriotism of our people. The toleration of such conditions is a menace to our Country.

MEMOIRS OF DECEASED MEMBERS

DESMOND FITZ GERALD, Past-President, Am. Soc. C. E.*

DIED SEPTEMBER 22, 1926.

Desmond FitzGerald was born on May 20, 1846, at Nassau, New Providence, Bahama Islands. His father, an officer in the British Army, in which he attained the rank of Captain, was born at Turlough Park, in the western or northwestern part of Ireland, of Irish gentry. Desmond FitzGerald, in 1901, went to this region, enjoyed a pleasant visit with cousins and other relatives, and was able to trace his family back through several generations. The lands which had been long in the family retained several interesting ancient landmarks.

His maternal grandfather, a native of Scotland, had been Judge of the Court of Admiralty and President of His Majesty's Council at Nassau. His mother, although born in Nassau, came of Colonial stock and through her he was a descendant in the seventh generation from Roger Williams, a prominent figure in New England history, who, when banished from Massachusetts on account of his religious and political opinions, established the City of Providence, R. I., and the First Baptist Church there. He secured to Providence Plantations full power to rule themselves, and was the first Governor of Rhode Island. As late as 1923, Desmond FitzGerald owned several lots of land in Providence, part of a tract which was granted to Roger Williams and had never been out of the family.

Mr. FitzGerald thus had an unusually fine inheritance, and it is not to be wondered at that he was able to maintain an independence of action and to secure a freedom from improper interference with his duties as Engineer or Superintendent by members of committees or commissions whose experience was political rather than technical. His success in this way was so striking that it became the subject of comment.

In 1848, after the death of his grandfather, the family moved to Providence, where they lived for many years.

Mr. FitzGerald's early education was received in the public schools of Providence. He did not receive college training either in the arts or engineering. Following his Providence schooling, he spent a year studying art in France, as at that time he desired to become a sculptor. On his return to the United States he entered Phillips Academy, at Andover, N. H., from which he was graduated in 1864. At this fine Academy he evidently improved his opportunities to learn how to study and acquired the habit of thoroughness. After a short interval, and while still under age, he became Deputy Secretary of the State of Rhode Island, and, in 1866, was Private Secretary to General Burnside, then Governor of the State. During this period he found time to engage as "student" in the engineering office of Cushing and Dewitt.

* Memoir prepared by the following Committee: George F. Swain, Past-President, Am. Soc. C. E., and C. Frank Allen, M. Am. Soc. C. E., and William E. Foss, Esq.

Here, again, he was fortunate, or wise, for the Cushing office was for many years the leading engineering office in Providence.

In 1867, he was enterprising enough to start West to seek his fortune, first as Axeman on the Indiana and Vincennes Railroad. It has been stated that the fact that his stakes were better formed and better marked than was usual brought him to the notice of his Chief. A mastery of Henck's Field Book also gained him a desirable reputation, and within a year he became Locating Engineer. He was engaged on various railroads in the Middle West as Locating, Division, or Assistant Chief Engineer, and for a time was in the Federal employ on river improvement work.

In 1871, he returned to Boston, Mass., residing in Brookline where he lived until his death. He soon became Engineer of the Boston and Albany Railroad, accepting this position, which was none too well paid, in preference to a Government position on construction in Boston Harbor; also, in preference to a partnership in an architect's office. Much important construction work was in progress on this railroad, and Mr. FitzGerald, still a young man, was fortunate in having as Consulting Engineer the late Edward S. Philbrick, M. Am. Soc. C. E., upon whom he could rely in part.

His work on this railroad brought him in contact with the late Joseph P. Davis, M. Am. Soc. C. E. This led to his appointment as Superintendent of the Western Division of the Boston Water-Works, which included the Brookline and Chestnut Hill Reservoirs, Lake Cochituate and the connecting aqueduct, embracing substantially all the sources of supply of the city. This position he held from 1873 until 1898.

While in office as Superintendent, he was the active factor in overcoming a reluctance on the part of the City authorities (other than the City Attorney, who supported him) in bringing suit to secure elimination of pollution of the water supply, partly by manufacturing wastes and partly by municipal sewage. This was the case of Pegan Brook in Natick, Mass. Upon Mr. FitzGerald fell the task of securing evidence and tracing actual cases of pollution to their source. The case, perhaps the first of its kind in the United States, after seven years of litigation, resulted in a final decision by the Supreme Court of the State in favor of the City of Boston.

Desmond FitzGerald was the pioneer in the study of color in water and methods of reducing it, resulting in the draining of swampy lands within the water-shed contributing to the water supply, and also to take advantage of the sunlight in bleaching storage waters, as well as stripping top soil and humus from reservoir beds.

He was the first to establish a biological laboratory in connection with water supply and to study especially the bacteriology of water, employing the late George C. Whipple, M. Am. Soc. C. E., then a young graduate in civil engineering, to carry on that work. This was the first and for many years the only biological laboratory operated in this country in connection with a water-works system. He made other studies and investigations in hydraulic engineering, along lines closely connected with his work. His paper on

"Evaporation"* received the Norman Medal in 1887, and has recently been closely confirmed by laboratory experiments. A later paper, "Rainfall, Flow of Streams, and Storage",† also received the Norman Medal, this time in 1893. Other worthy papers along similar lines were presented by him before this and other societies. His studious habit of mind is well attested by these papers and his investigations while in the employ of the City or the later Commission.

When the old system of supply for Boston was absorbed under the newly created Metropolitan Water Board in 1898, its Chief Engineer, the late Frederic P. Stearns, Past-President, Am. Soc. C. E., retained Mr. FitzGerald as Engineer of the Sudbury Department. During his employment with this Board it was understood and provided that he was free to act as Consulting Engineer for other municipalities, and he was actively engaged in this outside work.

During his terms of service on the water supply of Boston he had charge, as Resident Engineer, of the construction of some of the most important storage reservoirs of the System.

In 1902 he resigned from the position which in one form or another he had held since 1873. Previous to this time he had been given leave of absence for six months in 1899 to become Consulting Engineer to the Chicago Drainage Canal, at a salary reputed to be the largest paid to any civil engineer up to that time.

Mr. FitzGerald was a member of a Commission under the Secretary of War, to investigate the Lydecker Tunnel, designed by the United States Corps of Engineers, and then under construction for the water supply of the City of Washington, D. C. The City of San Francisco, Calif., also employed him in connection with its water supply in the important matter known as the Hetch Hetchy case.

He served as Consulting Engineer on the water supply and sewerage of Manila, in the Philippines, involving many questions comparatively new in character. Incidentally he was of considerable assistance in connection with an important highway project there. Later, he was called as one of the experts for the Metropolitan Sewerage Commission of New York with relation to the proper standard of purity for the waters of New York Harbor.

He acted as Consulting Engineer for a considerable number of cities and towns in other States as well as in Massachusetts. He was also retained, and appeared as expert, in a number of noted water cases.

An invitation to become a Lowell Institute Lecturer in Boston is a recognized honor, and Desmond FitzGerald delivered four lectures in a course of twelve on Engineering, his subject being "Water-Works." That his record as a civil engineer was highly distinguished cannot be questioned.

He also set a high standard of public-spirited citizenship. For the Commonwealth of Massachusetts he served for several years as Chairman of the Topographical Survey Commission under the direction of which the New

* *Transactions*, Am. Soc. C. E., Vol. XV (1886), p. 581.
† *Loc. cit.*, Vol. XXVII (1892), p. 253.

York-Massachusetts State line was re-run. This was made difficult by the fact that the important State monuments had been forcibly removed and shifted far from their proper positions. The difficulty was overcome and the line, although at first rejected, was afterward accepted by the State of New York. The re-setting of town bounds also presented problems which were successfully met. He was an active and a valuable member of the Metropolitan Improvement Commission of Massachusetts, in which capacity he not only gave much attention to railroad problems, but also made a study and a report on foreign harbors.

In the Town of Brookline, where he made his home, Mr. FitzGerald was Chairman of the Park Commission from 1897 until his health made it advisable for him to retire in 1926. He was also President of the Civic Society of Brookline and was one of the Trustees of the Public Library from 1887 to 1926. He was one of the Trustees of the Walnut Hills Cemetery, under town control from its establishment in 1875. He and the two other members first appointed served continuously together for more than fifty years until his death.

When the Town Meeting became so large that a smaller representative body was elected, he was chosen as a member, and had much influence in its meetings. He was unusually effective in securing what he felt was needed in connection with his official interests even when considerable opposition was manifested. During the World War he drilled with the local unit, lectured on patriotism, and was otherwise active for the cause.

Not altogether from self-interest, Desmond FitzGerald was a member of many societies and semi-public bodies, not all of them professional; he gave as well as received.

He was, at the time of his death, third in seniority of service on the Corporation of the Massachusetts Institute of Technology, on which he was an active and influential member; a Fellow of the American Academy of Arts and Sciences; Fellow of the Royal Meteorological Society of England; an officer in the New England Meteorological Society; member of the Council of the Society of Colonial Wars, of the Massachusetts Society of Sons of the American Revolution, and of the New England Historical Genealogical Society, to which he contributed in 1911 a booklet showing much research as to his ancestry both in Ireland and the United States. He was also a member, and at one time Councillor (on Art), of the Appalachian Mountain Club, with the interests and activities of which he had a natural sympathy. In 1925, in his eightieth year, he spent the summer months in the mountains of the Pyrenees, traveling partly on foot, partly on mule-back.

Desmond FitzGerald was a lover of art. When eleven years old he went to Paris and spent a year there in school. His cousins with whom he resided were people of wealth and influence, and this, in connection with the opportunities which Paris afforded, may have had great influence on his taste for art and his love of it. He seemed then much interested in sculpture, but finally chose engineering as a career. He could undoubtedly have been an artist of note had he chosen that field. His circumstances as well as his taste

and temperament, later in life, qualified him to become a patron of art as well as a connoisseur and critic, and in these combined capacities he was a leading figure around Boston. Dodge MacKnight, a brilliant water color artist, most highly regarded in Boston, received his first substantial recognition from Mr. FitzGerald, who not only led in public encouragement of the artist, but also acquired and owned three-score of his pictures, covering various stages of his development; and, in addition, he was the author of a monograph on Dodge MacKnight, privately printed and circulated.

Desmond FitzGerald also was among the first in this country to appreciate the early impressionist, Claude Monet, and others who followed in the same school. He was on terms of personal friendship with MacKnight and Monet, and also with John Singer Sargent.

To accommodate his paintings, he built an art gallery, 27 by 61 ft., adjoining his residence, which later proved all too small for his collection. This gallery was open to the public. He was a Trustee of the Boston Museum of Fine Arts. Following his death, the Trustees adopted the minute of which a part is as follows:

"By the death of Desmond FitzGerald on the twenty-second of September the Museum lost a friend who was deeply interested in its work. In 1916 he was appointed a member of the Board of Trustees by the Institute of Technology, a position which he held up to the time of his death. From 1914 he was a member of the Visiting Committee of the Department of Paintings, and for the last seven years of his life he served as its Chairman. He was affiliated with a great variety of institutions and commissions, and was more or less associated with all the societies that had to do with art in Boston. As a member of the Copley Society he was for years the Treasurer of the committee that had charge of its many memorable loan exhibitions; and he was always generous in lending his own pictures to those exhibitions, and in lending them to other exhibitions where he thought the public would have a chance to see and enjoy them. He had great sympathy with young painters, and he bought their work and did all that he could in other ways to help and encourage them. He was an extensive traveler and traveled intelligently, for he cared for the things he saw from the point of view of an artist as well as from that of an engineer. He loved Nature and even more he loved its pictorial representations, and in his museum in Brookline he had a remarkable collection of modern landscapes and other paintings, and some fine examples of Oriental pottery. He was an optimist enamored of the fine arts, and was kindly, courteous, and cheerful, for to him art was always a joyful inspiration—an inspiration that added greatly to his gaiety and happiness throughout his long and useful life."

Mr. FitzGerald was not without ability as an amateur artist, and his crayon portraits of members of his family were to be seen on his walls. He traveled much, and his artistic taste and his skill as a photographer resulted in several interesting illustrated lectures, mainly if not altogether to his friends, personal and professional.

His professional activities were constant. He was active in the revival of the Boston Society of Civil Engineers in 1873 and 1874, and was among the earliest of the younger men to be elected President. Later, he was elected an Honorary Member. For many years he had made a liberal annual contribution to the Society's permanent fund, and remembered it in his will. He

also, in 1910, established a fund for the award of a bronze medal annually to the author of the best paper of the year; a medal of bronze which could be kept in sight, rather than of gold usually placed in a safe for protection, the honor rather than the value being the essential point.

Mr. FitzGerald had been President of the New England Water Works Association, and Honorary Member of the American Water Works Association, and was also a member of the American Institute of Consulting Engineers.

As President, Honorary Member, and twice Norman Medallist of the Society, he attained a unique distinction. His standing as an engineer is secure.

Of clubs, he had membership in the Union, St. Botolph, Boston Art, Engineers', and the Country Club of Brookline. At the time of his death he was Senior Warden of St. Paul's Protestant Episcopal Church, of Brookline.

Slight in stature, he had an abundance of physical and mental energy, and accomplished much in the various lines of his activities, and his genial presence supplemented his other fine qualities. As a public citizen, few gave more for the betterment of the community. In his love for art and its encouragement, and in his church work, he qualified in the finer things of life, artistic and spiritual.

Desmond FitzGerald was married in 1870 to Elizabeth E. C. Salisbury, and is survived by two daughters and two sons.

He was much more than a mere technical engineer. He was a broadly cultivated man with many points of contact outside of engineering. He was thoroughly human, not enclosed in a rigid shell of mathematics or technical detail. Great as he was in engineering, he could have been great in other fields. He was delightful as a companion and had hosts of friends, in the hearts of whom his passing will leave a void which can never be filled.

Mr. FitzGerald was elected a Member of the American Society of Civil Engineers on September 3, 1884, and an Honorary Member on October 15, 1923. He served as Director from 1892 to 1894, as Vice-President from 1895 to 1896, and as President in 1899.

JAMES EKIN ALLISON, M. Am. Soc. C. E.*

DIED SEPTEMBER 19, 1926.

James Ekin Allison was born at Xenia, Ohio, on May 10, 1865. He was the son of Matthew Corey Allison, a manufacturer at Xenia, and of Frances (Ekin) Allison. He attended the public schools of Xenia and prepared for Harvard University, at Andover, Mass. He received the degree of Bachelor of Arts at Harvard in 1887.

Mr. Allison's first professional experience was as Manager and Engineer of the Xenia Gas, Light and Coke Company, which position he held for two years. He left this work to become Manager and Chief Engineer of the Southern Manufacturing Company, at Nashville, Tenn. This and miscellaneous enterprises occupied his attention until the Spanish-American War, when he was appointed Captain and Adjutant of John Logan's Volunteer Illinois Cavalry.

From 1898 to 1907 Mr. Allison practiced as a Consulting Engineer in St. Louis, Mo. During this period he was employed by the Louisiana Purchase Exposition and invented the gates which were used at that Exposition, to record, at a central control office, the entrance of each person passing through them. In 1907, he became Head of the Department of Boilers and Elevators and Chairman of the Board of Engineers for St. Louis. He held this latter position until 1909, when he was appointed Commissioner and Chief Engineer of the St. Louis Public Service Commission, in which capacity he served until 1913. From 1913 until his death, he maintained an engineering office in St. Louis, where, as a Consulting Engineer, he specialized in public service valuation work. In this work he became very well known and was called upon by utilities and municipalities in all sections of the United States and Canada. Many of the largest utilities in the country came to him as clients, and among the municipalities were St. Louis, San Antonio, Tex., and New Orleans, La.

Mr. Allison held the principle that "reproduction new" costs should govern in finding the value of the physical items of a plant. His belief in this principle was founded on a deep and careful study of economics. He was an early and outstanding opponent of the theory of depreciation based on the so-called straight-line method.

He wrote many treatises and articles on valuation and other economic subjects. The most noteworthy of these are "Analysis of Rate Calculations" (1910); "Ethical and Economic Elements in Public Service Valuation" (1912); "Should Public Service Utilities Be Depreciated to Obtain Fair Value in Rate or Valuation Cases" (1912); "Rate of Return" (1914); "Criticism of Theoretical Depreciation" (1915); and "Theoretical Depreciation" (1917).

He held membership in a number of social clubs and learned societies. Among his other technical affiliations the following may be mentioned: Engineer's Club of St. Louis, American Institute of Consulting Engineers, and

* Memoir prepared by the following Committee of the St. Louis Section: Messrs. Edward Flad, *Chairman*, J. H. Porter, C. E. Smith, Members, Am. Soc. C. E., and H. J. Pfeifer, Esq.

American Society of Mechanical Engineers. He also was, for several years, a member of the Faculty of Washington University, at St. Louis.

Mr. Allison had an active and keenly analytical mind which delighted in discussions of abstract theories and the effort required to ally them with every-day practical problems. In his valuation work he strove to fasten all his methods to basic economic principles. His efforts were to establish methods whereby values could be ascertained that would be true in all cases, for the future as well as for the present. His forceful and attractive personality made many sincere and enduring friendships.

On October 15, 1895, he was married to Jeanie Bass, of Nashville, Tenn. He is survived by his widow and one child, Frances Allison Porter.

Mr. Allison was elected a Member of the American Society of Civil Engineers on October 1, 1913.

CHARLES IRVING ANDERSON, M. Am. Soc. C. E.*

DIED JUNE 15, 1927.

Charles Irving Anderson was born on July 27, 1878, at Fahlun, Sweden. While still a child he came to America with his parents, who settled in Georgetown, Colo., where Mr. Anderson attended the public schools. He received his technical training at the University of Colorado, at Boulder, Colo., from which he was graduated in May, 1905, with the degree of Bachelor of Science in Civil Engineering.

Mr. Anderson's experience in engineering work, as exemplified in mining and tunneling and the use of mining tools, began prior to the time he entered the University of Colorado. As early as 1898, he was engaged in mining operations and contracted for tunneling work, which contracts he fulfilled both before entering college and during his vacation periods as a student.

Immediately after his graduation in June, 1905, he took charge of a field party in the service of the U. S. Coast and Geodetic Survey. He continued in this work until he entered the Engineering Department of the Illinois Central Railroad System in November of that year, as Masonry Inspector on concrete bridge and retaining wall construction.

In June, 1909, Mr. Anderson left the employ of the Illinois Central Railroad Company to become Superintendent of Construction for shops then being built by George B. Swift Company, at Macon, Ga., for the Central of Georgia Railway Company, and, in March, 1910, he again changed employers to act as General Foreman for the Bates and Rogers Construction Company on the building of subways, retaining walls, conduits, and signal bridges in connection with its contract on the Passenger Terminal of the Chicago and North Western Railway Company, in Chicago, Ill.

In December, 1910, Mr. Anderson returned to the Illinois Central System and was engaged in engineering work with that Company until his death, with the exception of a short period from March 11 to September 30, 1918, when he was given a leave of absence to assist in the construction of the U. S. Government Explosives Plant C, at Nitro, W. Va.

His duties with the Illinois Central Railroad Company were in connection with construction, valuation, and special work relating to ordinances and other matters, sometimes of a technical and at other times of a diplomatic nature. His judgment in matters assigned to him for handling and solution was usually approved by his superiors without question.

At Nitro, his opinions were particularly sought, especially as to foundation conditions, although he was also in charge of roads, drainage, and building construction, subject to orders from the Director.

In the winter and early spring of 1926, Mr. Anderson's health began to fail quite noticeably, and it was thought that a change of climate might be of some benefit. Accordingly, in June, 1926, he was transferred, at his own request, from the position of Assistant Engineer of Buildings in Chicago to

* Memoir prepared by W. C. Pauli, Assoc. M. Am. Soc. C. E.

that of Assistant Engineer in charge of track elevation and new passenger facilities at Clarksdale, Miss., and he was so engaged when he was stricken with the illness which culminated in his death. This work, his final assignment, was practically completed at that time.

Mr. Anderson had the happy faculty of making loyal friends, but he also gave loyalty and friendship in prodigal fashion. He seemed to see the best side of a person's character, and was always ready to defend those he knew against attacks reflecting on their ability or integrity.

His life was marked by devotion to his family. Mrs. Anderson survives him, with six children, three sons and three daughters.

He was a member of the Tau Beta Pi Fraternity; Georgetown Lodge No. 12, A. F. and A. M., Georgetown, Colo.; Western Society of Engineers; Structural Engineers Association of Illinois; and the American Railway Engineering Association.

Mr. Anderson was elected a Member of the American Society of Civil Engineers on January 13, 1919.

WARREN MARTIN ARCHIBALD, M. Am. Soc. C. E.*

DIED JANUARY 16, 1928.

Warren Martin Archibald, the son of Charles D. and Martha R. Archibald, was born in Medford, Mass., on August 25, 1876. After receiving his preliminary education, Mr. Archibald was registered from 1895 to 1899 as a Special Student at the Massachusetts Institute of Technology, at Cambridge, Mass. During the summers he was employed as Rodman for the New York and New England Railroad Company, and also for the City of Medford. After leaving college, he was engaged as Rodman and Instrumentman for the Metropolitan Water-Works, in Boston, and Clinton, Mass.

In 1900, he entered the employ of Ford, Bacon and Davis, Consulting Engineers of New York, N. Y., remaining with this firm until 1908. During this time he acted as Draftsman and Designer on street railway construction, in Atlanta, Ga., later taking full charge of lines, grades, and construction for one division of track work in Birmingham, Ala. Subsequently, he went to Kansas City, Mo., where he was engaged as Chief Designer of special track construction and Resident Engineer on tunnel reconstruction, in charge of the building of three bridges across the Kaw River. From 1904 to 1908, he was in charge of track and building construction for the Nashville Railway and Lighting Company, in Nashville, Tenn. This work included the design and construction, with Company forces, of steel and concrete structures for a fireproof car barn and terminal building, power-houses, bridges, etc., valued at $2 000 000.

In May, 1908, Mr. Archibald returned to New England, where he served as Resident Engineer on the construction of a 12-mile, high-pressure pipe line and temporary dam and intake, in New Britain, Conn. In 1909, he acted as Superintendent for the contractor on dam construction, in Russellville, Ark.

During the following two years he was again with the firm of Ford, Bacon, and Davis, as Resident Engineer in Houston, Tex., on the design and construction, with Company forces, of a new underground conduit system, complete, with the necessary sewers, manholes, paving, wires, transformers, poles, etc., for operating the entire system.

In 1911, Mr. Archibald was appointed Engineer of Maintenance of Way with the Houston Electric Company, at Houston, in full charge of all track and overhead line construction. This work included paving, drainage, and public relations as well as the usual track and overhead problems. He was also engaged in a consulting capacity with the Galveston-Houston Interurban Railway Company.

From June to September, 1917, he served as Superintendent of steam railroad track construction at Camp Travis, San Antonio, Tex., after which he again entered the employ of Ford, Bacon, and Davis, as Senior Engineer in charge of field and office work in the Report and Valuation Department. His work consisted of reports on public utilities, inclusive of all the States east

* Memoir prepared from information on file at Society Headquarters.

of the Rocky Mountains and foreign countries. These reports related to financing, rate cases, etc., and demanded a complete inspection of the properties as to their condition and maintenance as well as to the general business conditions in the immediate vicinity. During 1920, he was Assistant to the Chief Engineer on the report and design for a water supply system, sewer system, and sewage disposal for the Cities of Athens and Pireaus, Greece. He also made two trips into Honduras on valuation reports and the inspection of railroads and tram tracks, together with the shops and their equipment.

In 1924, Mr. Archibald resigned his position because of ill health caused by an attack of influenza some years before. He took a year's needed rest, and in June, 1925, entered the employ of Henry A. Symonds, M. Am. Soc. C. E., as Resident Engineer at Lynnfield, Mass. In 1926, he was appointed Assistant Engineer in the City Engineer's Office at Medford, and was made Acting City Engineer in December of that year. Just previous to his death, he had been told of his appointment as City Engineer.

He was a member of the Houston, Tex., Lodge of the Benevolent and Protective Order of Elks and of the Kiwanis Club and Mount Hermon Lodge, A. F. and A. M., of Medford. His church affiliations were Unitarian.

Mr. Archibald was quiet and unassuming, of a stern integrity, and always loyal to friend or employer. A former Chief Engineer, with whom he had been associated for several years, says of him,

"We have been through many a hard campaign together and no one knew better than I his sterling qualities as a man and his remarkable ability as an engineer".

He was never married, and is survived by his sister, Jennie S. Archibald, of Medford, Mass.

Mr. Archibald was elected a Member of the American Society of Civil Engineers on January 3, 1911.

THOMAS WILLIAMS BALDWIN, M. Am. Soc. C. E.*

DIED SEPTEMBER 29, 1926.

Thomas Williams Baldwin, the son of Thomas Williams and Margaret Josephine (Bacon) Baldwin, was born on December 27, 1849, at Bangor, Me., where his parents were then residing.

He was a descendant on his mother's side of Stephen Hopkins who came to America on the *Mayflower* and on his father's side of Thomas Cushing who was a member of the Continental Congress, as well as Acting Governor of Massachusetts in 1785, and of John Avery, Secretary of State in Massachusetts for several terms in Revolutionary times.

Mr. Baldwin prepared for college at Phillips Academy, Exeter, N. H., from which he was graduated in 1869. He was graduated at Harvard College in 1873, and, in 1874, entered the Junior Class of the Massachusetts Institute of Technology, from which he was graduated in 1876 with the degree of Bachelor of Science. During vacations in his college years he served as Rodman and Transitman on surveys for the European and North American, and the Bangor and Piscataquis Railroads.

In 1878, Mr. Baldwin opened an office in Bangor, Me., for the practice of his profession, and was Acting City Engineer until March, 1879, when he was elected City Engineer, which position he held until 1883. Declining further service in that office he accepted the position of Division Engineer on the Bangor and Piscataquis Railroad extension work, but retired after a few months' service on account of illness. Upon recovery he returned to private practice in his Bangor Office.

In 1895, he removed to Boothbay Harbor, Me., to engage in business and, in 1903, became President of the Baldwin Fish Company, which position he held until he removed to Boston, Mass., in 1908.

While in Boothbay Harbor Mr. Baldwin served for ten years on the School Committee, and was a Representative for two terms in the Maine Legislature. He was also a Director of the First National Bank and a Corporator of the Savings Bank of Boothbay Harbor.

On removing to Massachusetts, he became actively interested in genealogical research and published a genealogy of William Patten, who, in 1636, settled in Cambridge, Mass.; also one of Michael Bacon who was in Natick, Mass., in 1640. In addition, he edited and published with a memoir the "Revolutionary Journal" of Col. Jeduthan Baldwin, his great-grandfather. He also compiled and published the vital records of twenty-one Massachusetts cities and towns, a lasting monument to his patient and persevering labors.

Mr. Baldwin held minor positions with the Highway and Civil Service Commissions of Massachusetts, after taking up his work of compiling vital records, but the state of his health did not permit active practice of his profession.

* Memoir prepared by John Carroll Chase, M. Am. Soc. C. E

Although of a retiring disposition he always had a keen interest in people and in public events; and was patriotic, affectionate, and loyal. His liking for historical and genealogical matters made his later occupation very congenial to his tastes. In his more active years, he had traveled extensively throughout the United States and Canada.

Mr. Baldwin was a Life Member of the American Unitarian Association and was affiliated with the Republican party. He was also a member of the New England Historic Genealogical Society, the Sons of the American Revolution, and the Society of the Cincinnati.

After a short residence in Boston he lived in Wellesley, Cambridge, and Hardwick, Mass., where the end came after several years of failing health.

On December 8, 1880, he was married to Maud, daughter of John and Emeline (Young) Patten, of Bangor, who survives him, with two daughters, Mrs. Chalmers Stevens Clapp, of Abington, Mass., and Miss Dorothy Arno Baldwin, of Hardwick. He also leaves four grandchildren.

Mr. Baldwin was elected a Member of the American Society of Civil Engineers on April 2, 1884.

THOMAS HOWARD BARNES, M. Am. Soc. C. E.*

DIED NOVEMBER 15, 1927.

Thomas Howard Barnes was born in Waltham, Mass., on December 15, 1860, the son of Phineas H. and Elizabeth Howard (Miles) Barnes. His childhood was spent on a farm and his early education was obtained in the public schools of Waltham. In 1877, he entered the Massachusetts Institute of Technology, with the Class of 1881, but lacked sufficient means to continue after the second year.

His first professional position was as an Assistant Engineer in the office of the City Engineer at Cambridge, Mass. After five years in this position, he returned to Waltham as Inspector of Plumbing for the Board of Health. He was also engaged in private practice as a Civil Engineer.

In 1887, Mr. Barnes went to Alabama to lay out and plan the Town of New Decatur. The following year he went to New Birmingham, Tex., where for four years he was employed in similar work.

After a brief period in the City Engineer's office, in Newton, Mass., he again engaged in private practice in Waltham. While there, he was appointed Engineer of the Medford, Mass., Sewerage Commission, in charge of the design and construction of the sewers of that city. This was followed by his appointment as the first City Engineer of Medford. In 1900, he resumed private practice, this time in Boston, Mass., where for the next four years he specialized chiefly in sewerage and water-works design and construction.

In 1904, Mr. Barnes made his first trip to tropical countries, in which field he was later to become an authority. His mission included the study and design of water supply and sewage disposal systems in the Cities of San José and Puerto Limon, Costa Rica. He then went to Bocas del Toro, Panama, to undertake the filling and sanitation of that port. The site of the town was a mangrove swamp, which made it necessary for all buildings to be erected on piles; elevated plank walks served as streets, and the ebb and flow of the tides was the sole and dubious means of sewage disposal. A sea-wall was built around this town, sewer pipes were laid, and sand, which had been dredged from the harbor bottom, was pumped in. Thus, the transformation from an unlivable jungle site to a healthy town was complete. Mr. Barnes later served as Engineer on other projects of a similar nature.

While engaged in the work at Bocas del Toro, Mr. Barnes was retained by the United Fruit Company to design and construct a wharf at Almirante, Panama, which town was the outlet for the banana trade from the Company's entire Changuinola Division. This wharf, it is believed, was the first to be built of reinforced concrete, and, until its completion and a thorough demonstration of its reliability, was a source of concern to many engineers and practical construction men. Time demonstrated the soundness of the design, and to-day the wharf stands as an example of resistance to deterioration under unfavorable tropical conditions. Other wharves of a similar type were

* Memoir prepared by C. MacCallum, Esq., New York, N. Y.

designed and built in various ports of Central America, many of them by Mr. Barnes, until he came to be recognized as an authority on tropical wharf construction.

From 1908 to 1913, Mr. Barnes served both the United Fruit Company and the International Railways of Central America. His work included the design and construction of wharves, hospitals, warehouses, office buildings, water-works, sewer plants, and other projects in Guatemala, Salvador, Honduras, Panama, Colombia, and Jamaica. From 1913 to 1918, he acted as Consulting Engineer for these two companies, with headquarters in New York, N. Y., with frequent trips to Central America and the West Indies.

In 1918, he re-entered private practice as a Consultant on Tropical Engineering. During the ensuing nine years, he served such companies as the International Railways of Central America, the Demerara Bauxite Company, the Cuyamel Fruit Company, and the International Products Corporation, as well as several of the large oil companies, and various Latin-American municipalities and governments. His more important work included a $3 000 000 beef-packing plant and dock facilities at Covenas, Colombia; hospital designs for Santo Domingo, Dominican Republic, Maracaibo, Venezuela, Cartagena, Colombia, and Puerto Cortés, Honduras; railroad shops in Salvador and Guatemala; wharf construction at Puerto Barrios, Guatemala; work for the American Legation at San Salvador; and a harbor and dock improvement project of great magnitude in Callao Harbor, Peru, on which he was engaged at the time of his death.

During his twenty-three years' practice in tropical engineering, Mr. Barnes visited virtually every country and every important town in Central America and the West Indies. His grasp of the human and economic, as well as the strictly technical, aspects of tropical problems, gained for him the respect of the many important companies which he served. Time and again, it was necessary first to plan and provide sanitary measures, living quarters, water and food supply, and to import labor and the most elementary building material, before actual work on the project in hand could be started.

His consideration for the physical and mental well-being of his employees, high and low, and his unswerving fairness and loyalty to them, won for him, not only respect, but unalloyed affection. His knowledge of the Spanish language and the Spanish temperament, combined with a singular mixture of uncompromising uprightness and firmness of purpose, and his realization of the devious circumlocution necessary in negotiating with Latin-Americans, commanded for him widespread respect and prestige, and a measure of personal affection seldom accorded a "gringo".

The following tribute comes from his Class, Massachusetts Institute of Technology, '81:

"Howard was one among us who seemed to have discovered the fountain of perpetual youth. His sturdy figure and pleasant smiling countenance underwent little apparent change as the years rolled by. Youthful enthusiasm and the joyful zest for living were undiminished, and whenever he returned from the South Countries—after long or short absence—he slipped into his accustomed seat by the fireside of our friendship, quite naturally and without undue commotion.

"And so—for all his friends, men who knew him for a generation, or for some shorter period—Howard has gone back to his Far Country, but the seat by the fireside shall be his always."

On April 30, 1890, Mr. Barnes was married to Martha Middleton Simmons, of Rusk, Tex., who with a son, Harold Simmons, of Upper Montclair, N. J., and a daughter, Eleanor, of Yonkers, N. Y., survives him.

Mr. Barnes was a member of the Boston Society of Civil Engineers; the New England Water Works Association; the American Water Works Association; the American Public Health Association; and the American Association of Port Authorities. His clubs were the following: The Technology Club of New York; the Park Hill (Yonkers) Community Club; the Whitehall Club; and the Surf Club, of Cartagena, Colombia. He was a Trustee of the Church of the Divine Paternity (Universalist), New York, N. Y., and was also a Mason. On numerous occasions, he contributed technical articles, which were of genuine merit, to the various engineering societies.

Mr. Barnes was elected a Member of the American Society of Civil Engineers on October 4, 1899.

CORNELIUS CONWAY FELTON BENT, M. Am. Soc. C. E.*

DIED NOVEMBER 11, 1926.

Cornelius Conway Felton Bent was born in Boston, Mass., on July 3, 1849. He was the son of George Elbridge and Martha Conway (Felton) Bent, both natives of Massachusetts and descendants of old New England families of English extraction.

Mr. Bent was educated in the Latin School of Boston until his family moved to Philadelphia, Pa., where he entered Chase School, a private institution, from which he was graduated at the age of seventeen. Circumstances prevented him from following his ambition of attending Harvard University, of which his uncle, Cornelius Conway Felton, had been President at one time, and, in 1866, he entered the service of the Port Deposit and Perryville Railroad Company, in Maryland, as a Chainman. He continued with this Company until 1867 when he accepted a position with the Chester Creek Railroad Company, in Pennsylvania, having been, successively, Levelman and Transitman with this Company on location and construction work.

In 1869, Mr. Bent went West to become a Transitman on Location, and Engineer in Charge of Construction of the Lake Superior and Mississippi Railroad. He remained in the service of this Company until 1870, when he was appointed Chief Engineer of Location and Construction for the Lancaster Railroad Company, in Massachusetts. In 1875, he entered the service of the Pennsylvania Railroad Company as Assistant Supervisor and was promoted to be Supervisor in 1876. He remained with this Company until 1879, when he became Assistant Engineer for the Columbus, Chicago, and Indiana Central Railway Company, continuing with that Company until June, 1881.

At this point in his railroad career, Mr. Bent transferred his activities to the field of operation, holding, successively, the following positions: From June, 1881, to October, 1882, he served as Superintendent of the Chicago Division, of the Columbus, Chicago and Indiana Central Railway Company, and from October, 1882, to January, 1884, he was Superintendent of the New York and New England Railroad Company. From April, 1884, to October, 1885, he held the position of Superintendent of the Louisville, New Albany and Chicago Railroad Company, and from December, 1885, to 1889, he was Superintendent of the Ohio and Mississippi (now the Baltimore and Ohio) Railroad Company. Mr. Bent was engaged as General Superintendent of the Ohio and Mississippi Railroad Company from 1889 to February, 1894, when he was appointed Superintendent and General Agent of the Baltimore and Ohio Railroad Company at Philadelphia, where he remained until April, 1905.

From April, 1905, to January, 1907, he was General Superintendent of the Baltimore and Ohio Railroad Company at Baltimore, Md. In January, 1907, he was appointed General Manager and transferred to Cincinnati, Ohio, where he remained until July, 1910, when he was made Vice-President of the

* Memoir prepared by H. A. Lane, M. Am. Soc. C. E.

Staten Island Railway Company and General Superintendent of the Baltimore and Ohio Railroad Company, New York Division, at New York, N. Y. Mr. Bent held this position until January, 1916. In April, 1916, he was appointed General Agent of the Baltimore and Ohio Railroad Company, at Philadelphia, which position he held at the time of his death.

About eight years before his death, Mr. Bent was compelled to undergo a serious surgical operation which weakened him physically for the remainder of his life. His death resulted from pneumonia after an illness of only four days.

He was a man of sterling integrity, well liked by his associates and superiors, and famed for his justice and fairness to his subordinates. That he was also a man of great ability, is evidenced by his rise from one of the lowest to one of the highest positions in railroad service. He belonged to several New York and Philadelphia clubs.

Mr. Bent was elected a Member of the American Society of Civil Engineers on May 1, 1889.

CHARLES WALTER BRYAN, M. Am. Soc. C. E.*

DIED JUNE 25, 1927.

Charles Walter Bryan was born in Warren County, Missouri, on May 5, 1863. He was the second son of Archibald Bryan and Mary Elizabeth Sterigere, and a lineal descendant of Daniel Boone. The Bryan family came to Missouri about 1800 and were prominently identified in the early settlement of Kentucky and Missouri.

From 1869 to 1875, he attended private schools, and from 1875 to 1880 the public schools of Washington, Mo. During the summers from 1878 to 1880, Mr. Bryan worked on his father's steamboats, which carried supplies to the Upper Missouri and Yellowstone Rivers. During these trips as an Assistant Pilot he saw many phases of frontier life. In the fall of 1880 he entered Washington University, St. Louis, Mo., and was graduated therefrom with honor as a Civil Engineer in 1884. In 1905, Washington University conferred upon him the honorary degree of Master of Arts.

From July to November, 1884, Mr. Bryan was a Draftsman with the Pond Engineering Company, St. Louis. In November, 1884, he was called to the Edge Moor Iron Company, of Wilmington, Del., as a Draftsman by George H. Pegram, Past-President, Am. Soc. C. E., Chief Engineer. From November, 1885, to June, 1886, he was a Draftsman with the noted bridge engineer, the late C. Shaler Smith, M. Am. Soc. C. E., at St. Louis, and from June, 1886, to June, 1887, he was again a Draftsman with the Edge Moor Iron Company. From June to September, 1887, he was in the Bridge Department of the Missouri Pacific Railway, and, in September, 1887, he returned to the Edge Moor Iron Company as Engineer in charge of design and construction. During 1888, the Edge Moor Bridge Works was organized and Mr. Bryan continued his work with the new Company. He was appointed Chief Engineer in February, 1896, and retained this position until the Edge Moor Bridge Works was acquired by the American Bridge Company during 1900. At Edge Moor, he designed and had charge of the construction of the Wheeling Bridge, Wheeling Bridge and Terminal Railway; the Steubenville Bridge and Cincinnati Bridge, Pennsylvania Lines West; the Kenova Bridge, Norfolk and Western Railway; the Cincinnati Bridge, Cincinnati and Covington Suspension Bridge Company, and many other important structures.

During the Edge Moor period, Mr. Bryan developed unusual ability as a salesman, in addition to his skill in purely engineering work. The American Bridge Company appointed him as Agent, in the Railway Contracting Department, at Pittsburgh, Pa., and during 1901 he became Division Contracting Manager of the American Bridge Company of New York, at New York, N. Y. During 1906, he was appointed Chief Engineer of the American Bridge Company of New York, in addition to his duties as Division Contracting Manager. Early in 1911, he was relieved of his duties as Division Contracting Manager and appointed Chief Engineer of the American Bridge Company, which posi-

* Memoir prepared by Otis E. Hovey and C. G. Emil Larsson, Members, Am. Soc. C. E., and George H. Pegram, Past-President, Am. Soc. C. E.

tion he held at the time of his death. In this position Mr. Bryan was the executive and responsible head of the engineering organization of a large corporation engaged in the construction of bridges, buildings, and other structures in the United States and in many other countries. In addition to his engineering duties, he was frequently called upon for advice in matters relating to contracting.

Mr. Bryan was joint author with the late J. B. Johnson and F. E. Turneaure, Members, Am. Soc. C. E., of the well-known treatise, "Modern Framed Structures", first published in 1893.

He was one of the founders of the Huguenot Trust Company, in New Rochelle, N. Y., of which he was a Director and served as President from 1912 to 1915, and afterward as Chairman of the Board of Directors. He had also served on the Board of Education, the Board of Public Works, and the Park Commission of New Rochelle. He was one of the organizers of St. Paul's Protestant Episcopal Church, a Vestryman, and Chairman of the Building Committee.

"If a man die shall he live again?" It is generally believed that he will, and all agree that a man of such fine character as Mr. Bryan does live in his permanent influence for good. He was a gentle, modest, and friendly man whose qualities endeared him to all his friends and associates. He was considerate of the feelings and opinions of others, but had definite ideas of his own, and when it was necessary to insist upon them, he had a way of quietly leading one to his point of view in a shrewd and effective manner which left no sting of disappointment. His mind was keen and active, and he seemed to sense a situation almost by instinct. He had unusual ability to see another man's point of view, and it often seemed as if he penetrated hidden motives by intuition. He was gifted with a quaint and sparkling humor which made even a business interview with him a pleasure to be remembered. He had a genius for friendship in both business and social relationships. His friends were friends to the end, and there are many who will sadly miss the intimate associations of years.

In his earlier experience Mr. Bryan was largely occupied in the design of bridges. He had excellent technical ability and was accurate and very rapid in his work. His designs were marked by simplicity of construction and were well adapted to their economic use. In the later period, while Chief Engineer of the American Bridge Company, his executive responsibilities largely prevented him from undertaking actual designs. His work was rather to guide those associated with him toward better design and better methods of construction in the great number and variety of structures built by the Company. He was freely consulted by members of the Engineering Staff and by customers, their engineers, and others, and in this way his influence toward better engineering was greater and more widely felt than would have been possible if he had been engaged in private practice. He always sought for the best, and kept fully abreast and often in advance of the progress of engineering practice.

With his attainments as an engineer Mr. Bryan combined good business ability, and for many years his work was of a kind in which each was of equal

importance. He quickly established cordial relations with customers, and they became and continued to be his friends.

Mr. Bryan's personal qualities, his ability, and his keenness of mind were such that his influence on his associates was strong, and was particularly stimulating to younger men, in whom he was much interested. Many applied to him for advice and guidance, and he gave freely of his time and thought in their behalf.

Mr. Bryan maintained a growing interest in his Alma Mater, and did much for its advancement. He was one of the founders of the Washington University Alumni Association in New York, and frequently served as its President.

He was a good citizen and, as such, was always interested in public questions and gave liberally of his time whenever he found a way to be of service to the communities in which he lived. His public service was unselfish and for the good of all and never for his own advancement.

One cannot write the sum of the influence of the life of such a man as Mr. Bryan; but one can be sure that it is great and will continue. The members of the Engineering Profession are fortunate to have been able to count him among their number, and will remember him as another of the great men who have finished their work and left a record which will be an inspiration to those who follow.

In 1889, Mr. Bryan was married to Mary Elizabeth Shaw, daughter of David and Ann Poole Shaw, of Philadelphia Pike, near Edge Moor, Del. He is survived by his widow and by his four children, Charles W. Bryan, Jr., of New York, Philip D. Bryan, of Albany, N. Y., Mrs. William F. Washburn, of Rochester, N. Y., and Mrs. Lowell Milligan, of Worcester, Mass.

He was a member of the American Iron and Steel Institute, the American Society for Testing Materials, and the St. Louis Engineers' Club. He was also a member of the New Rochelle Yacht Club, the Wykagyl Country Club, and the Engineers' Club and the Railroad Club, in New York.

Mr. Bryan was elected a Member of the American Society of Civil Engineers on June 3, 1903.

GEORGE ANSEL CARPENTER, M. Am. Soc. C. E.*

DIED DECEMBER 15, 1927.

George Ansel Carpenter, the son of George Albert and Lydia Clark (Gage) Carpenter, was born on March 4, 1864, in what later became the City of Pawtucket, R. I. He was educated in the public schools, having been graduated from the High School in 1883.

On leaving High School, Mr. Carpenter entered the employ of the late D. Lawrence Wilkinson, a Civil Engineer of Pawtucket, and remained with him until August, 1888. Mr. Wilkinson became City Engineer when Pawtucket was incorporated as a City in 1886 and Mr. Carpenter became his First Assistant. From August, 1888, to February, 1891, he was Chief Engineer for the Board of Sewer Commissioners of that portion of the Town of Lincoln, R. I., which shortly afterward became the City of Central Falls.

In February, 1891, Mr. Carpenter succeeded Mr. Wilkinson as City Engineer of Pawtucket and held this position continuously until his death, during a period of nearly thirty-seven years. The City of Pawtucket increased in population severalfold during this time and his re-appointment year after year, regardless of the changes in political administration, is a striking tribute to his ability and to the universal confidence which he inspired, both among the politicians of all parties and among his fellow citizens. As City Engineer, he designed and supervised the construction of highways, sewers, water-works, bridges, and other municipal structures, and was called on and expected to advise regarding a variety of problems covering almost the entire field of municipal activities, both engineering and non-engineering.

From April, 1899, to May, 1911, Mr. Carpenter was also Chief Engineer on investigations for grade-crossing elimination in the Cities of Pawtucket and Central Falls, in which work the late Edwin P. Dawley, M. Am Soc. C. E., acted as Consulting Engineer. His plans were finally adopted, and the work was completed in 1915.

The sewer system of Pawtucket was designed and built by Mr. Carpenter, as were also the major additions to the original water-works. In recent years, routing of street traffic, street widenings, and improvements better to accommodate motor vehicles, systems of street signals, etc., occupied his attention, with a resultant marked improvement in a difficult traffic problem.

Although Mr. Carpenter devoted his entire professional life to his native city, refusing to be attracted by offers of more alluring financial rewards elsewhere, his interests were broad and his acquaintanceship large.

He was a member of the Boston Society of Civil Engineers for 33 years and of the New England Water Works Association for 17 years, and was President of the latter at the time of his death. He was also a member of the American Society for Municipal Improvements for 22 years and was active in its work. He was one of a small group who, in 1915, organized the Providence Engineering Society. This Society, which had grown to a

* Memoir prepared by Francis B. Marsh and Frank E. Winsor, Members, Am. Soc. C. E.

membership of 1 200 before he died, owes much of its marked success to his wise counsel and sustained interest. He served as its President in 1918-19.

Mr. Carpenter was a Past Master of Union Lodge No. 10, A. F. and A. M., and a member of the Holy Sepulchre Commandery, Knights Templar, of Pawtucket, and of Palestine Temple, Nobles of the Mystic Shrine, of Providence. He was a member of the High Street Universalist Society, of which he was President for about 20 years, a member of the Board of Trustees of the Pawtucket Memorial Hospital, and a member of the Pawtucket Lions Club.

He was a keen analyst, with an unusual facility of expression, carrying his points clearly and forcibly, but so kindly as to disarm opposition and to leave no sting among those at variance with him. He was extremely modest, with friendly qualities which endeared him to a multitude of lifelong friends, as well as to the younger men of the profession who were so fortunate as to be associated with him. His native city owes him a debt of gratitude which is inestimable, and his influence in the community will continue to live after him and be an inspiration to those who follow.

On January 5, 1888, Mr. Carpenter was married to Jennie Smith Shepardson, of Pawtucket, who, with two daughters, Gladys Randall (Mrs. Norman R. Earle) and Margaret Allyn (Mrs. Raymond C. Newton), both of Pawtucket, survives him.

Mr. Carpenter was elected a Member of the American Society of Civil Engineers on May 7, 1902.

REDMOND STEPHEN COLNON, M. Am. Soc. C. E.*

DIED OCTOBER 9, 1927.

Redmond Stephen Colnon, the son of John W. and Harriet (Perkins) Colnon, was born at Brownville, N. Y., on June 29, 1862. After his preliminary education, Mr. Colnon entered Cornell University, at Ithaca, N. Y., from which he was graduated in 1887, with the degree of Civil Engineer.

Soon after his graduation from college, he was engaged as Assistant Engineer in the office of the late Emil Kuichling, M. Am. Soc. C. E., at Rochester, N. Y. In 1889, he became Assistant Engineer with Charles H. Ledlie, M. Am. Soc. C. E., of St. Louis, Mo., and, in 1890, occupied a similar position with the firm of Johnson and Flad, in charge of the construction of an inclined cable, at an estimated cost of $75 000, for the Western Railway Company. From 1892 to 1895, he was employed as Engineer with the Fruin-Bambrick Construction Company, General Contractors, in charge of an inshore tunnel on the water-works plant for St. Louis. From 1895 to 1900 he was engaged in various construction work.

In 1900, Mr. Colnon entered into partnership with Mr. Jeremiah Fruin under the firm name of Fruin and Colnon, General Contractors. With this corporation, his work included the construction of a warehouse for the St. Louis Transfer Company and a water intake plant for the Anheuser-Busch Brewing Association, as well as city paving and sewers for St. Louis and East St. Louis, Ill., and the building of new settling basins for the City Water-Works at Chain of Rocks, Mo.

In 1908, the Fruin-Colnon Contracting Company was organized. This Company specialized in public works, railroad contracting, etc., and, from 1912 until his death, Mr. Colnon served as its President.

He was a member of the St. Louis School Board from 1903 to 1909. He was appointed a member of the St. Louis Terminals Commission in 1905, and was a member of the St. Louis Library Board from 1926 to his death. He was also a Director and Vice-President of the Missouri Portland Cement Company, and a Director of the Merchants Laclede National Bank, of the Scullin Steel Company, and of the St. Louis Frog and Switch Company.

Mr. Colnon was a member of the following social and fraternal organizations: The Noonday Club, the Racquet Club, the Circle Club, the Engineers' Club of St. Louis, the City Club, the Bellerive Country Club, the Sunset Hill Country Club, Theta Delta Chi Fraternity, Cornell University Alumni Association, and the St. Louis Council of the Knights of Columbus.

He was married on January 9, 1895, to Katherine Fruin, of St. Louis, who survives him.

Mr. Colnon was elected an Associate Member of the American Society of Civil Engineers on July 9, 1906, and a Member on July 12, 1926.

* Memoir prepared from information on file at Society Headquarters.

CHARLES GOBRECHT DARRACH, M. Am. Soc. C. E.*

DIED JUNE 1, 1927.

Charles Gobrecht Darrach, the son of William and Christiana Elizabeth (Gobrecht) Darrach, was born in Philadelphia, Pa., on September 8, 1846, and was of distinguished Colonial ancestry.

Mr. Darrach was graduated from the Philadelphia Central High School in 1866, and began his technical career as Assistant Engineer in the office of George W. Leuffer, Chief Engineer of the Philadelphia and North Branch Railway Survey, with whom he remained until 1867.

He held successively the following positions: In 1868, he was Assistant Engineer with the Reading Railroad Company and, during 1869, with the Jersey Shore, Pine Creek, and Buffalo Railroad Company. From 1870 to 1871, he served as Principal Assistant Engineer with the New Orleans and Selma Railroad Company; and, in 1871, he was employed as Locating Engineer with the Baltimore and Ohio Railroad Company, from Tiffin, Ohio, to Chicago, Ill. During 1872 and 1873, he was Assistant to the Chief Engineer of the Elizabethtown, Lexington, and Big Sandy Railroad Company (now the Chesapeake and Ohio Railroad Company); and from 1873 to 1875, Construction Engineer for the Reading Railroad Company.

In 1875, Mr. Darrach accepted the appointment of Principal Assistant Engineer of the Water Department of the City of Philadelphia, under Dr. William H. McFadden, and remained with the Department until 1885, when he became a member of the firm of Wilson Brothers and Company, Architects and Engineers. His work in this connection consisted in the design and construction of a large number of office buildings and institutions, among which were the Drexel Institute, the Reading Terminal, the United Gas Improvement Building, and the Fidelity Building, in Philadelphia. This construction covered a period of thirteen years. In 1888, Mr. Darrach also designed and constructed the Water-Works System in the Borough of Ridley Park, Delaware County, Pennsylvania.

In 1899, he engaged in private consulting practice which he continued about five years before his death which occurred on June 1, 1927, after an illness of several months. He was identified with much important appraisal work for railway and electric traction systems; made expert examinations and reports in legal cases; and prepared many reports, papers, and discussions on railways, public utilities, water and sewage purification, the mechanical installation for office and other large buildings, and the heating and ventilation of hospitals, etc. One of his most important contributions to engineering literature was his paper on "Mechanical Installation in the Modern Office Building".†

He also made reports on proposed improvements of port facilities and the betterment of water supply and sewage disposal in Philadelphia, and planned and constructed the water-works, drainage, and sewer systems for various

* Memoir prepared by J. W. Ledoux, M. Am. Soc. C. E.

† *Transactions*, Am. Soc. C. E., Vol. XLVIII (1902), p. 1.

towns, for the State Insane Asylum, at Wernersville, Pa., etc., as well as power plants, heating and ventilating systems, electric installations, etc., for large buildings in Philadelphia and elsewhere.

Mr. Darrach was a man of sterling integrity and, as a good citizen, was greatly interested in municipal matters, particularly those involving engineering problems. He had very strong religious convictions, which he practiced throughout his life.

He was the founder and first President of the Institute of Operating Engineers, a member of the American Geographical Society, and an Honorary Member of the American Association of Hospital Superintendents. He was also a member of St. James's Protestant Episcopal Church, of Philadelphia.

He was married, in 1876, to Martha Amy Elizabeth Tearne who survives him, together with three daughters, all of whom reside in or near Philadelphia, and two sons, Charles G. Darrach, Jr., of Los Angeles, Calif., and Walter T. Darrach, of Miami, Fla. He was a most affectionate husband and father.

Mr. Darrach was elected a Member of the American Society of Civil Engineers on January 5, 1876.

ROBERT FRANCIS EASTHAM, M. Am. Soc. C. E.*

DIED FEBRUARY 10, 1926.

Robert Francis Eastham, the son of Virginia (Fisher) and F. Dabney Eastham, was born in Flint Hill, Va., on August 24, 1882. He was educated in the public schools of Virginia and at the Virginia Military Institute, Lexington, Va., and was graduated from the latter as a Civil Engineer in 1902.

Soon after his graduation, and for a period of about three years, Mr. Eastham was engaged by the Whitebreast Fuel Company, of Illinois, in making surveys for the development of mines in Illinois and Iowa. In the fall of 1905 and in 1906, he was employed as Engineer in charge of construction of 36 miles of electric railroad in Northern Illinois.

In June, 1907, Mr. Eastham decided to engage in Railroad Engineering and started with the Baltimore and Ohio Railroad Company as Instrumentman on the construction of its double-track work west of Pittsburgh, Pa. Later, in the same year, he was engaged with the Board of Supervising Engineers on the reconstruction of the Chicago, Ill., City Railways.

During 1908, Mr. Eastham was employed by the Grand Trunk Railroad Company in charge of the construction of its shops at Battle Creek, Mich. Afterward, he became General Superintendent of the General Contracting Company, of Toronto, Ont., Canada, and was engaged principally in paving and reinforced concrete construction. In March, 1909, he was employed as Assistant Engineer on the location of the Illinois Central Railroad from Birmingham, Ala., to Jackson, Tenn., and, later, was made Resident Engineer in charge of the reconstruction of the yards of that Company at Centralia, Ill.

In 1910, Mr. Eastham returned to his home in Virginia and became interested in the improvement of highways in Rappahannock County. Through this work he became interested in Highway Engineering as a profession, and immediately associated himself with the Virginia State Highway Commission as Resident Engineer in charge of the construction of highways in several places in the State during the next four and one-half years.

In October, 1914, he resigned his position with the Virginia State Highway Commission to become Highway Engineer with the United States Bureau of Public Roads. Soon after Congress established Federal Aid in road building for the States, Mr. Eastham was selected to have immediate charge of such work in Maryland and Delaware, which position he retained until his death.

Mr. Eastham was married on February 22, 1913, to Mary B. Browning, of Flint Hill, Va., who, with four children, Robert, William J., Lucy Beale, and Frances, survives him.

He was of a most agreeable, courteous, and kindly disposition, always cheerful, with nothing delighting him more than to hear a good anecdote and to relate one. He will be greatly missed by all those who were acquainted with him.

Mr. Eastham was elected a Member of the American Society of Civil Engineers on September 10, 1923.

* Memoir prepared by Vernon M. Peirce, M. Am. Soc. C. E.

GEORGE DANA EMERSON, M. Am. Soc. C. E.*

DIED AUGUST 23, 1927.

George Dana Emerson was born at Wilmington, Del., on August 20, 1876, the son of Charles and Katherine (Hill) Emerson. His early boyhood was spent in Colorado where he received his preliminary education.

After graduation from the East Denver High School, Mr. Emerson entered the University of Colorado, where he remained for a period of two years before transferring to the Massachusetts Institute of Technology, at Boston, Mass., from which he was graduated in 1899.

His first employment was with the Edison Electric Illuminating Company, at Boston, in the making of surveys and preparation of plans for underground conduit construction. For a brief period he acted as Assistant to Howard A. Carson, Hon. M. Am. Soc. C. E., Consulting Engineer, in connection with some special studies for sewer systems.

Early in 1900 Mr. Emerson accepted employment with the Massachusetts Telephone and Telegraph Company, assuming charge of the survey and plan work involved in the installation of an underground conduit system for its lines in the City of Boston. Later, he supervised the construction of the works.

During 1901 and 1902 he was engaged by the Union Iron Works at San Francisco, Calif., on designs for various electrical and mechanical appliances.

In February, 1903, Mr. Emerson entered the employ of the Boston Transit Commission as a Special Engineering Assistant. For the first few years he was engaged chiefly in connection with experimental work, drafting, and designs for structures, ventilation, pumping plants, and miscellaneous features. He retained his connection with this service until December, 1917. During this period he filled many important assignments in connection with the development of the Rapid Transit System of the City of Boston.

In 1906 he was given charge of the difficult task of underpinning the Ames Building, at Washington and Court Streets, Boston, preparatory to the construction of Section 7 of the Washington Street Tunnel. This structure, built with walls of solid granite masonry, was at that time the heaviest building in the city. The methods adopted for re-supporting its massive exterior walls in order to permit the locating of the proposed tunnel immediately adjacent to the property line, at a considerable depth below the original footings, involved engineering and construction expedients of unusual ingenuity and novelty.

On the successful completion of this work Mr. Emerson was assigned to supervise the interior finish work of several of the Washington Street Tunnel Stations, and, in addition, the construction of the ventilation system of the Tunnel.

In 1909 he conducted the preliminary studies and prepared structural designs for a tunnel under Beacon Hill, which would extend the Cambridge Subway to a connection with the Boston Subway at Park and Tremont

* Memoir prepared by Charles R. Gow, M. Am. Soc. C. E.

Streets, and, subsequently he assumed charge of this construction. Later, in 1912, when this line was extended to Andrews Square, South Boston, he was assigned to supervise the greater part of the work. The most difficult undertaking involved in this extension was the construction of a sub-aqueous section of approximately 3 000 lin. ft., under Fort Point Channel, which was completed by the pneumatic process.

In the fall of 1917, Mr. Emerson was engaged for a brief period in connection with the building of Hog Island Shipyard. Early in 1918 he was employed by the firm of Fay, Spofford, and Thorndike, Consulting Engineers, in connection with the building of the Boston Army Supply Base where he exercised supervision over all construction work amounting in the aggregate to nearly $25 000 000.

On September 28, 1918, he was commissioned Captain in the United States Army and assigned as Assistant to the Constructing Quartermaster at the Boston Army Supply Base, in which position he served until February 20, 1919.

At the conclusion of his military service, Mr. Emerson retired from the active practice of his profession and made his home at Cocoanut Grove, Fla., devoting himself to fruit-growing and other local interests. For several years he served as a member of the Cocoanut Grove City Council and participated in many activities connected with the welfare and development of that community.

He was extremely fond of outdoor life, and spent considerable time in travel, mountain climbing, horseback riding, canoeing, and other forms of open-air exercise.

He was a member of the Florida Society of Civil Engineers, the Miami City Club, the Cocoanut Grove Community Club, the Appalachian Mountain Club, the Sierra Club, the Colorado Mountain Club, and the Mountaineers, of Seattle, Wash.

Mr. Emerson possessed a lovable personality. He was by nature somewhat quiet, reserved and conservative in manner, but extremely courteous and considerate in his treatment of others. He was uniformly just, generous, and tactful in the discharge of his responsibilities toward those with whom he had occasion to deal. He was admired alike, by his subordinates and superiors. His unusual sound sense, engineering knowledge, and rare good judgment elicited the highest praise from his associates, and from those whose activities he had occasion to supervise. Few engineers of his period possessed as fine a grasp of the essential principles of construction work. He had the rare ability of obtaining the highest quality of workmanship in all the undertakings assigned to him, without appearing to be unfairly exacting in his demands. His accomplishment in this regard stands as a worthy model, deserving of wide emulation.

He was married on January 7, 1911, at Somerville, Mass., to Mildred A. Avery, who survives him. He died very suddenly at Estes Park, Colo., on August 23, 1927.

Mr. Emerson was elected an Associate Member of the American Society of Civil Engineers on June 3, 1908, and a Member on April 14, 1919.

JOHN ERNST ERICSON, M. Am. Soc. C. E.*

DIED APRIL 16, 1927.

John Ernst Ericson was born in Upland, Sweden, on October 21, 1858, the son of Anders and Sophia (Lind) Ericson. He received his early education in the common schools, and in 1872 he entered the High School and College at Upsala, Sweden, which he attended until 1876, when he entered the Royal Polytechnic Institute at Stockholm, Sweden. He was graduated from this institution with the degree of Civil Engineer in 1880.

Mr. Ericson came to the United States in 1881, his first post of importance being that of Resident Engineer with the Toledo, Cincinnati and St. Louis Railroad Company, with headquarters at Cowden, Ill. He retained this position until the summer of 1882, when he accepted that of Bridge Designer with Hopkins and Company of St. Louis, Mo. In 1883, he was appointed Assistant on Government surveys in connection with the proposed enlargement of the Illinois and Mississippi River Canal and the construction of the Hennepin Canal. He had an important part in the making of the surveys on these projects as well as some share in outlining the entire plan.

In 1884 and during a part of 1885, he was a Draftsman in the Water Department of the City of Chicago, Ill. He became Assistant City Engineer of Chicago in 1885, and retained this position until 1889, when he was selected as Assistant Chief Engineer of the City of Seattle, Wash., to aid in developing the new gravity water-works system, which was then about to be built there.

In 1890, the Sanitary District of Chicago, the corporation which has control and supervision of the great Drainage Canal System, claimed the services of Mr. Ericson. He remained with the District until 1892, when he became Assistant Engineer in the Bureau of Engineering. In 1893, he was appointed First Assistant City Engineer of Chicago, and in 1897 was elevated to the post of City Engineer, which position he held until his death.

As First Assistant City Engineer and as City Engineer he was in charge of the design and construction of all additions to the water supply system of the city, projects involving the outlay of millions of dollars to provide water for the second greatest city in the United States.

As City Engineer, Mr. Ericson was also in charge of all bridge design, construction, and operation, and was called upon to give expert opinion on a multiplicity of engineering subjects connected with the many city betterments which are taken up every year by the City of Chicago in order to care for the increased business and living facilities necessitated by the rapidly spreading metropolis. Mr. Ericson had exceptional opportunities for experiments to determine the elements of flow of water in large tunnels, and presented an extensive treatise† on this subject to the Western Society of Engineers in 1911, for which he received the Society's medal. He also published

* Memoir prepared by Loren D. Gayton, Assoc. M. Am. Soc. C. E.

† "Investigations of Flow in Brick Lined Conduits," *Journal*, Western Soc. of Engrs., Vol. XVI, No. 8 (October, 1911), p. 657.

other papers and reports on water-works, paving, harbors, subways, etc., among which may be mentioned the following: "The Water Supply System of Chicago, Its Past, Present and Future"; "Report on Transportation Subways for Chicago"; "Report on Creosote Block Pavements"; and "Report on Public Water-Works".

He was President of the Swedish Engineers' Society of Chicago, and a member of the American Society of Mechanical Engineers, Western Society of Engineers, and the American Water Works Association.

Mr. Ericson was recognized as one of the leading authorities in the United States on city betterment, and as an engineer who successfully solved many of the great obstacles that beset the larger municipalities in devising systems of caring for their giant populations. Numerous structures and edifices stand to-day as monuments to his engineering ability.

He died on April 16, 1927, at the Presbyterian Hospital, in Chicago, after undergoing an operation. He is survived by his widow, Mrs. Esther Elizabeth Ericson, and a daughter, Mrs. Ralph Haven Quinlan.

Mr. Ericson was elected a Member of the American Society of Civil Engineers on May 7, 1902.

WILLIAM HENRY FINLEY, M. Am. Soc. C. E.*

DIED MARCH 17, 1926.

William Henry Finley was born near Delaware City, in New Castle County, Del., on January 22, 1862. His father, William Francis Finley, was born in County Galway, Ireland, and his mother, Mary Mortimer McDonough, was a native of Castle Bar, County Mayo, Ireland. His parents came to the United States in 1835, and settled in New York, N. Y., but later moved to a farm in Delaware where William was born.

When the boy was 13 years of age the family moved to Wilmington, Del., where he attended High School, finishing at the age of 16. He then secured employment with the *Delaware Gazette* as a printer's "devil". He did not remain long in this capacity, however, for at the end of four years he had become a journeyman printer. By this time he had concluded that the printer's trade was not to his liking.

Mr. Finley had a natural aptitude for mathematics and drawing and while working on the *Delaware Gazette* he began studying drafting at a night school. Subsequently, he entered the employ of the Edge Moor Iron Company as a blueprint boy, doing some tracing in his spare time. He continued to study at night, most of the time without an instructor, a fact that caused his associates to become interested in him and led them to assist him in his efforts to acquire an education.

The Edge Moor Iron Company had at that time one of the largest bridge shops in the United States and many large and notable structures were fabricated by it. Mr. Finley had the opportunity of seeing these structures designed and manufactured. While he was engaged with the Company, it was building the steel structural work for the Brooklyn Bridge, and he had a part in this work.

He remained with this Company until 1887, at which time he accepted a position with the Engineering Department of the Chicago, Milwaukee and St. Paul Railway Company, where his opportunities and responsibilities were greater. He was an indefatigable worker and took full advantage of the opportunities presented to him in this position with the result that, in 1892, although only 30 years of age, he was offered the position of Engineer of Bridges of the Chicago and North Western Railway System, then aggregating about 6 000 miles of lines. He accepted this position and, in 1901, was promoted to be Principal Assistant Engineer of that road. He left the employ of the Chicago and North Western Railway Company in 1905 to become Vice-President of the Widell-Finley Company, a contracting organization. After about a year with this Company he entered consulting engineering work.

However, in 1906, Mr. Finley returned to the Chicago and North Western Railway Company as Assistant Chief Engineer and, in 1913, was promoted to be Chief Engineer, which position he held until shortly after the railways were

* Memoir prepared by a Joint Committee of the Society and the Western Society of Engineers, consisting of E. T. Howson, *Chairman*, and I. F. Stern, Members, Am. Soc. C. E., G. W. Hand, Assoc. M. Am. Soc. C. E., and Charles F. Loweth, Past-President, Am. Soc. C. E.

taken over by the Government in 1918, when he was elected President of the Chicago and North Western Railway Company. In 1922, he was also elected President of the Chicago, St. Paul, Minneapolis and Omaha Railway Company. Because of failing health he resigned from these positions in 1925 with the intention of taking a rest for a year or more. The constant demands for advice and consultation, however, prevented him from realizing his intentions, and he finally opened an office as Consulting Engineer, in Chicago, in November, 1925. He died on March 17, 1926.

Mr. Finley was a great lover of the sea and as a boy spent much of his time about the shipbuilding works in Wilmington, gaining information which was of value to him in later years. As an illustration, when Bridge Engineer of the Chicago and North Western Railway Company he was confronted with the problem of replacing a drawbridge extending across the Chicago River at the entrance to the passenger station in that city. It was necessary to develop a method of erection which would not interfere with the operation of the structure it was to replace, while the track arrangement would not permit of it being placed anywhere except on the alignment of the old bridge. Drawing on the recollections of his boyhood days, Mr. Finley conceived the idea of erecting the new structure on ways on the bank of the river some distance from the site that it was to occupy and launching it as he had seen ships launched. This idea, while then novel to bridge builders in the West and regarded with no little skepticism by them, was successful as well as economical.

His later railroad connections were at a time when the railroad companies were rapidly expanding their lines and their engineering activities were extensive. Mr. Finley was connected therefore with a number of large engineering structures, including the Des Moines River Viaduct, at Boone, Iowa; several vertical lift bridges; the controlling of the channel of the Missouri River in the vicinity of several bridge crossings; and other equally important projects. To all of these he contributed largely and efficiently. He was one of the pioneers in the development of the rocker-bearing to take care of expansion in steel structures and his efforts in connection with cylinder piers in bridge foundation work did much to bring this form of construction into more general use.

Although Mr. Finley never had the opportunity to attend a technical school or college, he was always of the opinion that they were of great value and preferred to select his assistants from among the ranks of engineers who had been graduated from college. He possessed and applied a large measure of energy and had great strength of purpose, coupled with an abundance of initiative. Throughout his life he laid great stress on the necessity for the development of initiative and originality. One of his earlier associates writes of him:

"I first met Mr. Finley when I went to Edge Moor as a Draftsman during September, 1886. He had then been in the office for some time and was probably the best Draftsman in the office as far as neat and rapid production was concerned. As he had not had the advantage of a technical education, he was not versed in the methods of stress calculation and design. For some months

I observed that he seemed to think that there was little prospect of substantial advancement for him. My roommate and I easily induced him to take up more advanced studies of immediate interest to his work and he spent many evenings in our room, studying and talking about theory and design. I believe that previous to this period he had been studying mathematics alone and with some instruction from others. I remember those evenings with great pleasure, for his personal charm won our affections, and he was unusually quick to understand things then new to him."

A man of broad human sympathies, Mr. Finley was ever interested in the activities of his fellow men. It overflowed the limits of his own professional activities, but did not stand in the way of his giving to the organized efforts of his own chosen profession a very large measure of his time and interest. He was, therefore, active and helpful in the affairs of engineering societies in which he held membership, and his contributions in that respect were notable.

Mr. Finley became a member of the Western Society of Engineers in 1894, was made Second Vice-President in 1900, First Vice-President in 1901, and President in 1902. In addition, he served on a number of its important committees, contributed several notable papers, and frequently discussed constructively papers submitted by other members. He was also an interested member of this Society, and at the time of his death was serving his second term as its representative on the Washington Award Commission. He was for many years a member of the American Railway Engineering Association and had contributed to its technical work. He became interested in the American Association of Engineers early in its formation and was its President in 1918 and 1919 when his wise and sympathetic counsel were of great benefit.

On March 8, 1883, Mr. Finley was married to Sarah H. Ferré, at Philadelphia, Pa., who, with four children, three sons and one daughter, survives him.

Mr. Finley was elected a Member of the American Society of Civil Engineers on February 4, 1903.

FRANCIS CLARKE GAMBLE, M. Am. Soc. C. E.*

DIED NOVEMBER 13, 1926.

Francis Clarke Gamble, the son of Clarke Gamble, and Harriet Eliza (Boulton) Gamble, was born in Toronto, Ont., Canada, on October 23, 1848. As a boy he was educated in the public schools of that city, after which he attended Upper Canada College, where he received his primary education, later continuing his studies under private tuition. After four years of practice in field engineering on the Intercolonial Railway and the Great Northern Railway of Canada, Mr. Gamble entered Rensselaer Polytechnic Institute, Troy, N. Y., where for a year or more he took a special course. It was there that the writer first met him and, being fellow countrymen, a close friendship soon developed, that endured for more than half a century.

At Rensselaer, Mr. Gamble, being a special student, thus belonging to no particular class, and being several years older than most of the other students, did not become widely acquainted; but he was well liked by all who knew him intimately. In selecting his studies he chose those that were mainly of a utilitarian character, especially those that bore on his adopted specialty of railroading. That he probably made a wise selection is shown by the success he achieved in after life; for not only did he hold high positions in railroading in Canada, but he was also elected President of the Canadian Society of Civil Engineers (now the Engineering Institute of Canada).

After leaving Rensselaer, Mr. Gamble worked for a short time as Contractor's Engineer on the Prince Edward Island Railway, then returned to the Intercolonial Railway Company as Engineer in charge of ballasting. His next position was as Transitman on the Georgian Bay Branch of the Canadian Pacific Railway, and late in 1877, he served as Assistant Engineer of Construction on the Quebec, Montreal, and Ottawa Railway. He then returned to the Canadian Pacific Railway Company as First Assistant Engineer on Contracts Nos. 42 and 62.

In the spring of 1881, he entered the Department of Public Works of the Dominion Government in British Columbia; and, in 1889, he became Resident Engineer in that Department, having in charge all harbor and river improvement and the erection of public buildings. It was not long before he was placed in full charge of all public works under the Dominion Government in the Province of British Columbia.

In 1897, Mr. Gamble was engaged in private practice; and in 1898, he was appointed Public Works Engineer for the Provincial Government of British Columbia, becoming, in 1910, Chief Engineer of the Department of Railways for the Province, which position he held until 1918, when he retired from active practice. He continued to reside in Victoria until his death.

He took a great interest in the affairs of the Engineering Institute of Canada, of which he became a member in January, 1887. He was elected a

* Memoir prepared by J. A. L. Waddell, M. Am. Soc. C. E.

Member of Council in 1892 and again in 1898. In 1913 and 1914, he was Vice-President, and, in 1915, he became President. He was also a member of the Institution of Civil Engineers of Great Britain.

Within the profession and in all walks of life Mr. Gamble was held in the highest esteem by all with whom he came in contact. He was a man of the strictest integrity, and was always governed in his actions by the loftiest ethical principles and ideals. He was recognized throughout the Dominion as a high authority on the various professional works to which his energies were devoted.

He is survived by his only son, Clarke W. Gamble, of Cairo, Ill.

Mr. Gamble was elected a Member of the American Society of Civil Engineers on April 1, 1891.

HUBERT EDWARD GREEN, M. Am. Soc. C. E.*

DIED SEPTEMBER 7, 1927.

Hubert Edward Green was born at Edgbaston, Warwickshire, England, on August 17, 1859. He received his grammar school and college education in Auckland, New Zealand.

From 1874 to 1884, Mr. Green was with the Public Works Department of the New Zealand Government, on the construction of its railway system. In June, 1880, he was appointed Overseer, in charge of wharf building, and of road and bridge repairs, and in July, 1882, he was made Office and Field Assistant.

In 1884, Mr. Green came to the United States, and from February of that year until September, 1886, he served as Construction Engineer for the Sierra and Mohawk Valley Railway Company, a narrow-gauge line running west into California from a point about 30 miles north of Reno, Nev. During the following two years, he was in charge of the City Engineer's office at San Diego, Calif.

In 1888, Mr. Green entered the employ of the International Company of Mexico, with headquarters at Ensenada, Lower California, and made explorations to classify land over the Company's concession of 18 000 000 acres. He was engaged as head of the Railroad Engineering Corps and was employed on a railway survey from San Quintin to Yuma, Ariz., branching at Real del Castillo to San Diego. Considerable difficulty was experienced due to scarcity of water and transportation over the heavy sands through the Cocopo Desert and the intense heat.

Returning to the United States in 1890, he had charge of the construction of the railroad trestle across Elliott Bay, for the Seattle Terminal Railway Company. In February, 1891, he served on a location and canal survey for the Lands Department of the Northern Pacific Railway Company, between North Yakima and Prosser, Wash. He was also engaged from 1891 to 1893 on the location of railroad lines in Texas for the Atchison, Topeka and Santa Fé Railroad Company from Conroe, Tex., to the Trinity River. In July, 1893, he was placed in charge of levels, with the Imperial Valley and Colorado River Irrigation Company, under C. R. Rockwood, Chief Engineer.

From 1893 to 1896 Mr. Green was with the San Diego City and County and Coronado Beach Company, superintending the laying of the foundation of the Morena Dam, which extended 100 ft. below the stream bed. During 1897 and 1898 he was engaged in placer mining in British Columbia and in the general practice of civil engineering in San Francisco, Calif. In 1899, he was employed on the construction of electric railroads in Los Angeles, Calif., and from 1900 to 1902, he acted as Field Assistant for the United States Geological Survey.

During 1902 and 1903 Mr. Green served as Assistant to J. B. Lippincott, M. Am. Soc. C. E., in charge of surveys, estimates, and designs for pipe lines

* Memoir prepared by M. M. O'Shaughnessy, M. Am. Soc. C. E.

for the Seaside Water Company, of Long Beach, Calif. While engaged in this capacity, he made divisional surveys of the Hetch Hetchy Valley and Lake Eleanor Reservoir sites for the City of San Francisco.

On May 4, 1903, he was appointed Designing Engineer of the United States Reclamation Service, in charge of the construction of the Belle Forche Diversion Dam. He held this position until his resignation in 1907. From 1907 to 1910, he designed and built irrigation works for La Sierra Heights, at Riverside, Calif.

During 1910 and 1911 he was employed by the Mountain Power Company, of Crescent City, Calif., in making surveys and designs for the power dam on the Smith River, and from 1912 until his death, he acted as Chief Engineer for the Compañia Constructora Richardson, at Esperanza, Sonora, Mexico, where he died on September 7, 1927.

Mr. Green was a man of sterling character and ability, modest and retiring, the reason, perhaps, why he did not occupy as conspicuous a position as his abilities warranted. He will be greatly missed by his many engineering friends in California.

It was the writer's pleasure, as a young man, to work under Mr. Green on the construction of the Sierra Valley and Mohawk Railway, in Plumas County, California, in 1885. He then learned to have great respect for his keen knowledge as an engineer. Since that time, during a period of forty years, he had had many friendly experiences with him. He was possessed of great patience, but was firm in his decisions, as was illustrated by the difficulties he overcame in laying the foundation of the core of the Morena Dam, when he was representing the City of San Diego. At this time he encountered opposition from ignorant foremen who wished to use inferior concrete, which course Mr. Green, with his careful engineering training, resisted.

Mr. Green was twice married, first, to a young woman from San Francisco, who died in 1907, and, subsequently, to a New Zealand friend of his youth, who survives him.

Mr. Green was elected a Member of the American Society of Civil Engineers on December 2, 1903.

HENRY STEVENS HAINES, M. Am. Soc. C. E.*

DIED NOVEMBER 3, 1923.

Henry Stevens Haines was a descendant of Deacon Samuel Haines who settled in New Hampshire in 1632. His father, Henry Stevens Haines, had established himself in Wilmington, N. C. His mother was a member of the old Coffin family of Nantucket Island, Mass., and it was during a visit to her mother's home there that Henry Stevens Haines was born, on November 21, 1836.

After the discovery of gold in California his father sent a cargo of building material and partly constructed houses around Cape Horn to San Francisco, Calif., but he himself went by way of the Isthmus of Panama, stopping long enough to accept and complete a contract for cross-ties for the Isthmian road, then under construction. In the California venture he was very successful and was about to return to his home in Wilmington, when he died suddenly of smallpox, leaving his widow with four young sons, of whom Henry Stevens Haines was the eldest.

The boy had a keen mind and a retentive memory. He was taught by two masters in schools, one in Massachusetts and the other in North Carolina. He never went to college, but became a student of men and affairs, a first-class mathematician and geographer, with a good working knowledge of four languages.

Mr. Haines' first connection with railway service was in 1853 or 1854 when he was employed by the Wilmington and Manchester Railroad Company of North Carolina. His next work was with the North Eastern Railroad Company in North Carolina and South Carolina, in the machine shops and as Locomotive Engineer.

When the Civil War began, he was Assistant Engineer on the construction of the Charleston and Savannah Railroad. With his three brothers, he enlisted in the Confederate Army, but soon was returned to railroad construction where he could be of more service, the railroads being most important to the Confederacy. He completed several bridges and other structures in his district and in the course of his work witnessed many battles and was under fire on various occasions. When Charleston, S. C., fell, he was in charge of the transportation of the retreating Southern forces.

After the war, in 1866, Colonel Haines was appointed General Superintendent of the Atlantic and Gulf Railroad which, in common with Southern railroads at that time, was deficient in equipment and was in a bad financial condition. This line extended from Savannah to Thomasville, Ga. From it, however, Colonel Haines developed the Savannah, Florida, and Western Railroad, which, together with the Charleston and Savannah Railroad, became one of the important systems of the South. He later extended the line through Florida to Tampa, with steamers to Key West and Cuba. With the Alabama, Midland, and Montgomery Railroad, these lines comprised the

* Memoir prepared by Charles O. Haines, Esq., Norfolk, Va.

Plant System, of which Colonel Haines was General Manager and Vice-President from 1882 to 1895.

During these years, Colonel Haines and his wife, Elizabeth Owens, of Charleston, made their home for a time in Charleston and, later, in Savannah. They had six children, of whom only two sons survive him. During his long residence in Savannah, Colonel Haines was active in both City and State affairs whether working in the midst of a yellow fever epidemic or promoting the building of the Georgia School of Technology.

During the last years of his connection with the Plant System, he moved to New York, N. Y. By this time he had long been known as an experienced railroad executive. Largely through his efforts the American Railway Association had been organized, of which he served several terms as President. Colonel Haines was one of the first members of the Southern Society in New York. He was also a member of the Engineers' Club of New York and had served as one of its Vice-Presidents. He and his associates initiated standard time and the standardization of tracks throughout the South.

In 1895, the American Railway Association sent him to England as its representative at the first International Railroad Congress, where his speeches and addresses attracted wide attention. On his return from Europe in the autumn of 1895, Colonel Haines severed his connection with the Plant System to become Commissioner of the Southern States Freight Association, with headquarters in Atlanta, Ga. His wife died in December of that year. He held this office for about two years, when he resigned to travel abroad.

After his return to this country, Colonel Haines was married to Anna Davies, of Detroit, Mich., the daughter of the Bishop of the Protestant Episcopal Diocese of Detroit, who, with their two sons, survives him. For a short time after his return, Colonel Haines was Vice-President of the Atlantic and Danville Railroad Company. While living abroad some years later, he was appointed by the American Government as its representative at the International Railroad Congress held in Berne, Switzerland.

He retired from active business, however, in 1900, and after spending several years in travel, settled with his wife's people in Springfield, Mass., with a summer home at Lenox, Mass., where he died on November 3, 1923.

Colonel Haines' theory of railroad management was based on the delegation of authority as far as possible, but with the proviso that responsibility should rest on the chief operating official. He was of an eminently judicial turn of mind and just in his relations with other men. He was fond of people, always seeking to bring out their best qualities, was never overcritical, and was anxious that all subordinates or business associates should receive every possible acknowledgment of their efficient co-operation or assistance in the successful operation of the railroads entrusted to his care.

His interest in the welfare of the railway employees led to the organization of the Employees' Mutual Relief Association, a benefit and insurance society, and of the Co-Operative Store. In the latter not only were dividends paid to the stockholders, but there was a division of profits at certain fiscal periods.

At the suggestion of a member of his family, Colonel Haines collected his various addresses and published them, with some re-arrangement, in a book

entitled, "American Railway Management". It met with a sufficient demand for him to continue writing on various phases of railway problems, and he wrote continuously until his death. His other works are, "Railway Corporations as Public Servants", "Problems in Railroad Regulation", and "Efficient Railroad Operation".

His was a successful life in its truest sense; his work was well done, and those who were associated with him became his friends and remained so to the end.

Colonel Haines was elected a Member of the American Society of Civil Engineers on November 2, 1887. He served as Director of the Society from 1897 to 1899 and as Vice-President from 1901 to 1902.

EDWARD AUGUSTUS WHITE HAMMATT, M. Am. Soc. C. E.*

DIED MARCH 18, 1927.

Edward Augustus White Hammatt, the son of Samuel Parkman and Maria (White) Hammatt, was born in that part of West Cambridge, Mass., that is now Belmont, on September 30, 1854, and received his early education in the public schools of that place. Later, he entered the Massachusetts Institute of Technology at Boston, Mass., from which he was graduated in the Class of 1875.

After his graduation, Mr. Hammatt was employed as Rodman on a preliminary railroad survey, and, subsequently, as Rodman on the construction of the water-works, at Newton, Mass., until he became Assistant Engineer with the late J. P. Frizell, M. Am. Soc. C. E., in 1876. The following year he was engaged in miscellaneous work, and, in 1878, was appointed Draftsman on the water-works at Lewiston, Me., and, later, as Assistant Engineer with the New York and New England Railroad Company. During 1879 he served as Draftsman for the American Tool and Machine Company, and also for the Boston Bridge Works, and, in 1880, he became Assistant Engineer in the office of the Proprietors of Locks and Canals on the Merrimac River, at Lowell, Mass. During the following three years he was employed as Chief Assistant Engineer with the late M. M. Tidd, M. Am. Soc. C. E., on water-works construction at Marlboro, Hudson, Weymouth, Holbrook, Randolph, and Hyde Park, Mass., and at Gardiner, Me.

In 1883, Mr. Hammatt opened an office in Boston, Mass., where he engaged in private practice as a Civil Engineer. In addition to the regular work coming to such an office, of which he took charge, he designed and built several sewer systems, and did considerable topographical and hydrographical work for power development projects. In 1891, he opened a branch office in Hyde Park, where he was engaged in the engineering work of the city.

In 1906, he went with Charles T. Main, M. Am. Soc. C. E., and a party of engineers on an expedition to the Arros River, in Mexico. Their object was to investigate a hydro-electric development project for furnishing electric current to mining camps in Northern Mexico and in Arizona, and to select a site for a dam, head-house, and similar structures. Mr. Hammatt was left in charge, and remained there for about a month, doing, what he termed later, the hardest piece of work he ever attempted. He found numerous dam sites with heads varying from 70 to 285 ft. Owing, however, to lack of provisions, time, and the great expense entailed, the project was temporarily abandoned, and Mr. Hammatt returned to Hyde Park.

In 1912 he removed to Newton Center, and, in 1916, to South Orleans, Mass., where he continued his private practice as Civil and Hydraulic Engineer until his death.

He was married on October 16, 1882, to Mary Louise Fifield, who, with four children, Richard Fox, Francis Parkman, Robert Wallace, and Alice Louise, survives him.

* Memoir prepared by George Bowers and E. S. Dorr, Members, Am. Soc. C. E.

Mr. Hammatt had served as Secretary-Treasurer and Historian of the Class of 1875 of the Massachusetts Institute of Technology for forty-two years. He was a member of the Boston Society of Civil Engineers, the New England Water Works Association, and the Masonic Fraternity.

He was one of the kindest of men, a friend on whom one could always rely, unobtrusive in character, his life was one of faithful service. As an engineer he ranked high, loving his profession and serving it to the last.

Mr. Hammatt was elected a Member of the American Society of Civil Engineers on June 5, 1901.

GEORGE ALEC HARWOOD, M. Am. Soc. C. E.*

DIED NOVEMBER 4, 1926.

George Alec Harwood was born on August 29, 1875, at Waltham, Mass., the son of Alexander Thorndike and Emma Dean (Smith) Harwood. He was graduated from the Waltham Public Schools and the English High School of Boston, Mass., and then entered Tufts College, Medford, Mass., from which he was graduated in 1898 with the degree of Bachelor of Science in Electrical and Civil Engineering. In 1901, he received the degree of Master of Science and in 1913 the degree of Doctor of Science from the same college. During his high school and college career he was able, by his high scholarship, to earn awards that made easier for him the problem of financing his educational adventure.

In 1893 Mr. Harwood entered railroad service as a Chainman on the Fitchburg Railroad, where he continued as Rodman and Assistant Engineer during his college vacations and after his graduation.

In 1900, in response to an advertisement, he became a Draftsman in the Engineering Department of the New York Central and Hudson River Railroad Company. He successively filled positions as Chief Draftsman; Assistant Engineer in charge of construction at and near Syracuse, N. Y.; Assistant Engineer with special assignments from the Chief Engineer; Engineer of Grade Crossing Elimination; Assistant Terminal Engineer; and Terminal Engineer.

In November, 1906, Mr. Harwood was appointed Chief Engineer, Electric Zone Improvements. In 1916, he became Engineering Assistant to the Vice-President of the New York Central Lines and, during Federal Control of the railroads, he served as Engineering Assistant to the Federal Manager of the New York Central Railroad, and as Corporate Chief Engineer of the various companies comprising the New York Central System Lines. In 1920, he became Assistant to the President, New York Central Lines, and in April, 1924, he was elected Vice-President, in charge of improvements and development, which position he held at the time of his death.

Mr. Harwood was a Director of the Monongahela Railway Company; the New York and Fort Lee Railroad Company; the Pittsburgh, Chartiers and Youghiogheny Railway Company; the Raquette Lake Railway Company; the Chartiers Southern Railway Company; the Kanawha and West Virginia Railroad Company; the Michigan Air Line Railroad Company; the Fulton Chain Railway Company; the Hudson River Bridge Company, of Albany, N. Y.; the Hudson River Connecting Railroad Corporation; the Evansville, Mt. Carmel and Northern Railway Company; and the New Jersey Junction Railroad Company. He was also a Director of the Scarsdale Improvement Corporation; the Scarsdale National Bank; and the Mutual Fire, Marine and Inland Insurance Company.

He was a member of the American Railway Engineering Association; the Academy of Political Science; the Sons of the Revolution; the Century

* Memoir prepared by George W. Kittredge, M. Am. Soc. C. E.

Association; the New University Club, of Boston; the Railroad Club; the Scarsdale Town Club; and the Scarsdale Golf Club. He was also a Trustee of Tufts College and a member of the Alpha Tau Omega Fraternity.

Throughout his railroad life Mr. Harwood was noted for his industry, his thoroughness, his integrity, and his honesty. He was unassuming, but, at the same time, a man of force, ability, and mature judgment. As Chief Engineer of Electric Zone Improvements he was prominent in the development of the Grand Central Terminal and the area in its vicinity. In connection therewith, he showed his broadmindedness by placing credit where credit was due in a talk given by him during the period of greatest activity, when there were employed approximately 150 men on engineering designs and plans, 100 on supervision, and 3 000 on field construction. He then stated:

"If this terminal is a success, it will be so because it is not a one-man affair, but a splendid piece of team work in which the thought and experience of the operating man, the traffic man, the business man, the lawyer, the architect, and the engineer have been combined".

The following is extracted from the Minutes of the Board of Directors of the New York Central Railroad and the other roads comprising the System Lines, at meetings held subsequent to his death:

"Mr. Harwood ranked high in his profession as a civil engineer. His knowledge of engineering, however, was but the foundation of his great ability in solving difficult problems and of his capacity to bring to successful conclusion important undertakings. He had an all-round and well-balanced mind. His breadth of vision, his grasp of affairs, his sound judgment, his industry made him a unique man. That he was such a man was demonstrated by the work which he did during the reconstruction of the Grand Central Terminal; and this was fully confirmed by his entire subsequent service."

Mr. Harwood's interest in the Village of Scarsdale, in which he lived, was always great. He freely rendered generous service in connection with the financing and installation of the sanitary sewer system; with securing property for the Athletic Field and the adjoining area for park purposes; with shaping the policy of the village as expressed by the Charter Commission; with educational matters, having served for many terms as President of the Board of Education; with problems relating to village planning; and with improvements in many directions throughout the neighborhood where the results of his wise counsel and advice may be noted. As a citizen and as a property owner, he was active in all things pertaining to its welfare.

In 1900, Mr. Harwood was married to Grace Isabelle Hawley, who, with two sons, Herbert Hawley Harwood and Robert Thorndike Harwood, survives him.

Mr. Harwood was elected an Associate Member of the American Society of Civil Engineers on February 5, 1902, and a Member on February 5, 1907. He served as a Director of the Society from 1915 to 1917.

BENJAMIN FRANKLIN HOWLAND, M. Am. Soc. C. E.*

DIED MAY 27, 1927.

Benjamin Franklin Howland, the son of Reuben R. and Martha Y. (Brightman) Howland, was born at New Bedford, Mass., on June 8, 1877. His early years were spent in his native city, where he received his primary and secondary education. He later attended the Friends' School, at Providence, R. I.

After a few years of business experience in Boston, Mass., Mr. Howland removed to Hawaii in 1899, entering the employ of a firm of civil engineers and surveyors at Hilo, and for several years was engaged in a variety of work having to do with railroad location, underground water development, and intricate surveys. In 1903, he became the Engineer for a large sugar company, and, in 1905, was employed, at Honolulu, by the Engineering Bureau of the Public Works Department for the Territory. In this position he was responsible for the design of extensions to the sewer system, roads, bridges, reservoirs, and City water-works, also acting at times as Engineer for the City and County, with its numerous and varied demands.

In 1909, he spent a number of months in Cuba, as Engineer for a large sugar corporation, and, after his return to Hawaii in 1910, was employed in several responsible capacities, until he left to take a special course at the Massachusetts Institute of Technology, where he spent most of 1912 and 1913.

For several years, following his return to Honolulu, in 1914, Mr. Howland was employed by a prominent contracting company in designing, estimating, and as Superintendent of Construction, on numerous important contracts, several of which were for buildings of the United States Government.

In 1920, he became Chief Engineer for one of the large sugar agencies, controlling thirteen important plantations, in which capacity he designed and erected sea walls, dams and reservoirs, sewer systems, water supply and power pipe lines, together with numerous buildings and residences.

At various times, he was employed by the Territorial Survey Department, as an expert in adjusting old surveys. In the later years of his life, he was a partner in an engineering organization, specializing in the design and installation of fire protective apparatus for safeguarding large concentrations of value in and about the sugar-mills and pineapple canneries of the various Islands in the group.

Mr. Howland's alert mentality, unswerving integrity, and tireless energy, combined with a long and varied experience in the multitude of engineering problems of a rapidly growing city, and in the development and operation of the hydraulic and transportation elements of large-scale sugar production, made his services and advice of inestimable worth in the community, to the welfare of which he devoted so large a share of his professional career. He was a member of the Benevolent and Protective Order of Elks.

* Memoir prepared by Sidney G. Walker, Esq., Honolulu, Hawaii.

On November 24, 1914, he was married to Rheta C. Macdonald, of Boston, Mass., and to this union were born two daughters, Rheta Russell, and Anne Bartlett Howland, all of whom survive him.

Possessing rare qualities of heart, his home life was exceptional, and his passing has bereft a large circle of friends and intimates which he had built around a useful and unselfish life.

Mr. Howland was elected a Member of the American Society of Civil Engineers on October 2, 1922.

JOSEPH WRAY HUNTER, M. Am. Soc. C. E.*

DIED MAY 19, 1927.

Joseph Wray Hunter was born on July 23, 1853, in Haverford Township, Delaware County, Pennsylvania. His father was Thomas and his mother, Henrietta (Schwend) Hunter. His early life was spent in Lower Merion Township, Montgomery County, and Radnor Township, Delaware County, Pennsylvania, and he was educated in public and private schools, having been graduated in 1870, second in his class from the Mantua Academy, in West Philadelphia, Pa.

Mr. Hunter's first work was with the late Samuel L. Smedley, M. Am. Soc. C. E., Surveyor and Regulator of the 11th Survey District, of Philadelphia, with whom he served until 1874, when he became engaged with Mr. G. M. Hopkins on map survey work. In 1875, he moved to Jenkintown, Pa., where he resided for the remainder of his life. In 1878, he engaged in the private practice of surveying in Jenkintown, and, in the same year, entered public life by being elected Justice of the Peace in his community.

Mr. Hunter started his long experience in highway work when, in 1890, he began, as the Borough Engineer of Jenkintown and Township Engineer for Cheltenham and Abingdon Townships, the construction of roads of the macadam and Telford macadam types. From 1902 to 1904 he was a member of the State Commission appointed to determine, survey, and re-establish the boundary line between the City of Philadelphia and Delaware County, Pennsylvania. He carried out a considerable part of the field work in this connection.

In 1903, he was appointed by Governor Pennypacker as the first State Highway Commissioner of Pennsylvania. He organized this Department and served in it in various capacities until his death.

During his early life Mr. Hunter filled a number of positions to which he was elected and in which he served faithfully, as he held all such matters of public trust in the highest regard. He was elected and re-elected Justice of the Peace. He was elected County Surveyor of Montgomery County, in 1872, and in 1887 Register of Wills for the same county. These elections and the manner in which he filled the positions led to his appointment as the first State Highway Commissioner. When he appointed Mr. Hunter to this position, Governor Pennypacker expressed his high regard for him as an Engineer, and this expression was repeated by successive Governors who re-appointed him to the Department. He served under Governors Pennypacker, Stuart, Tener, Sproul, Brumbaugh, Pinchot, and Fisher.

Mr. Hunter was outstanding as an engineer, a public servant, and, most of all, as a man. He was the most widely known and most loved man in highway circles in Pennsylvania. He had a depth of understanding and sympathy that won the unswerving loyalty of hundreds of young men whom he started on careers and whose close friendship he retained to the end. He was widely

* Memoir prepared by H. A. Thomson, Esq., Upper Darby, Pa.

known to thousands of Township Supervisors of Pennsylvania whose counselor he was for many years and whose State Association had conferred on him the honorary title of "Dean of the Highway Department."

By thousands of these Supervisors as well as by hundreds of engineers in the Highway Department the name of "Uncle Joe" Hunter was revered. His advice was sought and heeded by many. He was a man who knew highway construction and was ahead of his time in the early years of the State Highway Department. He had tact and judgment; he did not force his ideas on an unwilling populace. He made suggestions quietly and lived to see his plans successfully adopted.

Mr. Hunter was closely associated at all times with the men who built the roads as well as with the people who provided the funds with which they were built. In laying the foundations for the great highway system of Pennsylvania, he had to deal with what was at first an unwilling majority, but by persistently demonstrating that his ideas were correct, he succeeded in converting his opponents to his views. This he accomplished not only by the soundness of his engineering ideas, but by his sense of appreciation of the other man's viewpoint. His was not a single-track mind, nor did he ever seek publicity. He was a mild-mannered, kind-hearted gentleman.

Mr. Hunter held membership in a number of technical clubs and societies, having been active in the American Society for Testing Materials and the Atlantic Deeper Waterways Association. He was a member of the American Road Builders Association; the Engineers Club of Philadelphia; Friendship Lodge, A. F. and A. M., of Jenkintown; Lu Lu Temple, A. A. O. N. M. S., of Philadelphia, and other branches of the Masonic order.

As long as the Pennsylvania State Department of Highways exists no history can be complete without a full and grateful recognition of the services of Joseph Wray Hunter in laying the foundations for the great organization in its early days. He will be remembered particularly for his services in organizing the Township Division and in purchasing the private turnpike system of the State, but most of all for his kindly and valuable advice given to successive executives of the State Highway Department. He was indeed the type of man for whom many treasure the thought that "he was my friend."

Mr. Hunter was elected a Member of the American Society of Civil Engineers on May 3, 1910.

CHARLES DAVIS JAMESON, M. Am. Soc. C. E.*

DIED FEBRUARY 13, 1927.

Charles Davis Jameson was born in Bangor, Me., on July 2, 1855, the eldest son of Charles Davis Jameson, who during the Civil War served as a General in the Union Army, and Julia Lambert (Smith) Jameson. He passed his boyhood chiefly in Maine, attending school in Stillwater, Bath, and Bangor, principally at Dillingham's School at the latter place. After the death of his father, he lived for some years in Memphis, Tenn., with his uncle, Judge Thomas R. Smith. Later, he attended Bowdoin College at Brunswick, Me., where he was a member of the Alpha Delta Phi Fraternity, and from which he was graduated in Civil Engineering in 1876.

Mr. Jameson's first work was on the Bangor Dam across the Penobscot River, following which he went to St. John, N. B., Canada. In 1878, he became Section Engineer on the Memphis and Charleston (now the Southern) Railroad from Memphis, Tenn., to Huntsville, Ala.

Two years later he accepted a position in Mexico as Engineer in Charge and Superintendent of Construction on the Mexican Central Railroad. He was first stationed in the City of Mexico, but, later, was transferred to the sections from Leon to Irapuato. He also built tramways in Leon and Guanajuato, and was engaged in the preliminary location from Silao to Lake Chapala and Guadalajara, and from Tepic to San Blas.

In 1883, Mr. Jameson went to the Isthmus of Panama where he was employed under Count de Lesseps, as Assistant Engineer of the American Contracting and Dredging Company, and, later, as Chief Engineer and Superintendent. Having contracted the Chagres fever, he was forced to return to the United States. In 1885, he made standard plans for wooden structures for the European and North American Railroad Company.

On June 23, 1886, he was married to Florence Miller, of New York, and Memphis, Tenn. During the winter of 1886-87 he taught Engineering at the Massachusetts Institute of Technology, Boston, Mass.; and from 1887 to 1895, served as Head of the Department of Engineering at Iowa State University, Iowa City, Iowa.

In 1895, Mr. Jameson went to North China where for the next twenty-three years he was actively engaged in his profession. He became Chief Consulting Engineer and Architect for the Imperial Chinese Government, and, as such, made many surveying trips throughout China, Manchuria, etc., penetrating to places never before reached by white men. He also built a number of Government buildings, notably the Wai-Wu Pu Foreign Offices, the best constructed Government building in China.

After the fall of the Empire, Mr. Jameson became Chief Engineer for the American Red Cross. In this connection, he drew up all the plans for river conservancy in connection with flood and famine relief in China. These elaborate plans, involving the expenditure of about $50 000 000 by the Chinese

* Memoir prepared from information on file at the Headquarters of the Society.

Government, were interrupted by the World War and subsequent conditions in China.

In 1918, he returned to the United States and made his home in Bangor. He died in Sarasota, Fla., on February 13, 1927. On January 31, 1927, Mr. Jameson was married to Margaret French, of Washington, D. C., and is survived by his widow, a son, Wylie Blount Jameson, and a grandson, Wylie Blount Miller Jameson.

He was a member of India House, the Cosmos Club, of Washington, D. C., and the Loyal Legion. He was the author of a book on the making of Portland cement, of numerous monographs in engineering journals, and of an account of his experiences during the Boxer troubles in China, which was privately printed.

Mr. Jameson was elected a Member of the American Society of Civil Engineers on March 7, 1888.

WILBER MACAULAY JUDD, M. Am. Soc. C. E.*

DIED NOVEMBER 13, 1924.

Wilber Macaulay Judd, the son of the Rev. Frederick F. Judd and Jeanette (Wilber) Judd, was born at Parsippany, N. J., on June 20, 1862. He entered Union College, Schenectady, N. Y., for the regular civil engineering course and additional academic subjects, so that at his graduation in 1884 he received both the degrees of Civil Engineer and Bachelor of Arts. His standing was the highest in his class, entitling him by appointment of the Faculty to the highest commencement honor, that of Valedictorian.

His first engineering work was done under the direction of his college preceptor, Cady Staley, M. Am. Soc. C. E., on the construction of a sanitary sewer system for Schenectady. This employment led to his becoming associated with the firm of Staley and Pierson in sanitary and hydraulic engineering work, which connection was continued during the first fifteen years of his professional career.

Some of the important pieces of work of which Mr. Judd had charge during this period were, as follows: From 1886 to 1887, he was Assistant City Engineer of Kalamazoo, Mich., and from 1887 to 1888, he had general charge of the construction of the sewer system of Watervliet, N. Y. From 1890 to 1891 he served as Assistant City Engineer of Lincoln, Nebr., and from 1891 to 1894 he was in general charge of the construction of sanitary sewer systems for Dayton and Conneaut, Ohio. From 1895 to 1896 he held the position of Assistant City Engineer of Peoria, Ill., and in 1897 was Construction Engineer for the Merodocia Levee and Drainage District, Albany, Ill. During 1898 and 1899, he carried out all civil engineering work for the Illinois Steel Company, at Joliet, Ill.

In 1899, Mr. Judd became associated with the late Selwyn M. Taylor, M. Am. Soc. C. E., and was in charge of mine development, etc., at Luzerne, Pa. Later, he was Resident Engineer for the plants at Luzerne, Footedale, and Buffington, Pa.

In 1903, he became a member of the firm, The W. G. Wilkins Company, Engineers and Architects, of Pittsburgh, Pa., and continued in this partnership until his death. As a member of the firm Mr. Judd had general charge of drafting-room work, estimating, and designing, and more or less field supervision of all civil engineering and mining work.

As to his standing as an engineer the writer quotes from a letter written by George S. Pierson, M. Am. Soc. C. E., with whom Mr. Judd was long associated:

"Mr. Judd was exceptionally well grounded in his profession. His personality was most pleasing and his judgment excellent and of a quality of expression and fairness as between conflicting interests that was most convincing."

* Memoir prepared by Professor James H. Stoller, Dept. of Geology, Union College, Schenectady, N. Y.

Mr. Judd was married on April 9, 1917, to Marietta Fallsbush, of Pittsburgh, who survives him.

As known to his college classmates he was of a quiet and modest bearing, genial and companionable to those who sought him out, a man of clear, strong mind and fine character.

He was a member of the Engineers Society of Western Pennsylvania; the Coal Mining Institute of America; the Chamber of Commerce of Pittsburgh; and the Civic Club of Allegheny County, Pennsylvania. He was also a member of the Presbyterian Church.

Mr. Judd was elected a Member of the American Society of Civil Engineers on October 4, 1905.

CHARLES ALBERT JUDSON, M. Am. Soc. C. E.*

DIED SEPTEMBER 30, 1926.

Charles Albert Judson was born on August 11, 1856, on a farm near Florence, Ohio. His early education was obtained in the district schools of Erie County. He lived and worked on the farm until he was twenty years of age, after which he taught school for several winters. He then attended the Academy at Delaware, Ohio, for a year, and spent four years in Oberlin College, having been graduated from the latter in 1882, with the degrees of Bachelor of Arts and Master of Arts.

Immediately after his graduation, Mr. Judson took up his residence in Sandusky, Ohio, where he studied and practiced civil engineering. His instructors were Mr. George Morton, and his father, Mr. Albert W. Judson, who at that time, was the Engineer and Surveyor of Erie County. From 1882 to 1884, Mr. Judson acted as Deputy Surveyor, following which he was City Engineer of Sandusky for eight years. In all, he served the City of Sandusky, either as City Engineer or Superintendent of Water-Works, for seventeen continuous years.

In 1902, Mr. Judson was elected State Senator from the Thirtieth District of Ohio. He served in this capacity for two terms, acting on a number of important committees, including those of Geological Survey, Sanitary Laws and Regulations, Railroads and Telegraphs, Roads and Highways, and Drainage and Irrigation. From 1904 to 1913, he was Collector of Customs for the Port of Sandusky.

From the time of his graduation until his death, Mr. Judson carried on almost continuously his engineering work. His surveying and engineering activities covered consulting work for the municipalities of Port Clinton, Fremont, Norwalk, and Huron, Ohio, including plans for, and the construction of, sewers, water-works, and interurban railways.

He made preliminary surveys for what is now the branch of the Pennsylvania Railroad from Sandusky to Columbus, Ohio, and had charge of the engineering on the construction work of that road from Sandusky to Bellevue, Ohio, as well as of the construction of the Lake Shore Electric Railway between Sandusky and Lorain, and between Norwalk and Ceylon Junction, Ohio. In addition, he made preliminary surveys for other lines. His activities also included a variety of bridge work, overhead construction, and street paving. At the time of his death, he was serving as one of the City Commissioners of Sandusky.

Mr. Judson was an active member of the Sandusky Masonic Lodge, and of the First Congregational Church of that city.

He was married to Roxie E. Lowry, of Berlin Heights, Ohio, in 1883. Both he and Mrs. Judson were killed on September 30, 1926, near Belmont, N. Y., when their automobile was struck by a fast freight train of the Erie Railroad Company. They are survived by five children.

* Memoir compiled from information on file at the Headquarters of the Society.

One who was an intimate friend and co-worker of Mr. Judson, has prepared the following tribute to him:

"Mr. Judson never laid aside his intellectual interests. He could botanize, work mathematical problems with the children, on occasion read a little Greek and more Latin, and prepare papers for the Literary Club of which he was for so many years a member.

"Mr. Judson lived a successful business life. His services as a civil engineer were valued all through this part of the State.

"He took a man's part in politics. He was Customs Collector and for two terms served in the State Senate. He had the high ideals of political action that are expected of a scholar, and these ideals rooted down into a steady participation in practical politics year after year.

"He was a strong Churchman, in the choir, in the Sunday School as a teacher, giving unsparing personal attention to all the work of the church. He was an outspoken Christian man, without apology and utterly without ostentation.

"In every sphere in which he worked what he did was characterized by a restrained force and tact that enabled him to see the other man's side of the matter fully and fairly and yet not always share it—if necessary, oppose it vigorously. There are two adjectives that applied to him, 'fearless' and 'friendly'. He was afraid of no one and friendly to every one. He had a keen sense of humor that went with his fearlessness and friendliness. He understood the fine art of getting on with people, and was always ready to take hold with bare hands and do what needed to be done. He was a plain, hard-working, high-thinking, right-minded, forward-looking, public-spirited citizen, who made himself felt in the community life".

Mr. Judson was elected a Member of the American Society of Civil Engineers on January 3, 1894.

GEORGE THOMAS KEITH, M. Am. Soc. C. E.*

DIED SEPTEMBER 4, 1927.

George Thomas Keith was born on February 4, 1843, at Bridgewater, Mass. He was the only son of Thomas Mitchell and Caroline (Jones) Keith, and a lineal descendant of Captain Miles Standish, John Alden, and Priscilla Mullens.

Mr. Keith was graduated from the Bridgewater State Normal School at the age of eighteen. In the same year, 1861, he enlisted in the Third Massachusetts Volunteers, Company K, and was sent with his regiment to Newbern, S. C. Although he was actively engaged in five great battles of the Civil War, among which were Goldsboro, Kingston, and Whitehall, he suffered no wounds or illness during his entire service. At the close of the war he refused to apply for a pension, but when it was decided that pensions be granted to all Civil War veterans, he finally agreed to accept one.

Following his discharge from the Army, Mr. Keith became a student for three years in the office of the late Thomas Doane, M. Am. Soc. C. E., of Boston, Mass. During this time he was employed as Land Surveyor on the Cape Cod Railroad and the Hoosac Tunnel.

He completed his apprenticeship in 1864, when he became Assistant Engineer on the construction of the Bradford Branch of the Erie Railroad, which position he held for one year. From 1865 to 1868, he was employed, principally, as Engineer in coal mines in the United States Land Company's office, in Bradford, Pa. He then served as Engineer of the Land Department of the Erie Railroad Company, at Hornellsville (now Hornell), N. Y., from 1868 to 1873.

In 1873, Mr. Keith was made Assistant Engineer in charge of construction of the reservoir of the Lawrence Water-Works, at Lawrence, Mass. He held this position until 1876, when he engaged in private practice, with offices at Olean, N. Y., and Bradford, Pa., until 1889. During this period he constructed water-works plants at Newark, Ohio, and at Chester, Pa., and was engaged at Bradford, Pa., on surveys for pipe lines for the transportation of crude oil. He was also employed as Contractor for the water-works at Cuba, N. Y. In 1889, Mr. Keith became a member of the firm of Woltman and Keith, of New York, N. Y., and as such constructed water-works at Tallapoosa, Ga., Henderson, N. C., and elsewhere. His greatest work during this period was, perhaps, the establishment of the water-works in the seven municipalities of Montreal, Que., Canada, all of which were included in the Montreal Water System. From 1896 to 1904, he was engaged on the construction of electric railroads at Olean, N. Y., and Oil City, Pa.

Ill health then made it necessary for Mr. Keith to retire from active work for a time. When he had recovered sufficiently, he applied for a position on the New York State Barge Canal which was then under construction. The appointments of engineers on this work were made by competitive essays,

* Memoir prepared from information on file at the Headquarters of the Society.

or themes, submitted to the Barge Canal Commission. Mr. Keith received the highest award for his paper, and consequently, became the first Resident Engineer to be appointed on the Barge Canal construction in 1904. By personal request to the State Commissioner of Highways, he was transferred to the New York State Highway Department, at Olean, in 1907.

He was the author of "Keith's Railroad Tables", and "Functions of Curves", for the "Transit Note Book", published by Keuffel and Esser, which is well known, and is used as a college text.

In 1870, Mr. Keith was married to Evelyn Agnes Moore, who died in March, 1916. He is survived by an only daughter, Mrs. Mildred Evelyn Thynge.

He was a member of the Grand Army of the Republic; the National Geographic Society; and President of the Cattaraugus County Society for the Prevention of Cruelty to Animals. He was also a member of the Olean Country Club and the Olean City Club.

Mr. Keith was elected a Member of the American Society of Civil Engineers on May 4, 1881.

THOMAS JAMES McMINN, M. Am. Soc. C. E.*

DIED SEPTEMBER 21, 1927.

Thomas James McMinn was born at Port Hope, Ont., Canada, on October 8, 1854. In 1874 he began his technical work on the construction of the new water-works for Toronto, Ont., Canada, under the late P. A. Peterson, M. Am. Soc. C. E. He remained on this work and its various subsequent extensions, until 1879, when he was made Assistant Engineer to the late R. J. Brough, M. Am. Soc. C. E.

The following year he was engaged in making surveys, plans, specifications, and estimates for the construction of a 6-ft. oak conduit, to be built and extended for a considerable distance into Lake Ontario. In 1881, he was appointed Resident Engineer on this "lake extension", and served in this capacity during 1881 and 1882.

From 1882 to 1889, Mr. McMinn was employed as Assistant Engineer and Draftsman in the Water-Works Department of Toronto. During this period he made a barometric survey of the country extending to the north of Toronto, in connection with a proposed gravitation supply for the locality.

On leaving the Water-Works Department, he came to the United States and entered the employ of the late Rudolph Hering, M. Am. Soc. C. E., who was engaged in the private practice of engineering, in New York, N. Y. Mr. McMinn remained with Mr. Hering until January, 1898, when he was elected Assistant Secretary of the Society, which position he retained until his retirement in 1919. Shortly afterward he removed to Bridgeport, Conn., and then to Philadelphia, Pa., where he died on September 21, 1927. During this time he was engaged in editing several technical books for the late Mr. Hering and others.

Such, in brief, is an outline record of a useful life. To most members—and Mr. McMinn was widely known in the Society—his most valuable work was comprised within his official term as Assistant Secretary. The duties of this office were varied, especially in the early days, when the smallness of the organization demanded a wide variety of service of each officer. Always, however, Mr. McMinn gave his main efforts to publications.

At one time he handled the many phases of this work—editing, attending to engraving, proof-reading, and supervising the printing. Later, however, as the work expanded, he devoted his time mainly to the editing. In this he was, happily, successful. Endowed naturally with a clear perception of the fitness of expression, he was at once painstaking, well read, and widely versed in engineering methods. Many of the details of style he instituted are still standard practice, to the lasting credit and reputation of the publications.

Throughout his life his interest in these publications never flagged. A year before he died he went over a number of *Proceedings* in detail and submitted a long list of suggested improvements in its grammatical form—re-

* Memoir prepared from information on file at the Headquarters of the Society.

visions that none but his practiced and discerning eye would have noted. A similar trait of character was noticeable in his reading. Much of his library came to the Society; many of his books, especially the engineering volumes, showed traces of his critical taste in apt marginal notations of improvement in style.

During so many years' intimate connection with the Society journals, he gained a wide and close acquaintance among the members. Endowed with a mildness of manner and a gentlemanly bearing, his relations were always pleasant. No one could exchange ideas with him anent engineering matters, especially the details of rhetorical expression, without feeling his innate grasp of such intricacies.

His qualities of person and character endeared him to his many colleagues at Society Headquarters. He had made for himself a solid place in their esteem. Apparently, the feeling was mutual; the several years after his retirement were punctuated by frequent visits to New York, at which times he always made it a point to keep his many friendships in good repair.

Mr. McMinn was essentially a literary editor and an excellent one. But he was also an engineer; and, above all, a man. His lengthening years of Society work only served to ennoble his character, to bring into stronger relief the qualities of mind and of person that made him revered and loved. His place in the annals of the Society is secure.

Mr. McMinn was married on June 4, 1884, to Ada Jeannette Petman, of Toronto, Ont., Canada, who survives him, together with four children, George, Stanley P., Mrs. Lowell Grossman, and Mrs. W. C. Hooven. His home life was ever an inspiration to his friends, and his family indeed lived "to call him blessed".

Mr. McMinn was elected a Member of the American Society of Civil Engineers on March 5, 1890. He was also a member of the Engineering Institute of Canada.

ALEXANDER MAITLAND, JR., M. Am. Soc. C. E.*

DIED DECEMBER 24, 1926.

Alexander Maitland, Jr., was born on February 9, 1866, on a farm, near Richmond, Mo. He was the son of Alexander Maitland and Mary Grieves (Oliphant) Maitland and the eldest of a family of eight children, two sons and six daughters. He was of Scotch-Irish descent, his father's parents having been born in Scotland, and his mother's parents having come from Ireland. On his father's side, he was a descendant of the Scotch Earl of Lauderdale.

He attended a country school until 1886, when he entered the University of Missouri, from which he was graduated in 1889, with the degree of Civil Engineer.

After his graduation, Mr. Maitland entered the service of the King Bridge Company, of Cleveland, Ohio, as a Draftsman, and for a period of two years he was employed by this Company and the Keystone Bridge Company, of Pittsburgh, Pa., in estimating and designing various classes of steel structures. In 1892, he returned to the University of Missouri as Assistant Professor of Civil Engineering.

The following year he entered the employ of the Missouri Pacific Railroad Company, as Assistant Engineer in the Bridge and Building Department, and remained in the service of this Company until 1899. His work consisted of the design and supervision of the construction of substructures and superstructures for permanent bridges and buildings.

From 1899 to 1900 Mr. Maitland was engaged as Resident Engineer at Kansas City, Mo., for the Pittsburgh Bridge Company, of Pittsburgh. From 1900 to 1904 he was Contracting Manager for the American Bridge Company at Butte, Mont., and at Kansas City. From 1904 until his death, he was President of the Kansas City Bridge Company, of Kansas City.

During 1918 and 1919 he was Manager of the Gulf District of the United States Shipping Board, Emergency Fleet Corporation, in charge of the construction of wooden ships, with headquarters at Houston, Tex. For several years, previous to and at the time of, his death, he was, also, a member of the firm of Fuller and Maitland, Consulting Engineers, engaged in the design and supervision of construction of the new water plant at Kansas City.

Mr. Maitland was endowed with great mental and physical energy, which made him a leader in civic and social matters, as well as in his professional activities. He was a man of winning personality, who made friends easily and held them by loyalty, and a sense of fair play. He was intensely interested in his life work, and was always willing to contribute his time and engineering experience to all his business associates, especially to the younger members of the profession. His loyalty and friendship will be treasured by his large circle of friends.

* Memoir prepared by George F. Maitland, Herbert S. Crocker, and Milo S. Ketchum, Members, Am. Soc. C. E.

On January 8, 1896, Mr. Maitland was married to Desdemona Henderson, of Pacific, Mo. He is survived by his widow and six children, Alexander, 3d, Gladys, Helen, George, Ralph, and John.

Mr. Maitland was a member of the Masonic Lodge, and of the Benevolent and Protective Order of Elks. He was also a member of the Engineers Club of Kansas City and the Kansas City Club.

Mr. Maitland was elected a Member of the American Society of Civil Engineers on November 6, 1901. He served as a Director from January 1, 1925 until his death.

CONRADO EUGENIO MARTINEZ Y RENGIFO, M. Am. Soc. C. E.*

DIED MAY 21, 1927.

Conrado Eugenio Martinez y Rengifo was born in Havana, Cuba, on April 26, 1881. He was graduated in 1896 from the High School, Santa Clara, Cuba, with the degree of Bachelor of Arts. Soon afterward, he came to the United States and entered Lehigh University, at South Bethlehem, Pa., from which he was graduated in 1901, with the degree of Civil Engineer, the first on the Roll of Honor.

After leaving college, Mr. Martinez obtained a position as Rodman with the Pennsylvania Railroad Company, which position he held until December, 1901.

He then returned to Cuba, and entered the Government Service in the Engineer Department of the City of Havana, starting in January, 1902, as Rodman and working his way up to the position of Superintendent of the Department of Streets and Parks, which position he attained in January, 1903, and held until January, 1907. He was then transferred, as Assistant Engineer, to the Direction General of Public Works. Shortly afterward, he was appointed Engineer in charge of the location and construction of the highway from Cabanas to Bahia Honda, a distance of 20 miles, on the North Coast, which position he held until August, 1907, when he was appointed Chief Engineer of Public Works for the Province of Matanzas, Cuba.

In March, 1909, Mr. Martinez was transferred to Havana as Principal Assistant Engineer of the Havana Sewer and Paving Contract, where he remained until February, 1912. During this period he frequently acted as deputy for the Chief Engineer.

From March, 1912, until August, 1914, he was engaged in important private practice in designing and construction. In August, 1913, he was appointed Engineer Member of the National Board of Health which position he filled until shortly before his death. In August, 1914, he was appointed Chief Engineer of the Havana Sewer and Paving Contract and remained on this work until August, 1915, when he was transferred to the Direction General of Public Works as Chief Engineer in charge of examination of projects and inspection of new construction work for the Department of Public Works. In November, 1916, he was appointed Chief Engineer in charge of the Sewerage and Paving Contract for the City of Cienfuegos, Cuba, and in June, 1917, he was made Engineer in charge of the construction of water-works for the City of Marianao, Cuba.

In June, 1918, Mr. Martinez engaged once more in private practice as Consulting Engineer, in partnership with his brother, Rolando A. Martinez, Assoc. M. Am. Soc. C. E. In that capacity he undertook varied and important engineering enterprises, such as bridge and wharf construction; the design and construction of water-works and sewers; extensive land sub-divisions; surveys; appraisals; design of molasses pumping plants, etc., until his death.

* Memoir prepared by Manuel D. Diaz, Esq., Havana, Cuba.

On November 22, 1924, Mr. Martinez received the degree of Doctor of Laws, from the University of Havana after having taken the full course prescribed for the degree. Subsequently, while engaged in engineering work, he found time for the successful practice of his new profession.

Although financially independent, his love for the profession originally chosen by him, made him an indefatigable and enthusiastic toiler. A lover of truth, he spoke it, and wrote it, irrespective of its bitterness. His blunt honesty with his modesty and great worth made him many friends to whom his untimely death was as severe a shock as it was to his family and to those closely associated to him socially and professionally.

Mr. Martinez is survived by his widow, and two daughters, Clara and Blanca, to whom he leaves an example of faithfulness, truth, and integrity.

He was a member of the Union Club, of the Country Club of Havana, of the Association of Members of American National Engineering Societies in Cuba, and of the Tau Beta Pi Fraternity.

Mr. Martinez was elected an Associate Member of the American Society of Civil Engineers on October 7, 1908, and a Member on September 9, 1919.

FRANK OLIN MARVIN, M. Am. Soc. C. E.*

DIED FEBRUARY 6, 1915.

Great achievement in engineering is not always evidenced by the magnitude and importance of the buildings, great bridges, or public works that have been designed and built, nor by the economic importance of the industries that have been conceived and developed by an individual. Many engineers have done such outstanding work along these lines of design, construction, invention, and development that their fame will be lasting; and the world has come, through that work, to a full realization of the great part that engineering has had in the development of the present civilization.

Of equally great human value is the work of the man who, in the training of engineers, not only places emphasis on truth, accuracy, and thoroughness, but who by precept and example urges broadness of training and of interest, the cultivation of things that are fine and beautiful, the participation in civic and social activities, and the living of a Christian life.

When such a man comes to an administrative place in any school of engineering, his influence in character moulding, in the building of good citizens, and the implanting of high ideals of citizenship, of literature, art, music, and religion, along with a sound and thorough professional training, is of incalculable benefit to the profession. The engineering of men, the building of engineers, while not spectacular, is of lasting value to the world.

Frank Olin Marvin, Dean of Engineering of the University of Kansas, was such a man. He lived a quiet, beautiful life. He exerted a great influence in many fields of activity. His life work was as an educator and character builder. He influenced the career of several hundred engineers who will pass on to other generations the ideals of this teacher of the truth.

Frank Olin Marvin was born at Alfred, N. Y., on May 27, 1852. He was the son of the Rev. James Marvin and Armina (LeSuer) Marvin. He was graduated with science honors from Allegheny College, at Meadville, Pa., in 1871. During his years in college his chief interest was in the sciences, especially botany and geology, but he undoubtedly there laid the foundation for the appreciation of literature and the arts which developed so fully in his later years. In 1874, he received the degree of Master of Arts from Allegheny College.

In July, 1871, Mr. Marvin entered the service of the Missouri, Kansas, and Texas Railway Company as Engineer on Construction. In 1872 he became Chief Draftsman for the Company, and, later, Chief Clerk in the Chief Engineer's Office. He began teaching in 1875, so that his subsequent engineering work was done either during vacation periods or in a consulting capacity. From 1878 to 1880, he was Chief Engineer for the Great Eastern Irrigation Company and designed and located 100 miles of irrigation canals and ditches, with the dams and other essential structures. From 1889 to 1892, or 1893, he was Consulting Engineer for the City of Lawrence, Kans., on the

* Memoir prepared by Henry Earle Riggs, M. Am. Soc. C. E.

revision of sewerage plans, and on the construction of storm sewers, arch culverts, and various minor structures. In 1894, and in later years, he designed heavy retaining walls and a stone warehouse for a milling company; as Engineer for the University of Kansas, he had much to do with grading, heating tunnels, and other improvements on the campus; he made various reports on sewage disposal, street railways, and other public works in cities and for institutions in Kansas; and, with the State Geologist, he made an extended investigation of the building stones of the State.

It was as a teacher that he did his real work. In September, 1875, he began teaching in the Preparatory Department of the University of Kansas. From 1876 to 1878 he was Principal of the Lawrence High School. In September, 1878, he became Assistant Professor of Mathematics and Engineering. In 1883 he was appointed Professor of Civil Engineering, and, in 1891, Dean of the newly created School of Engineering, which position he held until 1913, when he retired on account of ill health, and became Advisory Dean.

Of Professor Marvin's forty years of teaching work, thirty-seven years were devoted to the service of the University of Kansas during the period of its growth and development. The School of Engineering was his creation, and his personality and character were impressed on the graduates in Engineering, from the beginning of their instruction in the institution. He stood firmly for thoroughness of training in the basic sciences, for careful preparation and accuracy of presentation in class work. He was mild of manner, gentle of voice, of unlimited patience, and was never unfair or unjust to the students. He did not believe in doing work for the pupils, but insisted on each one doing his own thinking and solving his own problems.

Professor Marvin was one of the active leaders in the work of learned and technical societies. He was a member of the Kansas Academy of Science, Kansas Water, Gas and Electric Light Association, Kansas Engineering Society, and American Society for Testing Materials. He was a Fellow of the American Association for the Advancement of Science and Vice-President of Section D in 1896. In 1901 he was President of the Society for the Promotion of Engineering Education, having been one of the most active workers during its early years. He was a member of Phi Beta Kappa and of Sigma Xi for which he worked very earnestly, and of which he became National President in 1909 and 1910. Some of his most intimate contacts with his students came through his active interest in the Science Club of the University, an organization which brought the students of the Eighties very close to the human side of the members of the Faculty. He always urged upon his students the need, after graduation, for such contacts with other members of the profession.

Professor Marvin was married twice, first on August 30, 1876, to Elinor G. McKean who died October 1, 1899, and afterward on December 31, 1901, to Josephine B. March, of Lawrence, who survives him, and who since his death has been living in California. During the long years that his first wife was an invalid, his constant care for her, and his consequent foregoing of many social pleasures, won for him the highest regard of his neighbors. Home life

meant much to him. He built a substantial, comfortable house and found great enjoyment in his library and study in which practically all his work was done for many years.

No memoir of Professor Marvin would be complete that did not lay stress on his citizenship and on his intense interest in the fine things of life outside of the professional field.

He was a lover of music. He had a fine and well trained voice and was for a time a member of a well known quartette, but it was as an organist that he is best remembered. For twenty-six years, from 1877 to 1903, he was Organist of Plymouth Congregational Church. He wrote a number of compositions for the organ, which were usually prepared for some special occasion. He also wrote a number of Christmas and Easter carols, composing both the words and music.

He was also a lover of art. He owned a notable collection of etchings, and did excellent work in this line himself. His work was the first of the kind done in the West and his first etched plate is said to have been the earliest made in the State of Kansas.

He was a lover of literature. His library bespoke his taste for the fine things of all ages and all nations.

Professor Márvin was a good citizen, although a modest and unassertive one. His only active participation in civic affairs was to serve as a member of the City Council of Lawrence for a two-year term from 1900 to 1902, but as an adviser and councilor he assisted in straightening out many a tangle. For many years he was the unofficial consultant and adviser to the City Engineer, always regarding such unpaid services as the duty of a good citizen.

That his years of service were recognized is amply proved by the fact that the Engineering Building at Kansas University is named Marvin Hall; by the fact that the fine new organ recently dedicated in Plymouth Church was appropriately named the Marvin Memorial Organ; and by the fact that in the Engineering Library of the University, to which his books on professional subjects were given, there is a bronze portrait bust and tablet to his memory, placed by the Engineering Alumni in memory of a teacher and friend. These things show that he was known, loved, and appreciated. There is no doubt that his gentle, quiet, effective work for the University and the community endeared him to all with whom he came in contact, and commanded the respect of those who did not know him well.

The writer knew Professor Marvin, first as a teacher of ability, who never used a harsh or sarcastic word in his classes; then, as an adviser, who could always be depended upon to consider and weigh carefully every matter before passing judgment upon it; finally, as a friend of his maturer years, who seemed to find real pleasure in going over the work his "boys" were doing. He would offer a suggestion here, or a mild criticism in the form of a question there, always seeking to encourage more artistic design, or more finished construction. He was an unerring judge of the ability of his students. The writer has employed a number of them on Professor Marvin's recommenda-

tion, every one of whom made good in a large way, and every one of whom is now a successful engineer and an active worker in the Society.

Professor Marvin wrote no books. His writing was confined to papers and addresses before the various societies of which he was a member. The subjects had largely to do with pedagogical matters, but some of these subjects clearly indicate his interests, namely, "The Cultural Value of an Engineering Education"; "The Artistic Element in Engineering"; and "Why not Teach About Men?" Once, when the writer was discussing with him the subject of work for an advanced degree, Professor Marvin urged that it be along purely literary lines, because he thought every one ought to develop along lines other than those of his professional work. He continually urged that each of his "boys" cultivate some fad or hobby that would get him far from the field of his practice.

Some of his early writing was prophetic of the great change in American engineering and public works, which has recently been taking place. The finer design, the greater regard for the artistic, the abolition of the ugly things, that is so marked in present-day practice, were foretold by him more than thirty years ago.

More than twelve years have passed since Professor Marvin's death on February 6, 1915. To those of his students who knew him outside the classroom his presence is just as real to-day as it was when they sat in his classes or chummed with him in the years following their graduation, and his gentle, kindly personality and his many lovable qualities will always be a real inspiration to them. Judged by his works, the great engineering school he founded and built up, and the scores of fine and broad engineers who gained their inspiration from him, not only in accuracy and thoroughness, but in love of the fine things of life and in ideals of good citizenship, he may indeed be called a great teacher. As the writer, in recent years, has come to know more intimately the problems of the engineering schools and made contacts with the leading present-day teachers of engineering, he has been brought more fully to a realization of the true worth of Frank Olin Marvin.

Professor Marvin was elected a Member of the American Society of Civil Engineers on May 5, 1897.

THOMAS HOGGAN MATHER, M. Am. Soc. C. E.*

DIED MARCH 23, 1927.

Thomas Hoggan Mather, the son of William and Isabella Hoggan Mather, was born near Glasgow, Scotland, on May 2, 1860. His father was an engineer and encouraged his son to follow the same profession.

Mr. Mather's early engineering training was received as an articled pupil with Kyle, Dennison, and Frew, Civil Engineers of Glasgow, and as a student in special classes at Glasgow University. Upon the completion of his university study in 1879, he was appointed Surveyor of Roads, Cadder Parish, Lanarkshire, Scotland.

In 1882, Mr. Mather removed to Canada and for the ensuing nine years he was engaged in a variety of work in that country and in the United States. He served consecutively as Transitman for the Canadian Pacific Railway; Superintendent of the Las Vegas, N. Mex., Water System; Office Engineer and Chief of Location Party for the Canadian Pacific Railway; Chief of Location Party for the Quebec Central Railway and for the Témiscouata Railway; Chief Engineer on Reconnaissance for the Gaspé Short Line; District Engineer on Location and Construction for the Calgary and Edmonton Railway; and District Engineer for the Norfolk and Western Railroad.

In 1892, he removed to Syracuse, N. Y. With the exception of the four years from 1918 to 1921, he resided there continuously until his death.

A period of private practice in partnership with Henry C. Allen, M. Am. Soc. C. E., was followed by twenty years' service as Chief Engineer of construction and maintenance for high-speed electric railways. During 1915, Mr. Mather served as Commissioner of Public Works for the City of Syracuse. Two years of private practice were succeeded by more than three years of Government service as Supervising Engineer of Construction at Harrisburg, Pa., and as Superintendent of Utilities at the Quartermaster Corps Depot in the same city.

After a brief interval when he was engaged in private practice in Brooklyn, N. Y., he was appointed City Engineer for the City of Syracuse in January, 1922, which position he held for four years. At the time of his death, Mr. Mather was serving as Chief Engineer of the Syracuse Grade Crossing Commission, having been appointed to that position in January, 1926.

He is survived by his widow, Mrs. Isabella Layfield Mather, and by two daughters, Mrs. Harry H. Motheral, of Brooklyn, N. Y., and Mrs. John C. Adams, of Jersey City, N. J.

Mr. Mather was a member of the Syracuse Chamber of Commerce, Technology Club, and Citizens' Club of Syracuse. He was also affiliated with Central City Lodge, F. and A. M., of which he was a Past Master, and with Central City Commandery No. 25.

As he was endowed with good humor and possessed of a fund of good stories effectively told, he contributed enjoyment to any festivity which his

* Memoir prepared by Glenn D. Holmes, M. Am. Soc. C. E.

presence graced. For recreation, Mr. Mather sought the woods, at home and abroad, and the wild plant life—particularly the ferns—to be found there. His personal friends of whom there were many, found attraction and pleasure in his conversation and company.

The greater part of his life was spent in railroad work, the branch of the profession which he most enjoyed. Those associated with him acquired a high esteem for his professional ability and his attractive personal qualities. The Grade Crossing Commission, with which he was engaged at the time of his death, recorded a tribute to his exceptional skill, his impartial attitude to the solution of its many problems, his unlimited application to his work, and the serious and sincere devotion to his duty. The City of Syracuse has lost a very able, conscientious, and valuable public servant.

Mr. Mather was elected a Member of the American Society of Civil Engineers on October 1, 1902.

JOHN DEVEREUX O'REILLY, M. Am. Soc. C. E.*

DIED NOVEMBER 6, 1927.

John Devereux O'Reilly was born at Denver, Colo., on May 4, 1884, the son of Anthony J. and Fredrica (Devereux) O'Reilly. His early youth was spent in Colorado, but by the time he was of college age, his family had moved to New Orleans, La., where Mr. O'Reilly attended Tulane University. In 1904 he matriculated at the Virginia Military Institute, at Lexington, Va., and was graduated from that institution in 1907, having completed the course in Civil Engineering.

Immediately after graduation, he accepted employment as Instrumentman with the Asheville and Hendersonville Interurban Railroad Company. Later, he returned to New Orleans where he was engaged on various engineering projects from 1909 to 1915.

In May, 1915, Mr. O'Reilly was appointed Chief Engineer of the Board of Commissioners of the Port of New Orleans, in which position he continued until 1919. During his connection with this Board, which, as an agency of the State of Louisiana, owns and operates the port facilities of New Orleans, a number of very important projects were undertaken. Notable among these were the Public Cotton Warehouse, the Public Grain Elevator, and the Inner-Harbor Navigation Canal, all of which were undertakings of great magnitude.

During the World War, President Wilson appointed Mr. O'Reilly as a member of the Council of National Defense, which had headquarters at Washington, D. C. As a member of this Council, his duties included the preparation of civil and military defenses against possible hostile attacks in the Harbor of New Orleans and in other United States ports.

In 1919, he severed his connection with the Board of Port Commissioners and resumed the private practice of engineering and contracting in and around New Orleans, and he was engaged in this work to the time of his last illness.

A man of pleasing personality who made friends readily, he was well known socially in New Orleans. He was a member of the Louisiana Club, the Delta Kappa Epsilon Fraternity, and of other organizations.

On June 30, 1908, Mr. O'Reilly was married to Beatrice Gilmore, who, with five children, four girls and one boy, survives him.

Mr. O'Reilly was elected a Member of the American Society of Civil Engineers on August 31, 1925.

* Memoir prepared by Samuel McC. Young, M. Am. Soc. C. E.

CHARLES LESTER PARMELEE, M. Am. Soc. C. E.*

DIED APRIL 4, 1927.

Charles Lester Parmelee, the son of Myron Holly and Emma (Lester) Parmelee, and a descendant of one of the founders of Guilford, Conn., was born at Syracuse, N. Y., on January 16, 1873. He spent a year studying civil engineering at the University of Michigan and, in 1890, went to the Massachusetts Institute of Technology, from which he was graduated in 1895 as Bachelor of Science in Civil and in Sanitary Engineering.

His college vacations were spent in civil engineering work. From 1895 to 1898 he served as Assistant Engineer to George W. Fuller, M. Am. Soc. C. E., on the experimental water filters at Louisville, Ky., and again on the experimental filters and preliminary designs for the Cincinnati, Ohio, Water-Works.

From 1898 to 1902, Mr. Parmelee was Chief Engineer, successively, of the Continental Filter Company and the New York Continental Jewell Filtration Company, in charge of design and construction of filtration works for many communities and industrial plants, including the works at Little Falls, N. J., the first large concrete filter plant built on the American system. For the next two years he acted as Consulting Engineer to the New York Continental Jewell Filtration Company on various enterprises, including a dry dock for the Federal Government, at Charleston, S. C., Oak Lane Reservoir, Philadelphia, Pa.; First Street Tunnel of the Pennsylvania Railroad Company, Washington, D. C.; Wantagh Infiltration Works of the Brooklyn, N. Y., Water Supply, and other work having an aggregate value of about $5 000 000.

In 1904 and 1905 he held the position of Consulting Engineer to the City of Toledo, Ohio, on water-works improvements, including a 32 000 000-gal. filter plant. In 1906 and 1907 he served as Consulting Engineer to J. G. White and Company, in connection with a dam across the Colorado River near Yuma, Ariz., preliminary studies for the Los Angeles Aqueduct, and other investigations.

From 1907 to 1912, Mr. Parmelee was Chief Engineer of the T. A. Gillespie Company, General Contractors, and the East Jersey Pipe Company, manufacturers of lock-bar and riveted steel pipe. These engagements connected him with contracts totaling approximately $15 000 000, including water purification works for Pittsburgh, Pa.; two locks and dams on the Ohio River; the Rondout Creek and Hudson River pressure tunnels of the Catskill Aqueduct, of the New York, N. Y., Water Supply; Granite Dam across the Yadkin River, at Whitney, N. C.; extension of the power plant at Massena, N. Y.; pipe lines at Brooklyn and Lockport, N. Y., Pittsburgh, Pa., and Portland, Ore.

For the next six years he held the position of Consulting Engineer to a number of contractors on large construction in hydraulic and railroad undertakings. He also made examinations of railroad, water-power, water-works,

* Memoir prepared by Alfred D. Flinn, M. Am. Soc. C. E., and John B. Stein, Assoc. M. Am. Soc. C. E.

timber, oil, gas, and coal projects. In 1917, Mr. Parmelee served as Captain in the Engineers Reserve Corps, on cantonment work, and in 1917 and 1918 as Consulting Engineer for the Oil Division, United States Fuel Administration. From 1918 until his death, he practiced as a Consulting Engineer, mainly in charge of the construction of oil refineries for the Sinclair Refining Company, aggregating $40 000 000 in value.

In 1896, Mr. Parmelee was married to Helen F. Donnelly, who died in 1920. Two daughters by this marriage, Emma Lester and Helen Donnelly, survive him. In 1923, he was married to Gertrude M. Pankan, who also survives him.

He was a member of the following technical societies and clubs: American Institute of Mining and Metallurgical Engineers; The Engineers' Club of New York; Railroad Club of New York; University Club of Chicago, Ill.; Essex County Country Club of West Orange, N. J.; Glen View Club of Illinois; and Old Colony Club of New York.

Mr. Parmelee was elected a Member of the American Society of Civil Engineers on February 4, 1913.

JOHN CURTIS PATTERSON, M. Am. Soc. C. E.*

DIED JANUARY 6, 1927.

John Curtis Patterson was born in Germantown, Philadelphia, Pa., on July 12, 1857, the son of Joseph Patterson and Lavinia Horstman Patterson.

He received his early education at the Faires Classical Institute in Philadelphia and was the first student from this Institute to enter directly the Towne Scientific School of the University of Pennsylvania, as a member of the Class of 1878. He pursued his studies in Civil Engineering until December, 1877, in his Senior year, when he withdrew from college to take a position as Rodman with the Engineer Corps of the Madeira and Mamoré Railway, in Brazil, joining the ill-fated Collins Expedition sent out from Philadelphia to build this railway around the Falls of the Madeira River, a branch of the Amazon. Mr. Patterson was selected for this expedition because of his excellent physique and strong constitution, but he barely escaped the treacherous climate with his life, after suffering from the sickness which caused the abandonment of the enterprise for the time being.

On his return from South America in April, 1878, he entered the employ of the Philadelphia and Reading Railroad Company as Rodman and continued in this position until August, 1880, when he became Rodman on an Engineer Corps of the Pennsylvania Railroad Company.

In November, 1880, Mr. Patterson went to Colima, Mexico, where he served as Levelman and, later, as Division Engineer for the Mexican National Construction Company (the Manzanillo and Laredo Railway Company). Returning from Mexico in May, 1882, he was Assistant Engineer on surveys for the Gettysburg and Harrisburg Railroad, at Carlisle, Pa., until April, 1883, when he became Division Roadmaster of the Lebanon Division of the Philadelphia and Reading Railroad and continued in this position until February, 1885. He then became Secretary and Treasurer of the Philadelphia Drainage Construction Company, Limited, and, in November, 1887, he again returned to the Philadelphia and Reading Railroad Company as Assistant Engineer. He continued in this position until November, 1888, when he became Assistant Chief Engineer, and, later Chief Engineer, of the Poughkeepsie Bridge and Central New England and Western Railroad Company.

Following this Mr. Patterson was, successively, Engineer in Charge of Construction of the Quaker City Mortar Company's Plant in Philadelphia; Assistant Chief Engineer of Surveys for the Baltimore and Cumberland Railroad; Chief Engineer of the Pittsburgh and Eastern Railroad Company in Clearfield County, Pennsylvania; and Chief Engineer for the Government of Ecuador on the construction of the railway from Guayaquil to Quito, an interesting engineering achievement. After his return from Ecuador, until his death, Mr. Patterson was engaged in consulting work in Philadelphia.

He was married to Charlotte Dallas Morrell, by whom he is survived, with a sister, Mrs. Meredith Bailey, of Portland, Ore.

* Memoir prepared by Clark Dillenbeck, M. Am. Soc. C. E.

Mr. Patterson was a man of exceptionally genial and attractive personality, and a most delightful conversationalist, who will be greatly missed by his fellow engineers and his many friends. In his youth, he was a notable athlete, an excellent player of baseball and cricket, interested in the beginning of amateur baseball playing and also in that of the modern game of football.

He was a member of the Delta Psi Fraternity and of the St. Anthony's Clubs of Philadelphia and New York, and, at various times, of the Engineers' Club of Philadelphia, the Philadelphia Gun Club, the Germantown Cricket Club, the Huntington Valley Country Club, the Devon Golf Club, the Racquet Club, and the Philadelphia Country Club.

Mr. Patterson was elected a Member of the American Society of Civil Engineers on October 2, 1889.

FRANK WILLIAM PERKINS, M. Am. Soc. C. E.*

DIED MAY 18, 1927.

Frank William Perkins was born in Chicago, Ill., on September 5, 1882. On graduating from Grammar School, he accepted a position in the Map Department of the Underwriter's Mutual Insurance Company. After leaving this Corporation, he was employed by various firms as Draftsman.

When Mr. Perkins was nineteen years old he determined to become an architect and for a series of years his evenings were devoted to study. In 1908 he was examined for his Architect's License at the University of Illinois, and passed with high honors.

From 1906 to 1908, Mr. Perkins was in charge of the design and erection of new buildings at the Morton Salt Plant, at Hutchinson, Kans. For two years thereafter, he was engaged in the private practice of Architecture and Structural Engineering in Chicago.

In August, 1911, he entered the employ of the International Packing Company, as Architect and Structural Engineer, where he remained until 1913. From 1913 to 1916 he held a similar position with the Morton Salt Company, in charge of the design and construction of building operations at Hutchinson, Kans., Port Huron and Ludington, Mich., and Grand Saline, Tex. At this time Mr. Perkins was regarded as being more experienced in the design, both structural and mechanical, of salt plants than any of his contemporaries. In 1916, he received his engineering license and for the next five years was engaged in private practice, designing domestic, public, and industrial buildings.

In May, 1921, he went to Manistee, Mich., as Designer, Engineer, and Superintendent of Construction of the Ruggles and Rademaker Salt Plant, which had a daily output capacity of 8 000 bbl., and was probably the largest and most modern salt plant in the world.

When Mr. Perkins returned to Chicago in August, 1922, his interest turned to architectural designing, and he was employed as a designer for various architectural firms. From September, 1924, until February, 1927, he was engaged in remodeling the interior of the First National Bank of Chicago, which was incorporated with the First Trust and Savings Bank. From February to May, 1927, he was Chief Designer for Graven and Mayger, Architects, during which time he designed, in part, the Wetzman Theatre in Detroit, Mich., and the Albee and Keith Theatre, in Rochester, N. Y.

It was while working on the latter theatre that Mr. Perkins became ill with spinal meningitis. He died on May 18, 1927. He was married in 1901 to Vera Ramenstein. He is survived by a son, Frank W., and a daughter, Vera.

* Memoir prepared by Isidore Cohen, M. Am. Soc. C. E.

Mr. Perkins was of a modest and sympathetic disposition, a most lovable and agreeable companion. To those who knew him, his friends and associates, his death was a severe shock. The community at large has suffered by the premature death of a man and worker who mentally combined a rare esthetic taste with not inconsiderable engineering ability.

Mr. Perkins was elected a Member of the American Society of Civil Engineers on July 11, 1921.

CHARLES JULIUS POETSCH, M. Am. Soc. C. E.*

DIED OCTOBER 7, 1926.

Charles Julius Poetsch was born in Wriezen, near Berlin, Germany, on July 17, 1850. He was educated in the public schools and the German Real Schule (a college), and came to Milwaukee, Wis., in 1871.

Mr. Poetsch began his engineering work in the United States as a Draftsman and, later, was appointed Assistant Engineer on the survey and construction of the Milwaukee and Northern Railway, having been with this Company from 1870 to 1874. In 1875, he was Assistant Engineer for the Green Bay and Western Railway Company, all this work having been done in the State of Wisconsin. He then became Resident Engineer for the Chicago, Milwaukee and St. Paul Railway Company, at Minneapolis, Minn., which position he held from 1875 to 1878.

In 1878, he returned to Milwaukee, where he was appointed a Division Engineer in the City Engineer's Office, also acting as Assistant City Engineer. This work consisted of giving lines and grades for various street construction, water mains and sewers, bridge construction, and other miscellaneous municipal improvements. He remained in this position until 1899 when he was appointed City Engineer.

In this capacity, Mr. Poetsch was also *ex officio* President of the Board of Public Works, and his guidance in the policy of local improvements enabled the City to undertake many notable projects. The construction of the Grand Avenue Bridge, the first bascule bridge erected in Milwaukee, was directed by Mr. Poetsch. Since then all other bridges erected by the City have been of this type. Two long viaducts of steel construction, spanning the lowlands of the Menominee River Valley, were also designed and constructed under his direction.

A flushing tunnel, a pumping station, and an intake from Lake Michigan, delivering water to the upper reaches of the Kinnickinnic River to prevent stagnation of the river waters during the low-flow periods of the summer, was also built by Mr. Poetsch.

The water-works of the city were also directly in his charge, as Superintendent. In that capacity he directed the purchase of pumping equipment, the first enlargement of the present North Point Pumping Station on the shore of Lake Michigan, the inland high-service pumping station, and the extensions of large feeder mains and the pumping station at West Allis, Wis., a suburb of Milwaukee. The first method for treating the water supply with chlorine, using hypochlorite dosing, was designed by Mr. Poetsch.

In all his works, he was ever thoughtful of economy in construction, and the various local improvements were made at the greatest saving to the citizens.

In 1911, Mr. Poetsch severed his connection with public work and engaged in private practice. He established the firm of Poetsch and Geiger, Con-

* Memoir prepared by C. S. Gruetzmacher, Assoc. M. Am. Soc. C. E., and H. P. Bohman, Supt., Water Dept., Milwaukee, Wis.

sulting Engineers on municipal work of all kinds. Ill health in 1916, and subsequent thereto, caused the abandonment of his private practice and forced his retirement from active engineering work. He was President of the Cummings Boulevard Land Company and a Director in the Home Savings Bank of Milwaukee, and he devoted his time to these and other business activities in which he was engaged.

During the later years of his life, Mr. Poetsch always found time to revisit the scenes of his former activities in the City Engineer's Department, lending able advice. He was a frequent visitor at the meetings of the local engineering societies and the Old Settlers' Club of which he was a member. He was also a member of the Wisconsin Lodge No. 1, Knights of Pythias. During his long services in public office, he gained a vast acquaintance by whom he will be greatly missed.

He was married in 1873 to Minnie E. Rausch. They had one daughter, now Mrs. Daisy L. Laming, of Tonganoxie, Kans., who, with her mother, survives him.

Mr. Poetsch was elected a Junior of the American Society of Civil Engineers on May 4, 1881, and a Member on May 2, 1883.

MERLE WILLIAM ROSECRANS, M. Am. Soc. C. E.*

DIED OCTOBER 9, 1927.

Merle William Rosecrans, the son of William E. and Florence S. (Cornwell) Rosecrans, was born at Ruthven, Iowa, on September 1, 1889. He received his Grammar School education in the schools of Bridgewater, S. Dak. and his High School training at Canton, S. Dak. He was graduated from the Iowa State College, at Ames, Iowa, in 1912, with the degree of Bachelor of Science in Civil Engineering.

During his undergraduate days, Mr. Rosecrans spent his summers with various survey parties in South Dakota and Iowa. On graduating from college he entered the general contracting business with his father, Mr. W. E. Rosecrans, and they built a number of water-works and sewer systems for various cities in Iowa. In 1913, Mr. Rosecrans went to Oregon as Assistant Engineer for C. W. Woodruff, Consulting Engineer, of Portland, but resigned in 1915 to again enter into business with his father. He was engaged in the saw-mill and logging industry until 1918, when he closed out his interests and become Assistant Professor of Civil Engineering at the Oregon State College. In 1919, he left the College and became Assistant Bridge Engineer for the Oregon State Highway Commission, which position he held until his death in the Salem General Hospital on October 9, 1927, after an illness of one month.

Mr. Rosecrans was admirably fitted for the positions of trust and responsibility which he held. Entering the Highway Department, as he did, at an early period in its organization, his keen insight into human nature and his knowledge of construction did much to smooth out the many troubles incident to a young and rapidly growing organization. His executive ability and unquestioned fairness were great factors in binding the Department together and co-ordinating its work to the high standard of efficiency in which he left it. Beyond every other trait which he possessed stands out that priceless quality of loyalty, not only to his work and to his superiors, but also to those subordinate to him. It was this quality that endeared him to all who were so fortunate as to be associated with him. During his eight years of faithful service with the Highway Department, Mr. Rosecrans handled contracts amounting, in the aggregate, to many millions of dollars, and it is a remarkable commentary on his sterling character, kindly personality, and keen appreciation of his responsibilty that he was generally regarded, not as a stern task master and uncompromising public official, but rather as a sincere friend and valued adviser by all with whom he worked.

* Memoir prepared by L. P. Campbell, and C. B. McCullough, Members, Am. Soc. C. E., and G. S. Paxson, Assoc. M. Am. Soc. C. E.

Mr. Rosecrans was prominent in fraternal circles. At the time of his death he was Master of Pacific Lodge No. 50 A. F. and A. M. He was also Secretary of the Northwestern Society of Highway Engineers, and he was a member of Tau Beta Pi.

He was married in 1922 to Margaret Hodge who, with his father, William E. Rosecrans, and his brother, Richard Rosecrans, survives him. It can be truthfully said of him that he left a place in the hearts of his relatives, friends, and business associates that can never be filled.

Mr. Rosecrans was elected an Associate Member of the American Society of Civil Engineers on October 11, 1920, and a Member on October 1, 1926.

CHARLES HENRY RUST, M. Am. Soc. C. E.*

DIED SEPTEMBER 22, 1927.

Charles Henry Rust was born at Great Waltham, Essex, England, on December 25, 1852. He was educated at Brentwood Grammar School in the same county and, in 1872, went with his family to Canada.

Soon after his arrival in Canada, Mr. Rust accepted a position on the Engineering Staff which was then engaged on a preliminary survey of the Ontario and Quebec Railway. Five years later, he entered the service of the City of Toronto, Ont., as Rodman on the Engineering Force under the late Frank Shanly, who was then City Engineer.

In 1881, Mr. Rust was appointed to the office of Assistant Engineer by the late R. J. Brough, M. Am. Soc. C. E., City Engineer and Manager of Water-Works, and, in 1883 was made Assistant Engineer in charge of sewers, which position he held until 1891. During this period he also served as Principal Assistant Engineer, and in the spring of 1892, after the resignation of Mr. Granville C. Cunningham, who had been Acting City Engineer, he was made Acting City Engineer until the appointment of the new City Engineer, the late E. H. Keating, M. Am. Soc. C. E., in July of the same year. Mr. Rust was immediately appointed as Deputy City Engineer, and held this office until February, 1898, when, on the resignation of Mr. Keating, he was appointed City Engineer and Manager of the Water-Works.

During his connection with the City of Toronto, Mr. Rust originated and carried out a complete system of main drainage and sewage disposal; a modern filtration plant; a new intake and tunnel for the water-works; numerous important bridges; and many other improvements of lasting benefit to the city. His duties also included reports on many plans, which, although they required much time and painstaking study, were never brought to fruition.

He reported at intervals on water-works and sewerage problems for neighboring municipalities and occasionally acted as an arbitrator. Although his services were frequently in demand as a consultant and expert, his routine duties occupied so much of his time that he was unable to accede to many requests for professional advice.

In 1912, Mr. Rust, having been attracted by the mild climate, and the prospect of the pending construction of a new municipal water supply, resigned the position of City Engineer of Toronto to accept a similar one in Victoria, B. C. While in Victoria he was requested by the Government to report on the Greater Vancouver Sewerage Scheme. At this time he also reported on the Second Narrows Bridge, near Vancouver, B. C.

In 1918, he returned to Toronto under an engagement with the management of the Toronto Street Railway and Toronto Electric Light Company.

* Memoir prepared by A. C. D. Blanchard, M. Am. Soc. C. E.

Later, these organizations were brought under municipal control, and thus Mr. Rust again became identified with the City of Toronto, this time as an official of the Toronto Hydro-Electric System. He retained this position until his death.

In 1887, Mr. Rust was elected as one of the first members of the Canadian Society of Civil Engineers, now the Engineering Institute of Canada. He was greatly interested in its affairs and served in various capacities until in 1911 he was elected President of the Society. In 1902, he was elected President of the American Society of Municipal Improvements. He was also a member of the Executive Committee of the American Water Works Association and, for many years, of the Royal Canadian Yacht Club as well as of the National Club of Toronto.

In 1879, Mr. Rust was married to Alice Preston, who survives him. His kindly and affectionate disposition endeared him to all those who were privileged to know him intimately. His mature judgment, unfailing courtesy, and tactful manner fitted him for the numerous high positions which he held in the Engineering Profession. He was loved and respected by his many business associates.

Mr. Rust was elected a Member of the American Society of Civil Engineers on April 5, 1899, and served as Vice-President in 1913 and 1914.

GODFREY LEWIS SMITH, M. Am. Soc. C. E.*

DIED JULY 2, 1927.

Godfrey Lewis Smith was born in San Francisco, Calif., on July 13, 1876, the son of Charles J. J. and Julia B. (Kelley) Smith. He was graduated from the San Francisco Public Schools and High School. In September, 1894, he entered the Massachusetts Institute of Technology and remained there as a student, until February, 1899, with the exception of one year when he was ill.

As a boy, Mr. Smith spent many of his free hours in a machine shop owned by his uncle, Lewis Kelley. He was so adaptable that, at the age of fifteen, he was able to operate all the machines in the shop, including firing the boiler and running the steam engine.

On leaving college he entered the employ of the Newport News Shipbuilding and Dry Dock Company, at Newport News, Va., and from February until June, 1899, he was in charge of filing and indexing hull drawings. From June, 1899, to May, 1905, he was engaged in designing and calculating ships' lines and structure, testing materials, estimating the cost of hulls, and surveying of property.

In September of the same year, Mr. Smith was made Engineer in charge of construction, which position he held until March, 1909. During this time he was in charge of the design and construction of one of the largest dry docks then built in the United States. He was appointed Civil Engineer in March, 1909, and in that capacity had charge of all designs and construction of dry docks, piers, bulkheads, trestles, shipways, buildings, tracks, roads, foundations, and other plant work, including some mechanical equipment. He held this position until January, 1924, when he was transferred to the Sales Department of the Company where he remained until his death, at which time he was Acting Sales Manager.

Mr. Smith took a prominent part in the civic and political affairs of Newport News and at one time was President of the Chamber of Commerce and a member of the Board of Directors of that body for a number of years. He was also a member of the Chamber of Commerce of the State of Virginia.

He served several terms as a member of the City Council and during a part of this time he was Chairman of the Finance Committee. He waged an almost constant fight for sound city financing and was an authority on the subject.

For many years before the city management form of government was adopted in Newport News, Mr. Smith was an interested and active advocate of simplified municipal government, and it was largely through his efforts that

* Memoir prepared by E. G. Rogers, Esq., Newport News, Va.

this plan was accepted by the city. He was so active in behalf of the reform that he was known to many of his associates as the "Father" of the City Manager form of government and when the new method became effective, he was the only member of the old Council to be returned to office.

On June 9, 1908, Mr. Smith was married to Miriam Post who, with four children, Margaret Post, Elizabeth Lewis, Walter Post, and Godfrey Lewis, Jr., survives him.

Mr. Smith was elected a Member of the American Society of Civil Engineers on July 6, 1920.

JOHN CLARK SPENCER, M. Am. Soc. C. E.*

DIED JULY 6, 1927.

John Clark Spencer was born in Clinton, Iowa, on August 26, 1869. He attended the State University of Iowa, from which he was graduated with the degree of Civil Engineer in 1891.

After leaving college, he entered the employ of the Chicago Bridge and Iron Company, of Chicago, Ill., holding a position in which he detailed, designed, and estimated highway bridges. This work included the Winona High Bridge over the Mississippi River, at Winona, Minn., and the Vermillion River Bridge, at Danville, Ill.

In 1893, Mr. Spencer became Engineer for the Portland Bridge and Building Company, of Portland, Ore., in which capacity he had charge of all the preliminary work for the South Eleventh Street Viaduct, Tacoma, Wash. Two years later, as Engineer for the Clinton Bridge and Iron Works, Clinton, Iowa, he was in charge of the office and shop work comprising the design and construction of the Mississippi River Bridge, at Brainard, Minn. In 1897, he completed a course in law at the Cleveland Law School, Cleveland, Ohio, and successfully passed the bar examination. He practiced law to some extent, but soon returned to engineering.

From February, 1898, to May, 1900, he was employed with the Keystone Bridge Works, at Pittsburgh, Pa., as Squad Master in charge of bridge, viaduct, and heavy mill building. At this time, he also made preliminary studies for new Bridge Shops, and after being transferred to the Designing Department in 1899, he planned the major part of Hot Metal Bridge for the Union Railroad Company, at Rankin, Pa.

In May, 1900, Mr. Spencer served in the Berlin and New York Offices of the American Bridge Company. As Designing Engineer, he made the plans for all classes of mill and factory buildings, pier sheds, coal bunkers, and similar structures. Subsequently, he was employed for one year with the Brown Hoist and Machinery Company, on the design of coal and storage plants. Three years later, in the employ of the American Bridge Company of Pittsburgh, he designed all classes of structural steel for manufacturing, office, and mercantile buildings. Among these were the Masonic Temple, at Carnegie, Pa.; the Maloney Building, at Pittsburgh (thirteen stories, not built); the Candler Building, at Atlanta, Ga.; and the high, steel frame, power house for the Central Heating Company, at Detroit, Mich.

In 1905, Mr. Spencer opened an office in Cleveland, where he practiced as a Consulting Engineer. He designed the steel work for the Rockefeller Office Building, as well as several other large buildings in Cleveland and in various other cities. His last work was the planning of the steel construction for the new, 22-story, Brotherhood of Locomotive Engineers Bank Building, at Cleveland, which was completed previous to his death.

* Memoir prepared by Charles M. Clark, Esq., Cleveland, Ohio.

Mr. Spencer was always unselfishly interested in Cleveland's civic affairs and gave much of his time to the study and investigation of contemplated city improvements. He was a close observer of men, and very active in his profession up to within a short time of his death.

He was a great lover of books, his studies covering the arts, sciences, philosophy, and law. He was very modest and unassuming, and impressed all with whom he came in contact as dependable and honorable—a gentleman in every respect. He was very approachable and had helped many young men to get a start in life, either by good advice or by financial assistance. Those with whom he was associated learned to know him as one inspired by the highest motives.

He was married, soon after his graduation from the Iowa State University, to Mary E. Huston, the daughter of J. M. Huston, County Surveyor and Engineer, of Clinton, Iowa, who survives him. They had known each other since childhood, and their home life was ideal.

Mr. Spencer was elected a Member of the American Society of Civil Engineers on December 6, 1904.

ALLEN NEWHALL SPOONER, M. Am. Soc. C. E.*

DIED JANUARY 2, 1928.

Allen Newhall Spooner was born at Jersey City, N. J., on October 2, 1864. He was the son of Edward A. and Angela (Newhall) Spooner, a grand-nephew of William Howe, the inventor of the Howe truss bridge, and also, a second cousin of Elias Howe, Jr., the inventor of the sewing machine. Mr. Spooner's earlier education was obtained in the public schools of Jersey City. In 1882, he entered the School of Mines, Columbia University, New York, N. Y., from which he was graduated in 1886 with the degree of Civil Engineer. He was a member of the Psi Upsilon Fraternity, and active in behalf of his Alma Mater, both as an undergraduate and as an Alumnus.

Immediately after his graduation, Mr. Spooner entered the employ of the Pennsylvania Railroad Company as a Rodman and Draftsman, and, in 1888, he was appointed a Hydrographer in the Department of Docks of the City of New York. From 1889 to 1906 he was Assistant Engineer in charge of construction work, and built most of the granite bulkhead wall along the Manhattan shore of the East River. In 1906, he was appointed Commissioner of Docks under Mayor McClellan, and it was under his régime that the Chelsea Piers were completed, the South Brooklyn water-front developed from 24th to 39th Streets, and the Staten Island and 39th Street, South Brooklyn, Ferry Terminals put into operation. Previous to his appointment as Commissioner of Docks Mr. Spooner was retained as Consulting Engineer and expert on water-front real estate valuation by such well-known companies as James Shewan and Sons, Incorporated, the North German Lloyd and Hamburg-American Steamship Lines, the New York Dock Company, and the Standard Oil Company of New Jersey.

From 1910 to 1913, Mr. Spooner was Chief Engineer of the New York Submarine Contracting Company and successfully handled the difficult work of placing two 36-in. submarine gas mains across the Harlem River at 210th Street, and one 48-in. main at 129th Street. In 1914, he organized the contracting firm of Allen N. Spooner & Son, Incorporated, and through his indefatigable efforts, his power in handling men, and his exceptional executive ability, during the period of thirteen years prior to his death, he, as President of the Company, brought it from a position of the smallest to one of the largest and best organized water-front contracting organizations in New York Harbor.

Mr. Spooner's career was cut off when he was about to realize the rewards of a life devoted to business; at a moment when the responsibilities of a long period of both public and private service were to be laid aside for the quiet pleasures of retirement. His rare qualities of character were apparent to all who came in contact with him. He was most charitable and tolerant, profoundly sympathetic, and an accurate judge of human nature. He had unusual powers of organization and exceptional executive ability which made

* Memoir prepared by F. R. W. Cleverdon, M. Am. Soc. C. E.

it possible for him to secure the loyal co-operation of subordinates. Added to a modesty and generosity of spirit, was an inflexible integrity in behalf of the highest business and personal standards. All these qualities stand out as an inspiration to those in the profession, and a rich memory to his family and to all who had the privilege of his personal friendship.

He died at St. Luke's Hospital, in New York, after a major operation, on January 2, 1928. He is survived by his wife (*nee* Bertha Klaproth) and three children by his first wife (*nee* Emma F. Browne), Mrs. Violet Langsford Sears, John Irving Spooner, Affiliate Am. Soc. C. E., and Ray Newhall Spooner, M. Am. Soc. C. E.

Mr. Spooner was elected a Member of the American Society of Civil Engineers on December 5, 1900.

HORACE AUGUSTUS SUMNER, M. Am. Soc. C. E.*

DIED DECEMBER 31, 1926.

Horace Augustus Sumner, the son of Robert S. and Mary Beals Sumner, was born at Stoughton, Mass., on March 18, 1845, and received his education in the public schools.

In July, 1864, he entered the Engineering Department of the Old Colony Railroad Company and was engaged as Chainman and Rodman on location and construction in Massachusetts and Vermont. He was also employed on similar work on the Portland and Ogdensburgh Railroad.

From April, 1868, to January, 1870, Mr. Sumner served as Transitman on location of the Burlington and Missouri River Railroad in Iowa. During this time he had charge of a division and constructed thirteen miles of the road near Corning, Iowa.

In April, 1870, he became Transitman on location of the Burlington and Missouri River Railroad, in Nebraska, from Crete to Fort Kearney, and from July, 1870, to July, 1871, he was Engineer in charge of location and construction of the Burlington and Southwestern Railroad from Rulo to Humboldt, Nebr. From July, 1871, to November, 1873, he acted as Assistant Chief Engineer of the Burlington and Southwestern Railroad from Viele, Iowa, to Unionville, Mo., and from July, 1874, to May, 1875, he was Engineer of Public Works, Burlington, Iowa.

He then accepted the position of Division Engineer in charge of about ten miles of construction of the Knoxville Branch of the Chicago, Burlington, and Quincy Railroad, near Knoxville, Iowa, and carried on this work for a year.

Mr. Sumner was Chief Engineer of the Burlington and Southwestern Railroad Company, including the territory from Viele, Iowa, to Laclede, Mo., from May, 1876, to January, 1882, when he became Chief Engineer of the St. Louis, Keokuk, and Northwestern Railroad and the Chicago, Burlington, and Kansas City Railroad Companies. He held this position, until May, 1884, with headquarters at Keokuk, Iowa.

From June, 1885, to March, 1886, he was Resident Engineer on construction of thirty miles of the Chicago, Burlington, and Northern Railroad, at East Dubuque, Ill. In June, 1886, he engaged on location work in Colorado, principally in the mountains, on what is now the Moffat Railroad over the Continental Divide, and in February, 1894, he accepted the position of Chief Engineer of the Florence and Cripple Creek Railroad Company. He held this position until April, 1895, when he was appointed State Engineer of Colorado, which office he held for two years.

* Memoir prepared by R. S. Sumner, M. Am. Soc. C. E.

Mr. Sumner served as Chief Engineer of the Alamogordo and Sacramento Mountain Railroad Company, in New Mexico, from November, 1897, to September, 1898, when he was appointed Chief Engineer of the El Paso and Northeastern Railway Company and was engaged on construction from El Paso, Tex., to Dawson, N. Mex. He resigned in 1902 to become Chief Engineer of the Moffat Railroad, in which position he made surveys from Denver, Colo., to Salt Lake City, Utah, and was also engaged in construction work from Denver to Steamboat Springs, Colo.

From 1912 to 1914, he was Chief Engineer on location surveys in California and Oregon for a company that was absorbed by the Southern Pacific Railway Company which built the line from Medford to Marshfield, Ore. From 1914 until his death he was engaged in general consulting work in Denver, Colo.

Mr. Sumner is survived by his widow and two sons, Robert S. Sumner, M. Am. Soc. C. E., and Lewis A. Sumner.

His past record is amply covered by the following tribute:

"Mr. Sumner * * * was an engineer of National prominence; but he was also a moral engineer, for he constructed his life on the divine lines of force, of integrity and uprightness, humility and gentleness, love and magnanimity, a reasonable and sincere faith in God. He was a towering pine of the forest. His many friends join in sympathy with his wife and sons, not only because they are our friends, but because we share with them their love of this great man who has died."

Mr. Sumner was elected a Member of the American Society of Civil Engineers on October 4, 1899, and served as Director of the Society from 1909 to 1911.

ROBERT L'HOMMEDIEU TATE, M. Am. Soc. C. E.*

DIED DECEMBER 20, 1927.

Robert L'Hommedieu Tate, the son of Robert W. and Susan (L'Hommedieu) Tate, was born at Union Springs, N. Y., on September 3, 1888.

He attended the public schools of New York City, and was graduated from Morris High School in 1907. He then entered Cornell University, Ithaca, N. Y., from which he was graduated in 1912 with the degree of Civil Engineer.

Mr. Tate's preliminary professional apprenticeship was as a Surveyor and Topographer on the Costa Rica-Panama Boundary Survey in 1912. Subsequent to his return to the United States, he was engaged for a short period in the office of F. A. Molitor, M. Am. Soc. C. E., Consulting Engineer, New York City. Later, he became a Draftsman on a hydro-electric project in West Virginia.

In 1914, he was an Assistant Engineer for the Delaware, Lackawanna and Western Railway Company on Maintenance of Way and Construction, which position he retained until 1917.

During the participation by the United States in the World War, between May, 1917, and July, 1918, Mr. Tate was engaged in the military service of his country. He attended the first Officers' Training Camp, at Madison Barracks, N. Y., and on April 16, 1917, was commissioned a First Lieutenant in the Engineer Officers Reserve Corps. On May 26, 1917, he was ordered to active duty, having been assigned to the 303d Engineers, the Divisional Engineer Combat Regiment of the 78th Division. He went overseas with his regiment in May, 1918, was promoted to the rank of Captain in July, 1918, and served in the St. Mihiel and Meuse-Argonne offensives. During a portion of this period he acted as Regimental Personnel Adjutant. At the close of the war he returned to the United States, and was honorably discharged in June, 1919.

As a Junior Officer, Mr. Tate's military service was founded on the same patriotism as that which prompted so many of the younger engineers to "learn the game" at Officers' Training Camps. With many others of the same age he "did his bit" with fortitude and success, both from a military and an engineering standpoint.

Following his discharge from the Army, Mr. Tate again entered foreign service as an Assistant Engineer on the design and construction of a town and plant for the mining of bauxite in Dutch Guiana. Here, he designed and constructed a complete town site, with business and residential buildings for 4 000 people, including the installation of electric lights, as well as a sewer system and a surface mining plant. This work entailed a stadia survey, under difficult topographic conditions, through dense tropical jungles along the boundary line.

* Memoir prepared by Frederic Molitor, M. Am. Soc. C. E.

He returned from Dutch Guiana in April, 1921, and from the early part of 1922 until June, 1924, was engaged with A. B. Cohen, M. Am. Soc. C. E., Consulting Engineer, whom he assisted in the design, plans, and estimates for a reinforced concrete bridge that was to carry the Hudson Boulevard at Journal Square, Jersey City, N. J. From 1924 to the time of his death, he was engaged as a Resident Engineer on the Hudson Boulevard project, in charge of the field work incident to the construction of this bridge.

Mr. Tate's professional career was marked by a close attention to detail, thorough research studies, and a complete application to the problems assigned to him. He gave promise of a broad and distinguished future, and his many friends in the Engineering Profession expressed keen regret that such a career should have been cut short by an untimely and early death. Mr. Tate was noted for the warm friendships that he made in the profession and in the Army.

At the time of his death, he held a commission as Major in the Engineer Officers Reserve Corps. He is survived by his mother and his widow, Leonora T. (Van Derhoef) Tate.

Mr. Tate was elected a Junior of the American Society of Civil Engineers on March 4, 1913; an Associate Member on April 17, 1917; and a Member on December 14, 1925.

OSCAR HOLMES TRIPP, M. Am. Soc. C. E.*

DIED AUGUST 24, 1927.

Oscar Holmes Tripp was born January 15, 1852, at Waterboro, Me., the son of the Reverend Leander and Louisa A. Tripp. His father was a Baptist clergyman and his early years are difficult to trace because of the migrations made necessary by this calling. His youth was spent in Hancock County, Maine, where he received his primary education in the public schools. He afterward attended one of the Maine academies and later studied law, being admitted to the Hancock County Bar, and subsequently practicing at Bluehill, Me. As was not uncommon in the earlier days, he carried on the practice of surveying in conjunction with the practice of law, but gradually a keener interest in the problems of engineering drew him from the legal profession and it was as an engineer that he was known.

From 1881 to 1884, Mr. Tripp was employed as Assistant Engineer on the Bangor and Katahdin Iron Works Railway, and the Bangor and Piscataquis Railroad. Both these roads are now part of the Bangor and Aroostook System. In 1885, he opened an office at Rockland, Me., for the general practice of engineering, and except for occasional short engagements in other sections of Maine, and fifteen months of the years 1898 and 1899 spent as Assistant Engineer in the Sewer Department at Arlington, Mass., he was located at Rockland. During this period, he served for several terms as City Engineer.

He was an assiduous reader, with a taste for literature and history as well as science. He was very observant and this, coupled with the fact that he made a record of his observations and the happenings of the day, gradually made his office a treasure house of accurate information on local history.

Mr. Tripp was a member of the Knox County Bar Association and, for several years, had served it most efficiently as Treasurer and Librarian. He was a member of the Congregational Church. He was a Scottish Rite and a York Rite Mason. He was also a member of the Boston Society of Civil Engineers.

He died suddenly of heart failure in the Houston-Tuttle Book Store in Rockland, while browsing, as was so often his custom, among the new books. For several years Mr. Tripp had been in ill health and none realized as well as he, how near death hovered. Nevertheless, he continued his work up to the day preceding his death. He was unmarried, and his nearest surviving relative is a niece, Mrs. Flora T. Cooper, of Portland, Ore.

Mr. Tripp was elected an Associate Member of the American Society of Civil Engineers on October 7, 1896, and a Member on September 5, 1905.

* Memoir prepared by Walter C. Groves, Assoc. M. Am. Soc. C. E.

PETRUS WAHLMAN, M. Am. Soc. C. E.*

DIED MARCH 11, 1926.

Petrus Wahlman was born at Gefle, Sweden, on March 11, 1879. He received his early education at a school in Gefle and his technical training at the Royal University of Technology in Stockholm, Sweden, from which he was graduated in May, 1902, with the degree of Civil Engineer, having specialized in highway and hydraulic subjects. During his summer vacations he was engaged on railway location and survey work.

From June, 1902, to March, 1904, Mr. Wahlman held the position of Superintendent on the construction of the water-works and sewer system for Hudiksvall, Sweden, the cost of which was $110 000, and from March to August, 1904, he conducted the work on the extension of the water-works of Oxelösund, Sweden.

In September, 1904, he investigated the stresses, through elongation tests, in two of the bridges of the State Railways of Sweden and in November, 1904, he became affiliated with the Hydraulic Engineering Company, Limited, of Stockholm, continuing in this position until May, 1907. During this period he made field studies, reports, and complete designs of water power plants in Sweden and Norway and supervised the design and construction of the water-works and sewer system for Djursholm.

In 1907, Mr. Wahlman came to the United States and in June of that year secured a position as Draftsman with the firm of Vielé, Blackwell, and Buck, of New York, N. Y., on the design of the hydraulic plant of the Great Western Power Company.

From March, 1908, to February, 1909, he was engaged in work for the New York State Water Supply Commission, at Albany, making studies and designs for water power plants, storage dams, etc., and the utilization of the water powers of New York State for electrification. From March to June, 1909, he was occupied on hydraulic computations and the design for a power plant at Boulder, Colo., which was being erected by the Central Colorado Power Company. In June, 1909, he was engaged by the Ontario Power Company, of Niagara Falls, N. Y., to make hydraulic computations and designs for the extension of the Company's plant.

During the period from 1910 to 1913, Mr. Wahlman acted as Chief Engineer of the Construction Department of the Hydro-Electric Company of Tucuman, Argentine Republic, where he had responsible charge of the design and construction of an 18 000-h.p. water power plant on the Lules River and of two railways, the cost of which was $2 500 000. His duties included the building of a water-power plant for the utilization of two falls with a combined output of 40 000 h.p. situated at the foot of the Andes Mountains, approximately 600 miles from Buenos Aires, Argentine Republic. At times, he had as many as 1 000 workmen and many engineers in his employ.

* Memoir compiled from information on file at the Headquarters of the Society.

In 1914, Mr. Wahlman made reports on engineering conditions in the South American Republics on the Pacific Coast and also visited the then more recently constructed water power plants in the United States, Canada, and Alaska. He was also interested in the development of the Speel River water-power project in Alaska.

In 1915, he became associated with Mr. R. D. Johnson, and under the firm name of Johnson and Wahlman carried on consulting work in hydraulic engineering in New York. This firm also contributed toward the development of the water-power projects on the Canadian side of Niagara Falls, where many new and valuable designs were carried out.

Late in December, 1924, he was forced to withdraw from his work and go South for his health, returning a little later to his home in Sweden. All his efforts to recover his strength were in vain, and he passed away on his birthday, March 11, 1926.

Through his engineering affiliations and his large circle of friends Mr. Wahlman quietly assisted many Swedish engineers who came to the United States in search of employment. Although he did not consider his services of great consequence, he will long be remembered by those men whose road to success was made easier by his advice.

He was very fond of sports, having participated as gymnast and swimmer in the first modern Olympic Games at Athens, Greece, in 1906. His favorite games were football and tennis and as a fancy skater he had won a championship.

His individuality was strongly marked by a most unusual self-control, evincing itself in a demeanor of faultless good breeding and gentility, kindliness and modesty of disposition, and unselfish consideration for others. His most outstanding characteristic in the opinion of all his acquaintances was that of a thorough gentleman in every sense of the word. He was a true son of the Nordic race and his many fine characteristics made him esteemed by all who knew him.

Mr. Wahlman was elected a Member of the American Society of Civil Engineers on December 6, 1915.

PHILIP ALBERT WELKER, M. Am. Soc. C. E.*

DIED DECEMBER 24, 1926.

Philip Albert Welker, the son of Philip and Maria (Pauly) Welker, was born at Toledo, Ohio, on June 1, 1857. He received his education in the public schools of Toledo, and was graduated from the High School in June, 1874. He then entered Cornell University from which he was graduated in June, 1878, with the degree of Civil Engineer.

After serving for a year as Assistant with the City Civil Engineer of Toledo, he was appointed in July, 1879, to a position with the United States Coast and Geodetic Survey and was engaged on the transcontinental triangulation in Missouri.

From 1880 to 1890, Mr. Welker was occupied in primary triangulation and astronomical work in British Columbia, Washington, Southern California, Utah, Nevada, and Florida. He carried out work in precise levels in the States of Arkansas, Illinois, and Tennessee, as well as special surveys for the Navy Yard Site Commission in Escambia Bay, Florida, and for the location of the trans-meridianal line at Toledo. He also made hydrographic surveys of the harbor at Baltimore, Md., San Francisco Bay and tributaries, San Pablo Bay, and Suisun Bay, California, as well as of the Atchafalaya River, in Louisiana, Pensacola Bay and tributaries, in Florida, and, also, Maumee Bay, Ohio, for the State Fish Commission. During this period he made observations for the transit of Venus over the sun at Tepusquet, Calif., and a determination of the magnetic elements at the U. S. Coast and Geodetic Survey, as well as observations of the annular eclipse of the sun at San Francisco.

From 1891 to 1910, he carried out work in hydrographic surveying in Florida, Louisiana, and along the Atlantic Coast as far north as Maine. In 1893, he represented the Government of the United States in field observations connected with the survey of the boundary between Alaska and Canada. During the two years following, he continued to carry on boundary survey work in Alaska. In 1898, he was placed in command of the U. S. Coast and Geodetic Survey Steamer, *Bache,* continuing in this capacity until 1910, during which time he made surveys of Portsmouth Harbor and its approaches in New Hampshire and Maine, and along the coasts of the Atlantic Ocean and Gulf of Mexico, and in the Caribbean Sea.

In 1910, Captain Welker again represented the Government of the United States on a Commission of Engineers created for the purpose of determining the location and ownership of the Fort Myers Military Road, Virginia. While on a furlough of six months he organized the Welker Supply Company, at Cleveland, Ohio, and was elected President of the Corporation.

On the expiration of his furlough, Captain Welker was sent to Alaska where he determined the longitude of the Cities of Fairbanks and Tanana.

* Memoir prepared from information on file at the Headquarters of the Society.

On February 26, 1911, he was given charge of the Sub-Office of the U. S. Coast and Geodetic Survey at Manila, Philippine Islands, and until February 28, 1914, served as Director of Coast Surveys in the Islands. He also served as a member and Secretary of the Philippine Committee on Geographical Names and as a member of the Harbor Lines Commission of the Philippine Islands.

On October 10, 1914, he was appointed Assistant in charge of the office of the U. S. Coast and Geodetic Survey of Washington, D. C., and served in that capacity until July 1, 1917, when the designation was changed to Hydrographic and Geodetic Engineer in charge of the office. On July 1, 1920, he was designated as Personnel Officer of the U. S. Coast and Geodetic Survey and held that position until he was retired from active duty on August 1, 1921.

During approximately fifteen years of his service with the U. S. Coast and Geodetic Survey, Captain Welker was in command of vessels. His surveys of the coasts of Porto Rico and off the Isthmus of Panama formed the basis for some of the first complete navigating charts of these waters prepared by the Federal Government. His service included all branches of activity in the Bureau, from triangulation and astronomical observations in his earlier days, through the duties of Hydrographer, to responsible administrative positions in Manila and Washington.

He died at his home in Washington, D. C., on December 24, 1926, and is survived by his widow, formerly Gertrude M. Lanahan, of Baltimore, a son, Philip Lanahan Welker, and a daughter, Mrs. Howard R. Willis, of Cleveland, Ohio.

The conspicuous services of Captain Welker deserve more than the expression of regret for the loss of an able engineer. Through his systematic operations he played an important part in the security and extension of American commerce by determining and describing the dangers in its path. His results had always in evidence a distinctive mark of originality of execution scientifically accomplished, thereby increasing the efficiency and precision of the methods and work of the U. S. Coast and Geodetic Survey and the reputation which it has always sustained.

His kind and genial disposition gained for him the regard of all his associates in the field and office work of the Survey, and all those who dealt with him could rely implicitly on his innate sense of justice. In private relations, Captain Welker was high in the esteem of a large circle of acquaintances, and he will be remembered for the steady practice of all the virtues and amenities which adorn social life.

He was a member of the Washington Society of Engineers, Beta Theta Pi, Cosmos and Federal Clubs in Washington, the University Club of Manila, and the Philippine Club of New York, N. Y. He was also a member of the St. John's Protestant Episcopal Church, a Thirty-second Degree Mason, and a Knights Templar.

Captain Welker was elected a Member of the American Society of Civil Engineers on April 25, 1921.

LEVI LOCKWOOD WHEELER, M. Am. Soc. C. E.*

DIED MARCH 13, 1927.

Levi Lockwood Wheeler was born on a farm near Jackson, Mich., on February 5, 1851, the only son of four children, of Sarah Houseman and Lorenzo Dow Wheeler. After receiving his primary education at a country school, he was graduated from the High School at Jackson, in 1870, and, subsequently, entered the University of Michigan at Ann Arbor, Mich. He completed the regular four-year course in Civil Engineering, and received the degree of Civil Engineer in June, 1874.

Mr. Wheeler entered the Civil Service of the United States on May 8, 1874, as Sub-Assistant on the United States Lake Survey at Detroit, Mich., where, with the exception of one summer, he continued until April, 1881. While on this work he ran one of two lines of precise levels for determining the elevations of the Great Lakes above sea level and, later, he reduced the data relating to this subject and prepared them for publication.† During his connection with the U. S. Lake Survey, Mr. Wheeler aided in the comparisons of standards of length, in the determination of latitudes and longitudes, and in the reduction of the notes relating thereto.

During the summer of 1881, he worked on his father's farm in Jackson County, Michigan.

In February, 1882, Mr. Wheeler was appointed an Assistant Engineer with the Mississippi River Commission at St. Louis, Mo., and remained in this position for six years. He made the topographic and hydrographic surveys of the Mississippi River and adjacent territory from Vicksburg to Natchez, Miss., and for a reach 110 miles long above Memphis, Tenn. He revised the methods which had been in use on precise level work under the Commission, pointed out the errors in methods formerly used, and prepared instructions for field work, which were subsequently followed by the Commission and used on other important surveys in the United States. Mr. Wheeler also had charge of the Computing Division for a number of years and prepared data for the use of the Commission and for publication.

In September, 1888, he was placed in charge of a Government survey for a 14-ft. waterway from Lake Michigan to the Illinois River. He made surveys covering two locations from Lake Michigan to Joliet, Ill., the report and maps of which were printed and used by the Sanitary District of Chicago, Ill., in the construction of the main canal and the Calumet-Sag Canal.

In November, 1890, Mr. Wheeler was appointed United States Assistant Engineer in charge of the location and construction of the Illinois and Mississippi Canal, extending from the Illinois River, near Hennepin, to the Mississippi River, near Rock Island, Ill. The summit level of the canal is supplied by a Feeder carrying the water from Rock River at Sterling, Ill. The main line and Feeder have a surface width of 80 ft. and a depth of 7 ft.,

* Memoir prepared by John W. Woermann, M. Am. Soc. C. E.

† *Professional Papers No. 24*, Corps of Engrs., U. S. A., Chapter XXII.

the main canal being 75 miles long and the Feeder 29 miles long. Mr. Wheeler was in immediate charge of the Western Section of the main canal which is 27 miles long, and also of the entire Feeder.

The structures on the Illinois and Mississippi Canal (better known as the Hennepin Canal) include 34 locks, 9 aqueduct bridges, 9 railway bridges, 69 highway bridges, 60 culverts, 3 dams, 51 houses, and numerous smaller structures. Construction was commenced in 1892, and the water was turned into the canal on October 24, 1907. Mr. Wheeler was subsequently in charge of the operation and maintenance of the canal until his retirement in 1921. A large number of the structures were designed as well as built under his direction and about $4 200 000 was expended on this canal under his immediate supervision.

In addition to his Government work, Mr. Wheeler was engaged in private practice, mainly in hydraulic work, and as Consulting Engineer and expert witness in connection with a number of projects. He designed and supervised the construction of water-power dams across the Rock River, at Sterling, Dixon, Oregon, and Sears, Ill., two of which were crib dams and two, concrete dams. He also designed a dam for Grand Detour, Ill., which was not built.

Mr. Wheeler was retired from the Government Service on February 5, 1921, at the age of 70 years, the retiring age prescribed by Congress for the Civil Service. On April 5, 1921, he returned home from a visit to his son in the Hawaiian Islands, and on April 15 suffered a cerebral hemorrhage, from which he never recovered. Eleven months before his death, he fell in his room, breaking a hip, as a result of which he was confined to his bed until his death on March 13, 1927. His daughter, Mrs. Clingan, states that "Never, in all the six years of his illness did he complain, but was ever thoughtful of others, and wanting others to be happy."

Mr. Wheeler was a great lover of Nature in all her aspects. He loved to fish and hunt, and was well posted on fish, birds, animals, trees, and flowers. He always enjoyed working in his garden and took pride in the beauty and variety of his fruits and flowers, especially of his tulips and irises. He was also an authority on bees and kept a number of hives in connection with his garden.

Extremely thorough, methodical and accurate in all his work, Mr. Wheeler was satisfied with nothing less from his subordinates. In connection with the construction of the Hennepin Canal he established a record for economy and efficiency which seldom has been equalled. He was gifted with a mind and physique which made it possible for him to keep in contact with all the details of his work, as well as with its larger and broader features. He seemed to be equally at home in the field, on location and construction, and in the office, in computing and designing. He was a man of fine appearance, possessed of remarkable energy and unusual capacity for hard work.

On January 7, 1880, Mr. Wheeler was married, at Detroit, to Isabella Chambers, who died on January 16, 1912. He is survived by four children, Arthur Chambers Wheeler, M. Am. Soc. C. E., of Hilo, Hawaii; Frank Dow Wheeler, Civil Engineer, of Chicago; Mabel Alice Wheeler, of Detroit; and Mrs. Grace Wheeler Clingan, of Sterling; also, one grandchild, Lee Grant Wheeler, of

Hilo, Hawaii. Mr. Wheeler was greatly devoted to his family, always keenly interested in their happiness and welfare, and never more happy than when spending his evenings at home surrounded by them.

He was a member of the Benevolent and Protective Order of Elks, at the rooms of which, he was a frequent attendant after his wife's death, and was at one time President of the Sterling Club, a social organization. For a number of years prior to his illness, he had been a Trustee of the First Presbyterian Church of Sterling, from which he was buried.

Mr. Wheeler was elected a Member of the American Society of Civil Engineers on June 4, 1884.

PHILIP AYLETT, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 28, 1927.

Philip Aylett was born on April 30, 1867, at "Montville", the Aylett Plantation on the Mattaponi River, in King William County, Virginia. Although of unassuming mien, he could have boasted of an ancestry scarcely equaled by any of his peers. He could have claimed, among others, Alexander Spottswood, one of the early Governors of Virginia, and Patrick Henry, one of the founders of this Nation. His father was William Roane Aylett, who as Colonel commanded the 53d Virginia Regiment of the Confederate Army, and his mother was Alice Brockenbrough Aylett, of Richmond County, Virginia.

After Mr. Aylett had received a thorough preparatory training, he was entered, in 1884, as a Cadet in the Virginia Military Institute, at Lexington, Va., from which he was graduated as a Civil Engineer in 1888. Afterward, he accepted a position as Principal and Instructor of Mathematics at Sunnyside Academy in Virginia. He held this position for one year and then commenced his life work as a Civil Engineer.

It would take more space than is permitted, to tell of the various surveys, engineering projects, etc., undertaken and accomplished by Mr. Aylett. His work carried him south as far as New Orleans, La.; west as far as St. Louis, Mo.; and north as far as Albany, N. Y. Early in his career he was engaged as Assistant Engineer in charge of tunnel work for the Baltimore and Ohio Railroad Company, at Harper's Ferry, W. Va. At another time, he was Construction Engineer on the Albermarle Sound Bridge for the Norfolk and Southern Railroad Company, and during 1894 and 1895 he was Engineer of Bridges on the Seaboard Air Line Railroad, at Portsmouth, Va. In 1906, he was appointed Principal Assistant Engineer on the Mississippi River Bridge at St. Louis. Traces of his engineering handiwork may be found in widely distributed places, among which are McKeesport, and Johnstown, Pa., Radford and Manchester, Va., and Winston, N. C., and Algiers, La.

The last years of his life were spent in and around New York, N. Y., where he was connected with the Valuation Department of the New York Central Railroad Company as well as with other similar important enterprises.

During the years between 1889 and 1927, Mr. Aylett gave unstintedly of his time in the furtherance of his chosen profession. He not only accomplished the work before him, but also found time to invent and patent a lock-joint pipe of very definite value, as well as a suspension system for constructing arch bridges without falsework. He also contributed illustrated articles on bridges, foundations, etc., to various publications, including *The Engineering News, The Cement Age,* and *Engineering and Contracting.*

* Memoir prepared by Richard T. Goodwyn, Esq., Athens, Ga.

He was the author of Part VIII of "European Bridges", in Volume III of Hool's "Concrete Bridges and Culverts", and relative to this, made a trip abroad in 1914 to inspect concrete bridges.

Mr. Aylett was a man of strong personality and of unblemished character, who took particular delight in trying to uplift the down trodden and oppressed. Although small in stature, he was of great mentality. A propensity for speaking, possibly inherited from his paternal grandfather, Patrick Henry, led him as a college student, and, later, as a mature man, to discard the usual reticence of the average engineer, thus evincing his ability as a forceful and fluent speaker. He was a member of the National Security League and during the World War, and thereafter, proved a valuable speaker on "Americanization and What It Means".

Mr. Aylett was married in 1900 to Hilma C. Fernquist, of Hartford, Conn., who, with one daughter, Elsie, survives him. While sitting at his desk with the day's work before him, he suffered a stroke of apoplexy and was called to the Great Beyond.

Mr. Aylett was elected an Associate Member of the American Society of Civil Engineers on June 3, 1896.

OSCAR ERNEST BULKELEY, Assoc. M. Am. Soc. C. E.*

DIED JANUARY 4, 1927.

Oscar Ernest Bulkeley was born on April 2, 1885, at Oneida, Ill. He was the son of John A. and Emma H. (Copley) Bulkeley. His father was a native of Canton, Ill., and his mother came from Pennsylvania. John A. Bulkeley was an artist and photographer until the failure of his health necessitated the removal of himself and family in 1890 to Grand Junction, Colo., where he engaged in ranch work. Mrs. Bulkeley died in 1897 and three years later the family moved to Riverside, Calif.

Oscar Ernest Bulkeley attended the public schools and High School at Riverside and was graduated in 1902. He then entered Knox College at Galesburg, Ill., and completed the course with first honors in three years, graduating in 1905 with the degree of Bachelor of Science.

His first engagement was with the Grand Junction Electric Light Company. With a desire for practical experience in mining he entered the employ of the Amalgamated Copper Company in 1906, at Butte, Mont. He began work in the copper mines as a laborer in order to become familiar with mining methods. His ability was soon recognized and at the end of four years he had been promoted to be General Purchasing Agent.

In February, 1910, Mr. Bulkeley entered the University of Illinois to further equip himself for engineering work for he then believed he wished to be a civil engineer. He was graduated in the Civil Engineering Course in 1912 and took the position of Engineer of the Water Department of Rockford, Ill. He was soon promoted to be Assistant Superintendent and remained on that work until January, 1916. His success at Rockford resulted in his selection as Superintendent of the Water Department at Jackson, Mich., where he continued until April, 1918. At that time he was sought by the Dupont Engineering Company on the construction of the mammoth Government powder plant near Nashville, Tenn. Soon afterward he was placed in charge of its water-works plant, which position he retained until after the Armistice.

From February, 1919, to January, 1920, he was associated with the Ross P. Beckstrom Engineering Company, of Rockford, Ill. In January, 1920, Mr. Bulkeley went to Lansing, Mich., as Engineer for the Electric Light and Water Board. On May 1 of that year he was made Acting Superintendent and, on November 1, Superintendent of both the light and water activities of the City of Lansing. This position he held at the time of his death.

At the time Mr. Bulkeley went to Lansing the city was operating five water pumping stations. The Central Station was used both for pumping water and generating electricity. An old generating plant had been purchased from a private company and was not in efficient condition. This plant was changed almost entirely and converted into a municipal steam-heating station. The development of electricity was transferred to a fine new generating plant,

* Memoir prepared by Edward D. Rich, M. Am. Soc. C. E.

realized largely through Mr. Bulkeley's wise judgment and energy. This installation cost about $2 500 000 and with the extensions now projected and under way the investment will be nearly $4 000 000.

In 1924, a new pumping station, wells, and storage reservoir which furnishes a large part of the municipal water supply was completed under Mr. Bulkeley's direction, at a cost of nearly $350 000.

The Electric Light and Water Board placed great confidence in Mr. Bulkeley's advice in extending and improving the service. He was untiring in his efforts to work out a new street lighting system, in the removal of overhead wires in the business district, and in the development of an adequate water supply, all with broad vision of the future needs of the city.

He was always unselfishly interested and active in the upbuilding of his city and gave generously of his time to those civic, social, professional, and religious activities which are beneficial to mankind. He and Mrs. Bulkeley were members of and active in the work of the Plymouth Congregational Church. His unfailing courtesy and kindliness endeared him to a host of friends who mourn his departure as a keen personal loss.

Mr. Bulkeley was taken ill with influenza on December 14, 1926. Pneumonia developed and caused his death on January 4, 1927.

On December 21, 1912, he was united in marriage to Edna S. Best, at Chicago, Ill., as a culmination of a romance of their school days in California. His widow and two children, Mary Louise and William Warren, survive him.

He was a member of the Phi Gamma Delta and Tau Beta Pi Fraternities; Lansing Lodge No. 33 F. and A. M.; Lansing Rotary Club; American Water Works Association; and the Lansing Engineers' Club, of which he was President in 1924.

Mr. Bulkeley was elected an Associate Member of the American Society of Civil Engineers on October 9, 1917.

JOHN DUBUIS, Assoc. M. Am. Soc. C. E.*

DIED MAY 11, 1927.

John Dubuis was born on October 8, 1884, in the Tyrol, Austria. His mother died soon after his birth and his father, an American artist, working and studying in Europe, died three years later while still abroad. The 3-year old son was brought back to the United States, and, as a boy, lived in Kentucky and South Carolina. He was graduated from Presbyterian College of South Carolina in 1905, and received the degree of Civil Engineer from Cornell University in 1909.

Mr. Dubuis moved to Oregon in 1909, and for the next eighteen years he was associated with many of the more important engineering developments in that State. He was engaged in the investigation of irrigation projects in Warner Valley and at Grant's Pass, and in the construction of the Hood River Hydro-Electric Plant, of the Pacific Power and Light Company, and the irrigation system of the Walker Basin Irrigation Company, near Lapine.

As Chief Engineer, he supervised the construction of the Gold Hill Irrigation District System. He was also Consulting Engineer for the North Canal Company from 1921 to 1924, and for several smaller projects. He served one and one-half years as Instructor in Hydraulics at the Oregon State Agricultural College, and for three years as Engineering Inspector for the Desert Land Board of the State of Oregon. Mr. Dubuis' most important work was no doubt the water supply system for the City of Bend, Ore., involving a 13-mile pipe line, intake dam, reservoirs, etc., recently completed. His death occurred at Spokane, Wash., as the result of infection following an operation for appendicitis.

He was married in 1913 to Marion K. Curtis, of Ithaca, N. Y. He is survived by Mrs. Dubuis and by two daughters, Marion and Jeanne.

Mr. Dubuis was very active in Masonry, having been a member of Portland Lodge No. 55, Pilgrim Commandery of Knights Templars, of Bend, Al Kader Temple of the Mystic Shrine, and Bend Chapter No. 109 of the Eastern Star. He was especially active in the Pilgrim Chapter, De Molay, having been a member of the Advisory Board, and in the Boy Scouts, having served as Scoutmaster.

He was beset with the necessity common to most civil engineers of frequent removals from place to place; nevertheless, he was able to make a host of friends all over the State of Oregon. Those who knew him best will probably agree that his outstanding personal characteristic was his never-failing cheerfulness, even in the face of discouragement and adversity.

Mr. Dubuis was elected a Junior of the American Society of Civil Engineers on October 1, 1912, and an Associate Member on January 6, 1915.

* Memoir prepared by Fred F. Henshaw, M. Am. Soc. C. E.

HENRY GARNER HARPER, Assoc. M. Am. Soc. C. E.*

DIED MARCH 24, 1927.

Henry Garner Harper was born at Ashland, Pa., on November 15, 1891, the son of Henry C. and Catherine Harper. He received his public school education in Ashland and was graduated from the High School in 1908.

From 1908 to 1911, Mr. Harper was employed as Chainman at Ashland by the Philadelphia and Reading Coal and Iron Company. In the autumn of 1911 he entered Pennsylvania State College, from which he was graduated in 1915 with the degree of Bachelor of Science in Civil Engineering, as well as Bachelor of Science in Highway Engineering.

After his graduation from college he entered the service of the Pennsylvania Department of Highways, with which he was continuously employed until the time of his death, except during the period of his military service in the World War.

Mr. Harper's first assignment in the State service was for one year as Draftsman at the Harrisburg Office. This was followed by two years as Assistant Engineer in the Bureau of Township Highways. In June, 1918, he entered the Government military service and was commissioned a First Lieutenant in the Artillery. He served until he was honorably discharged early in 1919.

In May, 1919, Mr. Harper resumed work with the Pennsylvania Department of Highways as Resident Engineer in charge of construction work in McKean County. On January 1, 1920, he was appointed as District Engineer with headquarters at Sunbury. In August, 1921, he was transferred to Bedford, where he filled assignments as District Engineer and Assistant District Engineer, respectively, until June, 1923, when he was transferred to Hollidaysburg as District Engineer in charge of highway work in Blair, Cambria, and Huntingdon Counties. The latter assignment he was filling at the time of his death.

As District Engineer, Mr. Harper had charge of both construction and maintenance work, as well as of all other departmental activities. The Pennsylvania Department of Highways carried out its largest construction program during the period that Mr. Harper served as District Engineer, and many large construction projects were completed under his direction. In the midst of these activities he was stricken with spinal meningitis, following a mastoid operation, and died at the Altoona Hospital on March 24, 1927.

In 1917, Mr. Harper was united in marriage with Pauline Sharpless who, with a son and daughter, survives him.

He had a charming personality, with a keen sense of humor and a ready smile that won him many friends. He was known among his associates as a man of sterling integrity and possessed of the highest ideals of professional ethics.

* Memoir prepared by S. W. Jackson, M. Am. Soc. C. E.

After his graduation he kept in close touch with his Alma Mater and was particularly interested in the welfare of the Sigma Pi Fraternity of which he was a member. He was also a member of the American Legion, Fort Fetter Post No. 516, Hollidaysburg, Washington Lodge No. 265, F. and A. M., the Benevolent and Protective Order of Elks, of Bloomsburg, Pa., and the Kiwanis Club, of Hollidaysburg.

Mr. Harper was elected an Associate Member of the American Society of Civil Engineers on October 11, 1920.

GUY FREDERIC HOSMER, Assoc. M. Am. Soc. C. E.*

DIED JANUARY 27, 1928.

Guy Frederic Hosmer, the son of Nathaniel M. and Mary A. (Howe) Hosmer, was born in Shrewsbury, Mass., on March 14, 1877.

He was graduated from the Shrewsbury High School in 1892, at the age of fifteen. In 1894, he had his first engineering experience when he assisted Mr. Romeo E. Allen, of Shrewsbury, on the survey of the Old Post Road. The following year Mr. Hosmer became associated with the engineering office of Shedd and Sarle, of Worcester, Mass., and Providence, R. I. When this firm dissolved partnership, he remained in the office of O. Perry Sarle, M. Am. Soc. C. E., of Providence, with which he was connected for many years.

In this position, Mr. Hosmer had a varied experience, including general surveying, oyster bed surveying, triangulation, design and construction of water-works, sewer systems, wharves, dams, mill buildings, power houses, and the taking of stream-flow measurements. From 1903 to 1905, he was in charge of the preliminary surveys and construction for a system of water-works and sewers, including a pumping station, stand-pipe and sand filtration plant, for Hickory, N. C. During 1906 and 1907 he was in charge of the design and construction of brick and iron buildings, with reinforced concrete floors and columns, for the Penobscot Chemical Fibre Company at Great Works, Me., and, in 1908, Engineer in charge of extensive improvements in the water power system at the D. Goff and Sons Mill, at Pawtucket, R. I.

In 1913 and 1914, Mr. Hosmer supervised the building of a sewage disposal plant, at Central Falls, R. I., which involved the construction of an Imhoff tank and sprinkling filters. In 1914 and 1915, he was in charge of the field work for preliminary plans of a $1 000 000 water-works plant for the Town of Warwick, R. I.

Mr. Hosmer remained in Mr. Sarle's office until January 1, 1917, when he accepted a position as Engineer of the Maine Coated Paper Company, at Rumford, Me. In 1921, this Company was consolidated with the Oxford Paper Company, and Mr. Hosmer became Assistant to the General Engineer, which position he retained until his death. As such, he was in charge of the design and erection of new buildings and the alteration of old ones, as well as the laying out and installation of new equipment. He also designed and invented various improvements which were added to the machinery in the Coating Mill. While in this position, he had charge, in 1922, of the remodeling of the plant of the Nashwaak Pulp and Paper Company, at St. John, N. B., Canada.

Mr. Hosmer was very active in community affairs. He was President of the Rumford Mechanics Institute; a member of the Rumford Board of Selectmen; one of the promoters, as well as Director and Chairman of the Greens Committee of the Oakdale Country Club; Chairman of the 1927 Rumford Winter Carnival Committee; and a member of the Building Committee of the Rumford Community Hospital, and also of the Methodist Episcopal Church.

* Memoir prepared by Percy W. Sarle, Esq., Rumford, Me.

He was a member of the Association of Professional Engineers of the Province of New Brunswick, Canada, and the Bangor, Me., Lodge of the Benevolent and Protective Order of Elks.

Mr. Hosmer had a very keen and analytical mind and was ever ready to solve problems of his own and his associates. He was always greatly interested in new engineering ventures and kept himself informed as to the latest developments in the Engineering Profession.

The greatest tribute that can be paid him is that all his associates, within the organizations he served, or individuals of other organizations with whom he came in contact, are proud that they knew him.

In every position, industrial or civic, which he held, Mr. Hosmer was unsparing in his efforts, unusually efficient, and faithful to every detail. His work was always well done.

He was never married, and is survived by three brothers, William H. and Arthur C. Hosmer, of Camden, Me., and Harry P. Hosmer, of Boston, Mass.

Mr. Hosmer was elected an Associate Member of the American Society of Civil Engineers on November 6, 1907.

THOMAS WAKEFIELD MACARTNEY, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 23, 1926.

Thomas Wakefield Macartney was born in Des Moines, Iowa, on November 20, 1883. Following his preparatory education in the public schools of Des Moines, Mr. Macartney received his technical and engineering training at Purdue University from which he was graduated with the degree of Bachelor of Science in Mechanical Engineering in 1906.

Soon after his graduation he accepted a position as Draftsman with Mr. W. S. Hook at Los Angeles, Calif. After serving a year in this position he entered the office of the City Engineer of Seattle, Wash., where he served as Computer, Draftsman, and, later, assisted in the preparation of plans for street improvements, sewers, and extensions to the water system. He was also connected for one year with the Municipal Plans Commission.

In January, 1914, Mr. Macartney left Seattle to accept a position as Assistant County Drainage Engineer in Yakima County, Washington. In this position he assisted in the location, design, and construction of many large drainage systems and acquired much valuable experience in this field of engineering.

In August, 1917, he left the service of Yakima County and entered the employ of the Boering Airplane Company, of Seattle, soon afterward becoming its Chief Inspector.

He returned to Yakima County in January, 1919, as Chief Assistant Drainage Engineer and was appointed Chief Drainage Engineer in August, 1919, which position he held until his death. During this period he had charge of the design and construction of thirty drainage improvement districts having an aggregate area of 25 000 acres. On this work 20 miles of large open drains and 60 miles of deep closed drains were built at a cost of $876 000. The construction was difficult for this type of work and much of it was done by force account under the direction of Mr. Macartney. In addition, he had charge of the design and construction of several diking improvement districts for bank protection on the Yakima River.

In the field of drainage engineering for the reclamation of irrigated land, Mr. Macartney stood very high indeed, ranking with the best. The drainage systems that were built by him are models of excellent design and good construction. They reflect the skill and ability of the builder and the Yakima Valley owes to him a debt of gratitude for his work of reclamation and protection.

Mr. Macartney accepted responsibility conscientiously and served the public with highest integrity. His fine tact, good judgment, and even temperament enabled him to work harmoniously with many different district boards and commissioners. He was constantly and steadfastly guided by the best principles of engineering and sought to do that which was for the greatest good. He was wholly without conceit or sham, and his courtesy and

* Memoir prepared by L. T. Jessup, Assoc. M. Am. Soc. C. E.

lovable disposition endeared him to all who knew him. His very sudden and untimely death caused by pneumonia was a severe shock to his many friends.

He took an active part in civic and community affairs. At the time of his death he had served eight years as Vestryman of St. Michael's Protestant Episcopal Church, at Yakima, Wash. He was a member of the Rotary Club and of the American Association of Engineers.

He was married on September 6, 1911, to Margaret Scarborough, by whom he is survived. He is also survived by a son, Thomas Wakefield, Jr., a sister, Catherine N. Macartney, of Iowa City, Iowa, and three brothers, George W. Macartney, of Helena, Mont.; Robert H. Macartney, of Cheney, Wash., and Morton Macartney, M. Am. Soc. C. E., of Orlando, Fla.

Mr. Macartney was elected an Associate Member of the American Society of Civil Engineers on January 19, 1920.

JAMES ROY MAC BEAN, Assoc. M. Am. Soc. C. E.*

DIED JULY 8, 1927.

James Roy MacBean, the son of James Dean and Mary (Murphy) MacBean, was born in Philadelphia, Pa., on January 19, 1885. On the completion of his early education in the public schools, he entered Drexel Institute for a course in Civil Engineering.

In the spring of 1903, Mr. MacBean entered the employ of the Chicago, Rock Island, and Pacific Railway Company as Rodman and Instrumentman and remained with that Company for about three years. Subsequently, he was engaged for about six years on work with the Pennsylvania and Chicago Great Western Railroad Companies. He was employed by the Spanish-American Iron Company in charge of mining and railroad construction in Cuba during parts of 1906 and 1911.

For various periods between 1907 and 1924, Mr. MacBean was engaged for about five years as Draftsman and Chief of Party on sub-division and municipal work with private engineering firms of Philadelphia and Jenkintown, Pa. In 1918, as Assistant Superintendent for the Austin Company, he was engaged on the construction of a concrete roundhouse for the Philadelphia and Reading Railway Company. Later, he accepted a position as Erecting Engineer for the United Gas Improvement Construction Company, of Philadelphia, remaining with this Company until the summer of 1923.

From August, 1924, until his death, Mr. MacBean was employed as Resident Engineer for the New Jersey State Highway Department. As such, he was engaged on reconnaissance surveys in connection with the entrance and connecting roads for the Delaware River Bridge Extension from Camden, N. J., to the main State highway routes of Southern New Jersey. On the completion of the preliminary work he had charge of the construction of the northerly section of the connecting road. Shortly before his death, he had completed the construction of the concrete State Road between Egg Harbor and Mays Landing, in Atlantic County.

Mr. MacBean met his death as the result of an automobile accident while returning from work on the afternoon of July 8, 1927.

He was married on May 16, 1914, to Esther C. Copperfield, of New York, N. Y., who, with a son, Roy Hamilton, survives him. He was a member of the West Park Presbyterian Church, of Philadelphia.

Mr. MacBean was elected an Associate Member of the American Society of Civil Engineers on June 6, 1927.

* Memoir prepared by M. W. Grimes, M. Am. Soc. C. E., and E. H. Maier, Assoc. M. Am. Soc. C. E.

HOWARD B. MERRICK, Assoc. M. Am. Soc. C. E.*

DIED DECEMBER 14, 1926.

Howard B. Merrick was born at Wrightstown, Pa., on January 2, 1871, the son of George T. and Mary Ann (Short) Merrick. His father was a Pennsylvania Quaker and his mother was of Vermont stock, but not a Quaker. As a youth he attended the Friends' School at Wrightstown and also, for a time, the Newtown High School, but did not complete the High School course.

In the fall of 1893, he entered the University of Michigan by examination, but not having been prepared in all subjects necessary for entrance without conditions, he spent part of the time of the first semester in the Ann Arbor High School in order to complete his entrance requirements. He depended largely on his own earnings to pay the expenses of his University course, and each of the summers of 1894 to 1897, inclusive, he spent in surveying work, serving as Rodman for the Elkhart and Western Railway Company the first summer and for the Great Northern Railway Company the other three summers.

Mr. Merrick was graduated from the College of Engineering of the University of Michigan in 1898, having taken the degree of Bachelor of Science in Civil Engineering. One of the years intervening after his entrance into the University was spent in the College of Literature, Science, and the Arts. The summer following his graduation he was Masonry Inspector for the Great Northern Railway Company, and from October, 1898, to November, 1902, he served successively as Levelman, Transitman, Assistant Engineer, and Engineer in Charge of Location and Construction for the same Company, in Minnesota, North Dakota, and Montana. In the former State his work took him into the iron country on the Mesaba Range where he became interested in iron mining as carried on in that district, and from December, 1902, to September, 1903, he was Engineer in Charge of Drills for E. J. Longyear and Company. His work in this connection was the exploration of the territory in the vicinity of Hibbing, Minn., for the purpose of locating bodies of iron ore.

Five years after his graduation Mr. Merrick was called by his Alma Mater to serve as Instructor in Surveying, and began his teaching in the fall of 1903. He was advanced to Assistant Professor of Surveying in 1906 and to Associate Professor in 1918. In 1913, he was granted the degree of Civil Engineer, presenting as part of the requirement for that degree a thesis on "The Welfare of Railways in the United States Since the Passage of the Interstate Commerce Act". From 1922 until his death, he was Associate Professor of Geodesy and Surveying.

During his term of service at the University, Professor Merrick was engaged in some outside practice in general surveying, and undertook several special pieces of work. In June, 1913, he was with Mr. M. W. Thompson

* Memoir prepared by James B. Pollock, Professor of Botany, Univ. of Michigan, Ann Arbor, Mich.

preparing data for use in the Duluth, South Shore and Atlantic Railway rate case, and in August and September of the same year he worked on the valuation of the Lake Shore and Michigan Southern Railway for the same firm. In the employ of H. E. Riggs, M. Am. Soc. C. E., he was in charge of the computation of earthwork on the appraisal of the Pere Marquette Railway, from June to October, 1914. He also worked at appraising real estate belonging to the Eastern Michigan Edison Company, from September, 1915, to February, 1916.

Besides his teaching Professor Merrick served the College of Engineering in several other capacities. He was in charge of the Summer Camp of the Junior Civil Engineering students from 1904 to 1911, and was the first Head Mentor in the Freshmen Mentor System which was inaugurated at the Engineering College in 1913. He also had charge of the Freshmen Assemblies in the College of Engineering in 1917 and 1918. Shortly before his death, he had completed a committee assignment connected with the current study of engineering education. His professional services were not only utilized by the University of Michigan and by various railway corporations, but a foreign nation, China, availed itself of his engineering talents.

In 1918, Professor Merrick was one of three men chosen from the Department of Geodesy and Surveying of the College of Engineering to go to China under the direction of Joseph Ripley, M. Am. Soc. C. E., an eminent graduate of the same College, in the employ of the American International Corporation, to aid the Chinese Government in the improvement of the Grand Canal. From August, 1918, to November, 1919, Professor Merrick served as one of the Principal Assistant Engineers to the Grand Canal Improvement Board in China. He was also in charge of precise level work, covering a distance of 325 miles, and of the office work in the reduction and plotting of the field notes of the topographic survey parties.

At the request of the Chinese Government he was transferred in December, 1919, to the Commission for the Improvement of the River Systems of Chihli, a large province of Northeast China. He served as Engineer in Charge of Surveys, and, as such, re-organized the field and office forces and had complete supervision of the surveying and mapping of 30 000 sq. miles in the Province of Chihli. He directed a force of about 400 men, of whom 90 were engineers. A majority of the chiefs of parties were engineers who had been educated in America, England, or Japan, while many of the subordinates were graduates of Chinese engineering colleges having American teachers. Professor Merrick served the Commission for the Improvement of the River Systems of Chihli until June, 1922, having spent almost four years in China. He was then obliged to return to his duties at the University of Michigan.

That his work was done in a manner eminently satisfactory to all concerned, is attested by several facts. The Chinese Government was anxious to retain his services. Mr. Ripley, under whose direction Professor Merrick went to China, has expressed high appreciation of his accomplishments. Each of two groups of engineers under his charge in China, the staff and the substaff, presented him with a silver loving cup, engraved with an expression

of "their high esteem and affection for him as their Chief during three years of association in the Survey Department of the Chihli River Commission." After his departure for the United States the Chinese Government awarded him a Fifth Class Chiao Hu Decoration, in recognition of his valuable services. Mr. G. G. Stroebe, a graduate of the University of Michigan, who became Chief Survey Engineer of the Yangtse River Commission about the time Professor Merrick returned to the United States, writes that "Professor Merrick's surveys are considered equal to the very best of those executed by the U. S. Coast and Geodetic Survey in this country." Mr. Stroebe also remarks, "They all say here that Mr. Merrick was a past master in dealing with delicate situations in China."

In his family life he was an ideal husband and father. He was married on December 12, 1900, to M. Grace Green, of Holly, Mich. Mrs. Merrick survives him, as do two daughters, Ruth Carolyn, a Sophomore in the College of Architecture, and Alice Mary, a Senior in the University High School. Two sisters are left also to mourn his loss.

A man's personality is perhaps best appreciated by his neighbors and intimate friends, a teacher's by his students and colleagues. Judged by them, Professor Merrick ranks very high. Dean Mortimer E. Cooley, M. Am. Soc. C. E., of the Colleges of Engineering and Architecture, said* of him:

"Since the very beginning he was closely in touch with our students and enjoyed their confidence. His equable temperament, his kindly heart and his charming manners will long be remembered. He will be a great loss to the University, particularly to the Geodesy and Surveying Department, and his place will be hard to fill."

Neighbors wrote of him, "He was one of the finest, best, kindest men I ever knew." "His consideration for others was such an outstanding characteristic." A classmate reports, "Howard was one of the most esteemed members of our class of '98 Engineers." A student of a later time says, "I gained Professor Merrick's friendship while a student in his classes, and have valued it above most of my other friends."

Although reared a Quaker Professor Merrick was not so narrow in his religious views but that he could ally himself with other religious organizations and bear his share of their responsibilities, in a community where the Quakers had no organization. In recent years he was leader of a troop of Boy Scouts and freely gave them of his time, his wisdom, and his friendship.

In his professional relations he was a member of the Association of Chinese and American Engineers, the Association of American Engineers, and the Michigan Engineering Society.

Professor Merrick was a member of the Phi Sigma Kappa Fraternity, and of the Tau Beta Pi, an honorary engineering society, the University Club, and Huron Hills Golf Club.

He was also a member of the Masonic Order, and helped to found a lodge in Tientsin, to which he transferred his membership while he was in China, and which he served in various capacities. After returning to Ann Arbor,

* *Michigan Daily*, December 15, 1926.

he joined with others in the establishment of a third local lodge and at the time of his death was holding an important office therein.

In a summary of Professor Merrick's life it may be said in all truth and without exaggeration, that he was an ideal husband and father; the finest, truest, and most lovable of friends; a man ever thoughtful and considerate of others; an excellent citizen, an inspiring teacher, an efficient executive; a painstaking and exact worker in his profession, a civil engineer of high standing; a courteous advocate, pressing his point with reason and kindness rather than with aggressive domination; gentle in manner, but adamant in his advocacy of what he conceived to be right, like his ancestors the Friends or Quakers, accepting the "inner light" as his ultimate guide and authority.

Professor Merrick was elected an Associate Member of the American Society of Civil Engineers on July 1, 1909.

ROBERT BRUCE ROBINSON, Assoc. M. Am. Soc. C. E.*

DIED FEBRUARY 1, 1927.

Robert Bruce Robinson was born at Mount Holly Springs, Pa., on March 3, 1878. He received his technical education at the University of Illinois, and entered the service of the Union Pacific Railroad Company in April, 1899, as a Rodman on the Kansas Division. In 1904 he went to the Oregon Short Line Unit of the Union Pacific System where he was engaged for several years in locating and constructing new branch lines, one of which was the North Side Branch, extending from Rupert to Bliss, Idaho.

After some time spent as a Special Engineer on investigation work, he was made Division Engineer of the Idaho Division of the Oregon Short Line, and, in 1916, accepted the position of Engineer, Maintenance of Way, for that railroad, with headquarters at Pocatello, Idaho. He served in this capacity until May, 1919, when he was promoted to be Engineer, Maintenance of Way, of the Union Pacific Railroad with headquarters at Omaha, Nebr., which position he held at the time of his death.

He died at St. Joseph's Hospital, Omaha, on February 1, 1927, from blood-poisoning resulting from the extraction of an infected abscessed tooth.

Mr. Robinson was an indefatigable worker, who gave unstintingly of his time and energy because of an intense love for the upbuilding of the great railroad system which it had been his part, as an engineer and builder, to introduce to many unsettled sections in the mountain States of the West, where prosperous communities have since sprung into existence.

He possessed that priceless executive trait of being able to get the best from his men at all times. In the strenuous work in which he was engaged, emergencies are the natural order, and he himself was always on the scene at the earliest possible moment to direct operations whenever serious floods and other troubles threatened to endanger the track. His personality was such, however, that even under the most trying conditions, when some one had failed, his kindly criticism produced more lasting results than all the harsh words that could ever be spoken, and no employee ever left a conference with Mr. Robinson with a feeling of bitterness or resentment.

It can be said with all sincerity that no general officer ever had a firmer grip on the affections of his men, and he was likewise warmly respected by the executive officers of the Company.

His widespread popularity was attested by the large attendance of friends, including many from far distant points, in addition to those of the Union Pacific family, at the funeral services held February 3, at the Scottish Rite Cathedral, in Omaha, as well as by the exceptional number of beautiful floral offerings. On account of his love for the mountains, his remains were taken to Salt Lake City, Utah, and laid at rest on February 7, 1927, in the shadow of the stately Wahsatch Mountain Range. The services at Salt Lake City

* Memoir prepared by E. W. Plotz, Chf. Clerk, Maintenance of Way Dept., Union Pacific R. R., Omaha, Nebr.

were the occasion for a large outpouring of friends in that community where much of his earlier work had centered.

Mr. Robinson was a member of the American Railroad Association, the American Railway Engineering Association, the American Railway Bridge and Building Association, and other technical societies. He was also a member of various Masonic bodies and of El Korah Temple, A. A. O. N. M. S., at Boise, Idaho.

He is survived by his widow, Mrs. Audley B. Robinson, and two children, Eleanor and Robert. His parents, Dr. and Mrs. R. E. Robinson, two sisters, Laura Robinson and Mrs. P. H. Simpson, all of Morrison, Ill., and two brothers, Arthur Robinson, of Pocatello, and Edward Robinson, of Cleveland, Ohio, also survive him.

Mr. Robinson was elected an Associate Member of the American Society of Civil Engineers on July 9, 1912.

REUBEN BENJAMIN SLEIGHT, Assoc. M. Am. Soc. C. E.*

DIED NOVEMBER 14, 1927.

Reuben Benjamin Sleight, the son of Levi J. and Katherine C. (Buchler) Sleight, was born at Laingsburg, Mich., on June 30, 1889. He received his early education in the public schools of his native State, and in 1908 entered the University of Michigan, where he studied engineering for three years.

In June, 1911, Mr. Sleight was employed by the Racine Boat Manufacturing Company, at Muskegon, Mich., as a Draftsman in the mechanical and structural design of lightships for the Federal Government. The opportunities of the West attracted him to Denver, Colo., where he entered the office of the Field, Fellows, and Hinderlider Engineering Company, in September, 1912. His experience with this firm was in designing, drafting, and field surveys, for the Parkman Irrigation District of Wyoming and the Cherry Creek protective work, at Denver.

In January, 1913, Mr. Sleight left this work and was employed immediately as Construction Foreman and Concrete Inspector on irrigation structures and well development for the Tucson Farms Company, near Tucson, Ariz. In June he was transferred to a new line of work, a duty-of-water investigation in the Mesilla Valley, New Mexico. This study under co-operation between what is now the Division of Agricultural Engineering of the United States Department of Agriculture, the New Mexico Agricultural Experiment Station, and the farmers of Mesilla Valley, consisted in the design of gas and electric power pumping plants, their installation and testing,† and assistance in tests on submerged orifices, the results of which have been published.‡ Mr. Sleight's work in New Mexico was under the immediate direction of F. L. Bixby, M. Am. Soc. C. E.

On June 2, 1913, Mr. Sleight was appointed Assistant Irrigation Engineer in the U. S. Department of Agriculture, which position he held until he entered the Army in 1917. During the winter of 1913-14, he was assigned to the Headquarters Office of the Division of Agricultural Engineering at Washington, D. C., as an Assistant to F. C. Scobey, M. Am. Soc. C. E., on hydraulic engineering research. Subsequently, he returned to his former work in New Mexico.

In September, 1914, on leave of absence from his Government position, Mr. Sleight re-entered the University of Michigan from which he was graduated as a Bachelor in Marine Engineering in the early summer of 1915. During his Senior year at the University, he was made an Assistant in the Department of Civil Engineering. On leaving the University and resuming his Government connection, in July, 1915, he was assigned to the work of

* Memoir prepared by R. L. Parshall, Assoc. M. Am. Soc. C. E.

† The report of tests on turbine centrifugal pumps was published in *Journal of Agricultural Research*, Vol. XXXI, No. 3.

‡ "Research Studies on the Flow of Water in Open Channels Carrying Heavily Silted Water," *Bulletin 97*, New Mexico Agricultural Experimental Station.

establishing a research laboratory, at Denver, for the purpose of studying the evaporation from free water surfaces, soils, and river-bed materials. The results of these studies, which were started early in the season of 1916, were published under the title, "Evaporation from the Surfaces of Water and River-Bed Materials."* This discussion on a subject of great interest to the Engineering Profession was a comprehensive and authoritative scientific contribution of high value, and immediately attracted wide attention. Of the many manuscripts prepared by Mr. Sleight, it is thought his summary of the work on evaporation was the most outstanding.

Mr. Sleight's military career began in October, 1917, with his appointment as Production Engineer, Signal Corps, U. S. Army. In this capacity he directed his efforts to the compilation of production statistics until January 16, 1918, when he was commissioned as Second Lieutenant in the Signal Reserve Corps. He was promoted to First Lieutenant, Air Service, U. S. Army, on September 25, 1918, and made Tonnage Officer in charge of compiling estimates for the General Staff and the American Expeditionary Force, of tonnage of all air service material to be carried overseas. He remained in the Air Service until July, 1919, but had no foreign experience. He held the commission of Captain in the Air Service Officers' Reserve Corps until his death.

In September, 1919, Mr. Sleight accepted a position as Appraisal Engineer with H. E. Riggs, M. Am. Soc. C. E., at Ann Arbor. While with Professor Riggs, he assisted in the appraisals of the Detroit United Railways; the Kentucky and West Virginia Power Company; the Northern Ohio Light and Power Company; the Columbus Power Company; the Columbus Railroad Company; and the Gas Light Company, all of Columbus, Ga., as well as the Augusta-Aiken Railway and Electric Corporation. In this appraisal work, he was, first, a Field Inspector, then in charge of field investigations and, later, assigned to office engineering.

He severed his connection with the appraisal work at Ann Arbor in 1922 to take the position of Engineer with the Minnesota Tax Commission. An arrangement was made whereby the College of Engineering and Architecture of the University of Minnesota supervised the valuation of public utilities, and, occasionally, of other properties for the Tax Commission. The Engineering Department of the Commission was thus established, and Mr. Sleight was engaged to do the appraisal work. He placed the Department on an efficient and effective basis and was most highly thought of by all who came in contact with him during the five years he spent in Minnesota.

Because of his ambition and earnestness of purpose, he was recognized as an outstanding leader in engineering and scientific circles. His proficiency as a scholar gained for him a membership in the University of Michigan Chapter of Sigma Xi in 1915, while yet an undergraduate.

Mr. Sleight was a registered Civil Engineer of the State of Michigan, and a member of the Engineers' Club of Minneapolis. He was the author of a number of papers published in various engineering and scientific periodicals,

* *Journal of Agricultural Research*, Vol. X, No. 5, July 30, 1917.

and in 1927 wrote an important paper on Engineering Economics which, in a National contest, gained such recognition as to result in his appointment on the Engineering Staff of the Federal Department of Commerce as an Aide to the Secretary, Herbert Hoover, Hon. M. Am. Soc. C. E.

As an Assistant to Secretary Hoover, he was detailed to work out special waterways problems. At the time of his death, on November 14, 1927, he was in Vermont, having left Washington in an airplane to gather advance information for Mr. Hoover in the areas then flooded. The injuries from which he died were suffered in the landing of the plane at Montpelier, Vt.

He was married on October 30, 1913, to Doris M. Cutter, of Muskegon, Mich., who survives him.

By nature modest and retiring, Mr. Sleight's manner was tactful and most courteous. He had the power to command loyal service and form sincere friendships, and those who knew him well were continuously gratified by his successful advancement in his chosen life work.

Mr. Bixby, under whom he was engaged in New Mexico, states that Mr. Sleight's work was of the highest order, and that he possessed to a high degree the ability to combine an understanding of the technique of engineering investigations with the practical application of theory, while his pleasant personality and earnest willingness to co-operate with others in the solving of difficult engineering problems, gave promise of a successful career in scientific research. Moreover, his affability did not prevent his strict and conscientious attention to business when on duty, although his company in leisure hours was most enjoyable. Mr. Bixby feels that in the death of this young man the Engineering Profession suffers an inestimable loss.

Mr. Sleight was elected a Junior of the American Society of Civil Engineers on December 6, 1915, and an Associate Member on April 25, 1921.

RALPH JEROME SMITH, Assoc. M. Am. Soc. C. E.*

DIED AUGUST 8, 1926.

Ralph Jerome Smith, the only son and youngest of five children of the late Charles Aaron and Jennie (Snow) Smith, was born at Indian Orchard, Mass., on May 12, 1889. Here he resided until he moved with his parents to Longmeadow, Mass., in 1912, which has since been the family home. He was the direct descendant of a long line of old New England families. Through his mother, he was descended from John Alden and Priscilla Mullens, also from Francis Cooke, all of whom were passengers on the historic *Mayflower*. His paternal New England ancestry, of which he was the last male member in his line, dates from 1636 when Lieut. Samuel Smith with his family removed from Hadleigh, England, to America on the ship *Elizabeth*, settling first at Watertown, Mass., later, at Wethersfield, Conn., and, finally, going with a party from that place to settle the Town of Hadley, Mass. Ralph Smith's great-great-grandfather, Ebenezer Smith, was a soldier in the Revolutionary War.

Ralph Jerome Smith received his early education at Indian Orchard, having attended the Myrtle Street Grammar School. He then entered the Springfield, Mass., High School with the idea of fitting himself for the Medical Profession. About a year and a half later his father was severely injured, and he was obliged to leave school for a time to look after his father's business. Upon the latter's recovery, the business was disposed of, and Mr. Smith then entered Williston Seminary. He found that his professional leanings had changed from medicine to engineering, so he returned to the Springfield Technical High School from which he was graduated in 1909.

After leaving High School he worked as a Draftsman on machine detailing for the Consolidated Wrapping Machine Company, of Springfield. About a year later he became a Valve Draftsman for the Chapman Valve Manufacturing Company, of Indian Orchard. He then spent about two years as Rodman and Chainman on surveys in and around Springfield, first with Durkee, White, and Towne, of Springfield, then with the General Engineering Company of the same place, and, finally, with the Boston and Albany Railroad Company.

From 1912 to 1915, Mr. Smith was employed by the General Engineering Company, of Springfield, on reservoir and hydro-electric development work, road construction, and real estate development. During this time he worked as Computer of capacities of storage reservoirs; Inspector of wash-borings and soundings for the foundation of a proposed dam; Instrumentman on levels and surveys; Draftsman on maps and proposed buildings; Chief of Party on topographic survey for hydro-electric development; and Superintendent of road construction and general real estate development. He then spent a year as Production Clerk for the Strathmore Paper Company of Woronoco, Mass.

* Memoir prepared by Carl C. Cooman, Assoc. M. Am. Soc. C. E., and Robert B. Jeffers, M. Am. Soc. C. E.

In 1916, he became associated with the Fred T. Ley Company, of Springfield and New York, N. Y., and for the next four and one-half years he was engaged in that connection on construction work in the eastern part of the United States. He spent a year as Local Purchasing Agent on the construction of the James Deering residence at Miami, Fla. He then became Engineer of Construction for a large group of farm buildings built by the Company for the owner of the McCallum Silk Mills, at Plainfield, Mass.

During the World War, Mr. Smith was Employment Manager for the Fred T. Ley Company, Contractors, on the construction of Camp Devens at Ayer, Mass., the Ammonium Nitrate Plant for the Atlas Powder Company at Perryville, Md., and the aerial bomb-loading plant for the Marlin-Rockwell Loading Corporation at Rockwell Park, Mount Pleasant, Del. After the signing of the Armistice, he was employed in adjusting accounts in dispute between the vendors and the Government Accounting Department on the construction of Camp Devens, and as Custodian of Property for the Contractor during the period of transfer of the buildings and materials from the Contractor to the Government. Returning to Springfield, he became Specification Writer and Personnel Manager in the Company's Engineering Department.

In 1919 he was sent to Rochester, N. Y., as Engineer and Superintendent of Construction for the Company during the construction of a factory building for Bastian Brothers Company of that place.

In October, 1920, Mr. Smith became Assistant Engineer with the Eastman Kodak Company, of Rochester, N. Y., and was employed for five years in the Engineering and Maintenance Department at the Kodak Park Works. He at first supervised building construction in the field and, later, had charge of the planning and scheduling of shop work for the Department.

His health had been poor for some time and for this reason, thinking that a change of climate would benefit him, he went to Fulford, Fla., near Miami, in the fall of 1925, on real estate development work for Mr. H. B. Graves of Rochester. The climate, however, did not agree with him, so he returned to Rochester the following spring. On June 1, 1926, he began work as City Engineer of Olean, N. Y., which position he held at the time of his death.

Mr. Smith was an active member of the Masonic Fraternity. He was a life member of Brigham Lodge, A. F. and A. M., Ludlow, Mass., of which lodge his father was a Charter Member. He was also a member of the Morning Star Chapter, Royal Arch Masons, Springfield, Mass.; Springfield Council, R. and S. M.; Cyrene Commandry No. 37, Knights Templar, Rochester; Rochester Consistory, A. A. S. R., Rochester; Damascus Temple, A. A. O. N. M. S., Rochester, and Bela Grotto, M. O. V. P. E. R., Springfield. He was also a member of Lodge No. 948, Benevolent and Protective Order of Elks, of Miami.

From early childhood Mr. Smith was very fond of music, particularly of singing, and was possessed of a beautiful tenor voice. As a lad, he sang in the children's choir in the Evangelical Church at Indian Orchard. During his High School career, he was a member of the Glee Club. He also sang in

the choir of St. Peter's Protestant Episcopal Church and, later, of Trinity Methodist Episcopal Church, at Springfield. During his stay at Perryville, Md., he sang in the Methodist Episcopal Church at Havre de Grace, Md., and while in Miami, in 1916, in the White Temple as tenor soloist.

When he went to Rochester in 1920, Mr. Smith transferred his church membership to the Central Presbyterian Church, where he sang in the choir. He was also a member of the Chanters of Damascus Temple at Rochester and of a Male Octette organized among the Kodak Park employees of the Eastman Kodak Company. He often appeared at special functions as a soloist and occasionally sang over the radio after its advent as a regular medium of entertainment.

During his Grammar School days, he once won a story-writing contest given for the school children of Springfield by the *Springfield Daily News*. The prize was a fine picture which still hangs on the walls of the Myrtle Street School bearing a plate inscribed with his name and the reason for the award. He never cultivated this natural bent for writing, but was always a great reader, being interested especially in books on science, religion, philosophy, and theosophy.

Mr. Smith was a tall, rather heavily built man, deliberate of movement, and possessing a quiet, cheerful, friendly nature. He impressed all with whom he came in contact as being dependable, honorable, and unassuming. Those with whom he had any dealings found him to be all that his appearance indicated. He had a marked ability of smoothing out difficulties in a calm, unhurried manner that was usually effective and, at the same time, convincing and reassuring to all concerned, whether in personal or professional association. He was in every respect a gentleman.

On November 6, 1920, Mr. Smith was married to Mary E. Decker, of Rochester, formerly of Coudersport, Pa., who survives him. There were no children. He is also survived by his aged mother, Mrs. Jennie Snow Smith, and two sisters, Mrs. Frederick N. Fowler, and Mrs. Edson R. Dorman, both of Longmeadow, Mass.

Mr. Smith was elected an Associate Member of the American Society of Civil Engineers on October 10, 1921. During his sojourn in Rochester he was active in the Rochester Local Section. He was also a member of the Rochester Engineering Society.

HARRY BRONSON SNELL, Assoc. M. Am. Soc. C. E.*

DIED JULY 3, 1927.

Harry Bronson Snell was born in New Haven, Conn., on March 28, 1875, the son of Adolphus Gaylord and Mary Andruss Snell.

After his graduation from Sheffield Scientific School, Yale University, New Haven, Conn., he became Assistant Civil Engineer with the Hartford Street Railway Company, until August, 1903. He then accepted the position of Assistant Engineer for the Long Island Railroad Company, Atlantic Avenue Improvement, Brooklyn, N. Y.

In September, 1905, Mr. Snell was appointed Principal Assistant Engineer for the Brooklyn Grade Crossing Commission, Brighton Beach Improvement, and, in 1916, he became Superintendent of Construction for the Turner Construction Company, of New York, N. Y., and Boston, Mass., which position he held until his death.

Mr. Snell died at the Griffin Hospital, Derby, Conn., on July 3, 1927, following an operation for appendicitis and after an illness of only a week. He had just attended the re-union of his class at Yale.

On February 2, 1916, he was married to Emily M. Sturdevant, of Deposit, N. Y., and is survived by his widow and by his brother, Thomas C. B. Snell, M. Am. Soc. C. E.

Mr. Snell was elected an Associate Member of the American Society of Civil Engineers on December 5, 1906. He was also a member of the Sons of the American Revolution.

* Memoir compiled by T. C. B. Snell, M. Am. Soc. C. E.

HUNTER IMBODEN SNYDER, Assoc. M. Am. Soc. C. E.*

DIED JANUARY 28, 1928.

Hunter Imboden Snyder was born on March 29, 1884, at Elizabethton, Tenn. He attended the public schools at Covington, Va., and at Knoxville, Tenn. His technical training was received at the University of Tennessee, at Knoxville, where he was a student in Civil Engineering from October, 1901, to June, 1902, and from October, 1903, to June, 1904.

Mr. Snyder's early experience in engineering work included the following assignments: From June, 1902 to October, 1903, various positions preparatory to that of Assistant Resident Engineer with the Knoxville, La Follette, and Jellico Railway Company; from June, 1904, to July, 1906, Assistant to the Engineer in Charge, the Knoxville Terminal Buildings and Clinch Avenue Viaduct for the Louisville and Nashville Railroad Company; from July, 1906, to January, 1907, Assistant to the General Superintendent and Field Engineer for the Oliver Company on the construction of a reinforced concrete warehouse at Nashville, Tenn.; from January to November, 1907, Superintendent for the L. B. Davidson Company, of Knoxville, in charge of concrete work for the South and Western Railroad Company; from November, 1907, to May, 1908, Inspector of concrete work for the Knoxville Division of the Louisville and Nashville Railroad Company; and from May, 1908, to March, 1909, Designing Engineer in charge, the Memphis Branch of the Contractors Engineering Supply Company, of Knoxville.

In March, 1909, Mr. Snyder entered private practice as Consulting Engineer on structural work. He was continuously employed in this field until July, 1915, and his work in this connection consisted of the design and construction of many important reinforced concrete warehouses, among which were the following: A five-story cold storage warehouse at Tampa, Fla.; a five-story warehouse for the Cheek Neal Coffee Company and a ten-story warehouse for Delcher Brothers, at Jacksonville, Fla.; also a warehouse for the Dalton Flour Mills, at Dalton, Ga. Other similar work included a mill construction warehouse for the De Sota Oil Company at Memphis, Tenn. He was Consulting Engineer for the F. W. Long Company on the construction of the sub-structure for the Municipal Lighting Plant and the remodeling of a power plant into a sub-station for the City of Jacksonville. He also acted as Consulting Engineer for the Architects on a hospital building for the St. Luke's Hospital Association at Jacksonville.

From 1913 to 1915, Mr. Snyder was associated with H. G. Perring, M. Am. Soc. C. E., as Consulting Engineer on the design and construction of various projects in Florida, as follows: A double-tube tunnel under St. Johns River at Jacksonville; a paving program for the City of St. Augustine; structural work on the Duvall County Court House and the Duvall County Armory; the Barstow Jail; the Palm Beach County Court House; the Tampa City Hall; the Hillsboro Hotel, in Tampa, and private road work in Baker County.

* Memoir prepared by J. L. Savage, M. Am. Soc. C. E.

Mr. Snyder was also associated with Mr. Perring on the following bridge work: A reinforced concrete bridge over the Halifax River, at Daytona; a bridge over the San Sebastian River for the City of St. Augustine; bridges over McGirts Creek and Trout Creek and a number of other smaller bridges in Duvall County, Florida.

Mr. Snyder's engineering work during 1915 brought him in contact with various bond houses in connection with the purchase of county and district bonds and his success in this field attracted much attention. In July, 1915, he accepted an attractive offer from Dewitt, Trimball, and Company and thereafter was employed by different bond houses as follows: From July, 1915, to June, 1916, with Dewitt, Trimball, and Company, Chicago, Ill.; from July, 1916, to March, 1918, with Seasongood and Mayer Company, Cincinnati, Ohio; from March, 1918 to May, 1919, witth C. W. McNear and Company, Chicago, and from May, 1919, to February, 1920, with R. M. Grant and Company, Chicago and New York, N. Y.

In 1920 he was compelled to give up his work that he might seek a more healthful climate and from then until his death, on January 28, 1928, he spent most of his time in Colorado, in 1922 definitely establishing his home in Denver.

Mr. Snyder was a splendid type of man, having a high order of integrity, a brilliant mind, and a certain natural friendliness which gave him an unusually magnetic personality. Although practically an invalid for the last few years of his life, he never lost his cheerful disposition nor his hopeful outlook. His continued interest in the activities of the Society and in engineering activities in general, was a source of surprise and satisfaction to those of his engineering friends who knew of his long enforced separation from his work.

His life was marked by devotion to his parents and to his wife, Nancy Abell Snyder, all of whom survive him.

Mr. Snyder was elected an Associate Member of the American Society of Civil Engineers on January 7, 1913.

ROBERT TEETERS SOMERS, Assoc. M. Am. Soc. C. E.*

DIED APRIL 5, 1927.

Robert Teeters Somers was born in Angola, Ind., on September 21, 1889. He received his early education in the public schools of Auburn, and Huntington, Ind., and afterward attended Oberlin College where he received the degree of Bachelor of Arts in 1914. The same year he entered Purdue University from which he was graduated in 1916 with the degree of Bachelor of Science in Civil Engineering.

Mr. Somers began his engineering career as Draftsman in the Pittsburgh, Pa., Office of the Pittsburgh-Des Moines Steel Company. Soon after the United States entered the World War he tried to enlist in the Coast Guard Division, but was rejected because of near-sightedness. About this time the Pittsburgh-Des Moines Steel Company began fabricating eight radio towers for the Lafayette Radio Station in France. Mr. Somers continued with this firm as Production Engineer until 1920. This work involved the adjustment of steel stock to the requirements of contracts and overseeing shop schedules of contracts.

Long hours of service during the war period, followed by an attack of influenza, undermined his health, and from February, 1920, until June, 1921, he lived in the mountains of Pennsylvania.

After his recovery, he assisted Mr. E. Paul Rothrock, afterward State Geologist of South Dakota and Head of the Geology Department of the University of South Dakota, in plane-table mapping of the topography and structure in Lawrence County, Kentucky, for the Washington Oil Company, of Pittsburgh. On the basis of this survey, the Company leased considerable land.

When this work was completed Mr. Somers went temporarily with the Pittsburgh Division of the United States Bureau of Standards, his work consisting of testing the strength of certain materials and computing the strain which would bring the breaking point.

When the Bureau of Standards was moved to Washington, D. C., in September, 1922, he became Assistant Engineer of the Pittsburgh District of the Portland Cement Association. His work at this time was promotional and educational in the uses of concrete. He answered technical inquiries and expedited field work. His personal interest was in the use of concrete for bridges and roads, and he took great pleasure in inspecting new concrete bridges or stretches of road in the vicinity of Pittsburgh, although inspection was not one of his official duties.

It was with great regret that a second physical breakdown forced him to leave the Portland Cement Association early in 1924. Except for a few months of temporary work at the end of that year, Mr. Somers was never able to work again.

* Memoir prepared by Irving D. Goodwin, Assoc. M. Am. Soc. C. E.

He died of chronic myocarditis, on April 5, 1927, in San Antonio, Tex., where he and Mrs. Somers had gone in October, 1926, hoping that the milder climate would be beneficial to him.

Mr. Somers was a member of the Mt. Lebanon United Presbyterian Church, in Pittsburgh, and of the Theta Xi Fraternity.

In May, 1917, he was married to Rachael Wagner, an Oberlin College classmate, who survives him.

Mr. Somers was elected an Associate Member of the American Society of Civil Engineers on June 6, 1921.

HARRY THOMAS SPENGLER, Assoc. M. Am. Soc. C. E.*

DIED APRIL 23, 1927.

Harry Thomas Spengler was born in Bethlehem, Pa., on March 19, 1883. He attended the Bethlehem Public Schools, and when, in 1898, he removed with his parents to Easton, Pa., he enrolled as a pupil there. He prepared for college in the Easton High School and the Bethlehem Preparatory School, and entered Lafayette College in 1905 as a member of the Class of 1909. He was graduated from Lafayette with the degree of Civil Engineer, having been awarded the Bassett Prize in Civil Engineering as first in rank in his class.

Mr. Spengler's first position was with the Maintenance of Way Department of the Lehigh Valley Railroad Company at Easton. In 1911, he became Assistant Engineer in the office of the Chief Engineer, in New York, N. Y., resigning in 1912 to accept appointment to the Faculty of his Alma Mater. His last work with the Lehigh Valley Railroad Company was the supervision of the construction of the Newark Station, at Weequaic Park (Park View Station), N. J.

At Lafayette College he was Instructor in Surveying and Railroad Engineering from 1912 to 1915; from 1915 to 1918, he served as Assistant Professor of Surveying and Railroad Engineering; and from 1918 to 1921 he was Associate Professor of Civil Engineering. In 1920-21 he had charge of the Department of Civil Engineering, and in 1921, he was made a full Professor with the title of Professor of Railway Engineering, which position he held until his death.

Professor Spengler had served since 1922 as Engineer for the City of Easton Planning Commission; he was also a member of the American Association of University Professors; the Society for the Promotion of Engineering Education; and of the Engineers' Club of the Lehigh Valley.

He was a devoted member of the First Presbyterian Church of Easton and a Trustee of that congregation; a member of Dallas Lodge No. 396, F. and A. M., and of the Northampton County Historical Society, having served as its Secretary for several years. Until shortly before his death, he was a member of the Easton Rotary Club.

While in college he was a member of the Glee Club and in his Senior Year, its leader, as well as a member of the "Calumet Club", "Knights of the Round Table", and the "Sock and Buskin" dramatic organization. He was a member of the Gamma Epsilon Chapter of the Sigma Nu Fraternity, and Alumni Treasurer of the Chapter.

After his graduation from college, Professor Spengler studied music under Professor F. Bristol, of New York. For ten years he was baritone soloist in the choir of the First Presbyterian Church, at Easton, leaving this position to become Choir Director at the First Methodist Episcopal Church, and again

* Memoir prepared by F. O. Dufour, M. Am. Soc. C. E.

leaving this to become Director of the Musical Clubs and of the Chapel Choir at Lafayette College.

Professor Spengler was active in church, college, and civic affairs, and was a leader in all undertakings with which he was connected. His wide acquaintance in the community and his unfailing tact and good judgment were invaluable to the interests he served.

He was not only a friend of his colleagues on the Lafayette College Faculty, but he was respected and beloved as well by the many students who were privileged to know him as their teacher, adviser, and friend.

He was married in 1910 to Blanche E. Speer, of Easton, by whom he is survived, with two sons, Harry Thomas and Edgar Laubach Spengler, his parents, Mr. and Mrs. A. P. Spengler, a brother, Alfred L. Spengler, of Charleston, W. Va., and a sister, Mrs. John W. Magee, of Germantown, Pa.

Professor Spengler was elected an Associate Member of the American Society of Civil Engineers on January 17, 1921. He was also a member of the Lehigh Valley Section of the Society.

CLARENCE HARD THOMPSON, Assoc. M. Am. Soc. C. E.*

DIED MARCH 10, 1927.

Clarence Hard Thompson, the son of Lucella and Guy Thompson, was born at Odessa, N. Y., on December 2, 1867. After completing his studies in the public schools, he entered the Classical Course of the Cortland, N. Y., Normal High School from which he was graduated in January, 1888.

After having taught school for three years, Mr. Thompson, in 1891, entered the Engineering Department of the Groton Bridge and Manufacturing Company, of Groton, N. Y. As a result of his marked ability, he was made Chief Draftsman in 1894, which position he held until 1901 when he accepted a similar engagement with the Owego Bridge Company, of Owego, N. Y.

In 1903, Mr. Thompson entered the employ of the Solvay Process Company, of Syracuse, N. Y., as a Structural Engineer and Computer, where he remained until ill-health forced him to retire in February, 1926. During this period he was engaged in the design and supervision of plans for many buildings of structural steel framework, brick, and reinforced concrete.

He was very methodical in his business life and left a complete record of computations covering a period of twenty-three years. His keen judgment augmented by constant study, enabled him to solve many complicated problems in his line of work. Among his associates he was considered an authority on engineering projects dealing with construction work.

In disposition and manner Mr. Thompson was modest and cheerful, but firm in facing unpleasant situations, stoutly maintaining his opinion when he knew he was in the right.

He was a faithful member of the Good Will Congregational Church, of Syracuse, where he taught a large Bible Class for more than twenty years. He was married in 1896 to Mary H. Chapman, who survives him.

Mr. Thompson was elected an Associate Member of the American Society of Civil Engineers on September 7, 1904.

* Memoir prepared by Charles E. Harris, Esq., Syracuse, N. Y.

FRANK WAGNER, Assoc. M. Am. Soc. C. E.*

DIED DECEMBER 24, 1927.

Frank Wagner was born in Philadelphia, Pa., on December 16, 1887. He received his preparatory school training in the public schools of Philadelphia, having been graduated from the Northeast Manual Training School in 1907. The same year he entered the Civil Engineering Department of the University of Pennsylvania from which institution he was graduated in 1911 with the degree of Bachelor of Science in Civil Engineering.

While at college he worked on structural and railroad work during his summer vacations and after his graduation he was engaged with the American Bridge Company, at the Pencoyd Plant, as Structural Draftsman. With the advent of the Blankenburg Administration, he entered the employ of the City of Philadelphia, remaining from April, 1912, until June, 1918, first as Inspector and, later, as Assistant Engineer, specializing in roadway construction and the general improvement of highways.

In June, 1918, he became Inspector for the Merchant Shipbuilding Corporation, of Bristol, Pa., but only remained in that position a few months, transferring early the following year to the United States Railroad Administration, then to Cox and Stevens, and, finally, to the United States Army, where he remained until the spring of 1921. During this three-year period, he was engaged in inspecting machinery and other war materials, and also barges for service on the Mississippi River and the New York Barge Canal. About the latter part of this period, he was transferred to Cordova, Ala., to take charge of the design and construction of a large coal tipple. While at Cordova, in the spring of 1921, he suffered a nervous breakdown and was obliged to give up engineering and spend more than a year recuperating at Wernersville, Pa.

Restored to health in 1923, Mr. Wagner was for a time Town Engineer of Branford, Conn., and later, was with the Johns-Manville Company, as Estimator on building materials. In October, 1925, attracted by the Florida boom, he went South. After engaging in several projects he became, in 1926, Resident Engineer on the Matanzas Bascule Bridge, at St. Augustine, Fla., for the P. T. Cox Company, and remained on that structure until its completion in the middle of 1927.

During the spring of 1927, Mr. Wagner had an attack of influenza from which he never fully recovered. Soon after his return North in July, he suffered another nervous breakdown and went a second time to Wernersville for a complete rest. He seemed to be making progress toward recovery until about a week before Christmas when he had a relapse and was obliged to go to the hospital, where he passed away on December 24, 1927.

* Memoir prepared by William G. Grove, M. Am. Soc. C. E.

Mr. Wagner was never married. He was a member of the Lutheran Church and of the Masonic Order, and was a Licensed Engineer in the States of Florida and Pennsylvania. Perhaps his outstanding characteristic was his loyalty to his friends, particularly those with whom he grew up from childhood. His passing means a great personal loss to those who knew him best.

Mr. Wagner was elected an Associate Member of the American Society of Civil Engineers on May 19, 1924.

JESSE ALBERT CURREY, Affiliate, Am. Soc. C. E.*

DIED JUNE 23, 1927.

Jesse Albert Currey, the son of William B. and Anna Mary (Cloud) Currey, was born at Philadelphia, Pa., on August 2, 1873.

His first employment of a business nature probably moulded his career to a large degree for at the age of nineteen, he entered newspaper work in Philadelphia and continued in that field in that city and in Wilmington, Del., for ten years.

In 1902, he entered the engineering field by appointment as Superintendent of drilling operations for the Eastern Texas Oil and Mineral Company in the vicinity of Hemphill, Tex.

Mr. Currey devoted the next two years to work for the Baltimore Construction Company which had under way the construction of piers at Locust Point for the Baltimore and Ohio Railroad Company and the North German Lloyd Steamship Company, as well as improvements to docking facilities in Baltimore, Md., Harbor. During his connection with that organization, Mr. Currey held the position of Paymaster, Superintendent, and, finally, that of General Manager.

Traveling next claimed his attention and, beginning in 1904, he toured extensively throughout the United States. He finally located at Portland, Ore., where he first became engaged in the real estate business. In 1906, he was made Pacific Northwest Manager for the Truscon Steel Company, which position he held at the time of his death.

His connection with the Truscon Steel Company brought him in close contact with the major building operations in his territory, and he aided greatly in the design of large viaducts, hospitals, power stations, as well as bridges and buildings for various railroad companies. When he found his Company had no effective means of cutting metal lath, Mr. Currey invented a machine for this purpose.

He was married, in Philadelphia, on April 26, 1905, to Frances Whiteley, who survives him.

Although Mr. Currey had been affiliated with various engineering enterprises during the last twenty-five years of his life, he was perhaps better known throughout the United States and foreign countries for his activities in the culture of roses.

He was a member of the Royal Horticultural Society and the National Rose Society, of England, and, at the time of his death, a Director of the American Rose Society. His life work in the field of his avocation brought him honor and fame.

He was also a member of the Portland Rotary Club and the Portland Chamber of Commerce. His activities in both organizations were earnest and

* Memoir prepared by J. C. Stevens, M. Am. Soc. C. E.

painstaking. He was always ready to undertake any task great or small that had to do with the betterment and upbuilding of the community in which he lived.

Mr. Currey was elected an Affiliate of the American Society of Civil Engineers on February 1, 1910. He was very active in local Society matters, seldom missed a meeting of the Portland Section, and served with great credit on several important committees.

JOHN MILTON GOODELL, Affiliate, Am. Soc. C. E.*

DIED JUNE 21, 1927.

John Milton Goodell, the son of John B. Goodell, was born August 3, 1867, in Worcester, Mass. He was educated in the Public Schools and the Worcester Polytechnic Institute, from which he was graduated in 1888 with the degree of Bachelor of Science in Civil Engineering. He was also awarded the Salisbury Prize for scholarship.

After a year in Europe, studying at Zurich Polytechnic Institute and traveling, Mr. Goodell was engaged as Instructor in Mathematics at Adelphi Academy, Brooklyn, N. Y. Later, he spent a short time in the engineering office of the late Charles A. Allen, M. Am. Soc. C. E., of Worcester.

In June, 1890, he began his career as an editor of technical periodicals by joining the staff of *Engineering News,* of which later he became Associate Editor under the late Arthur M. Wellington, M. Am. Soc. C. E. In 1892, he transferred to the *Engineering Record,* of which Henry C. Meyer, F. Am. Soc. C. E., was Editor and Proprietor. His editorial work, in various connections, continued throughout a great portion of his life, although such work was interrupted by other engagements and during certain periods received but part-time attention. As an Editor, he was able, painstakingly accurate, and sound in his judgment of situations and men.

From 1895 to 1897, Mr. Goodell was Assistant Secretary of the Society and performed valuable service in the establishment of its effective office and publication methods. In 1901 and 1902, he was Resident Engineer on the staff of Joseph H. Wallace, M. Am. Soc. C. E., of New York, N. Y., on operations near Sault Ste. Marie, Mich. From 1913 to 1915, he collaborated with the late Leonard Metcalf, M. Am. Soc. C. E., and Harrison P. Eddy, M. Am. Soc. C. E., in the preparation of their three-volume work on "American Sewerage Practice." In 1915 and 1916 he devoted his energies to the re-organization of the American Concrete Institute, of which Leonard C. Wason, M. Am. Soc. C. E., was then President.

During 1916 and 1917, he did special work for Fairfax Harrison, President of the Southern Railway Company, assisted in completing the work for which the American Highway Association was organized, and was engaged in war-time organization work for several Government bureaus. For the first six months of 1918 he was Employment Manager of the Emergency Fleet Corporation, of New York, N. Y. Subsequently, he was Acting Chairman of the National Highway Council, which had charge of all materials, labor, and transportation for street and road work during the last six months of the World War. He also was Consulting Engineer of the United States Bureau of Public Roads, in connection with its re-organization.

* Memoir prepared by Alfred D. Flinn, M. Am. Soc. C. E.

The remainder of Mr. Goodell's life was devoted mainly to literary work related to engineering and to statistical investigations, the former including the *Journal* of the American Water Works Association and publicity for the Babcock and Wilcox Company. During his entire life his major interests were in the fields of water-works, highways, and sanitation. He translated Baumeister's "Cleaning and Sewerage of Cities", and was the author of "Water Works for Small Cities and Towns," as well as "Location, Construction, and Maintenance of Roads."

He was a member of the American Society of Mechanical Engineers, American Water Works Association, New England Water Works Association, and the Cosmos Club of Washington, D. C.

Mr. Goodell was elected an Affiliate of the American Society of Civil Engineers on July 29, 1891.

JOHN MICHAEL LALLY, Affiliate, Am. Soc. C. E.*

DIED OCTOBER 8, 1925.

John Michael Lally was born in Lockport, N. Y., on July 22, 1865. His parents, Michael and Elizabeth Lally, later moved to Detroit, Mich., where his early youth was spent.

Mr. Lally's first professional work was with his father's construction company, known as the McRae, Lally, and Sons Company. He was associated with this Company in various capacities ranging from Instrumentman to Superintendent of Construction. From 1881 to 1893, he was in charge of construction for the Michigan Central, the Pere Marquette, and other railroad companies, as well as water-works, docks, and dredging on various projects, in Michigan, Wisconsin, Pennsylvania, and New York.

From 1893 to 1894, he was Chief of Party in charge of a preliminary survey and estimates for a railroad from San Salvador to La Libertad in Central America, and from 1894 to 1898, he had charge of the construction of a dam at Sault Ste. Marie, Mich., for the Michigan Central Railroad Company, a 10-mile extension of the Chicago Stockyards, and track operation improvements in the vicinity of Detroit. During this same period, he placed 25 miles of railroad lines for the Hocking Valley Railway Company in Jackson, Mich., and an extension for the Pittsburgh, Shawmut and Northern Railroad Company, in Southern New York; also, 11 miles of double track on the New York Central Railroad, near Depew, N. Y.

From 1899 to 1906, Mr. Lally was engaged as Superintendent of Construction and Supervisor of Track on the New York Central Railroad, at Buffalo, N. Y., where he had charge of the territory from Batavia to Tonawanda, N. Y., including the Buffalo Railroad Yards. In 1906, he became General Superintendent in charge of construction of 140 miles of railroad for the J. G. White Company, General Contractors, from Raleigh to Washington and Newbern, N. C., which position he retained until 1909.

From 1909 until his death, he was in charge of construction and engineering work for the New York Central Railroad Company, and the following year he was Superintendent in Charge of Improvements on the Electric Zone. During the period of Federal Control, he was attached to the Corporate Organization of the System's various lines, inspecting and reporting on their condition. After the World War, and previous to his death, he was Assistant Engineer on the staff of the late George Alec Harwood, M. Am. Soc. C. E., at that time Vice-President in Charge of Improvements and Development of the New York Central Lines.

Mr. Lally was a man of sterling character, and exceptional ability as a Construction Engineer. All his life he had charge of large construction work with an organization of loyal men. His ability for keeping the good

* Memoir prepared by L. C. Hammond, M. Am. Soc. C. E.

will and confidence of the men who worked for him, helped him to secure excellent results in his work. Many younger men who received their experience under his direction remember him with gratitude and respect for the patient and kindly help which he was always ready to give them.

Death came suddenly from heart disease at his home, in Yonkers, N. Y. The funeral services were held in St. Denis Church, Yonkers, with the Rev. Joseph Cameron, of Rochester, N. Y., the Rev. Ignatius Cameron, of Geneva, N. Y., brothers-in-law of the deceased, and the Rev. James Doris, of Yonkers, officiating. Burial was in Detroit. He is survived by his widow, Mary C. Lally, and by three brothers and two sisters living in Detroit.

Mr. Lally was elected an Affiliate of the American Society of Civil Engineers on September 2, 1908.

FRANK PRICE, Affiliate, Am. Soc. C. E.*

DIED FEBRUARY 5, 1927.

Frank Price was born at Dos Oris, Glen Cove, Long Island, N. Y., on May 4, 1852, the son of George James Price, a prominent New York City business man and builder, and Susan Louise (Thompson) Price. He was educated in public and private schools, and by tutors, and gained a thorough mechanical and practical training by five years' service in the structural iron works of Bailey and Debevoise. He continued his practical experience on the Pacific Coast, with vacations spent as cowboy and sheep herder, thereby building up a rugged constitution.

In 1879, Mr. Price was Superintendent of First Order United States Lighthouses at the Phœnix Iron Works, Trenton, N. J. Later, he designed and supervised the construction of the machinery and apparatus for moving Cleopatra's Needle, the Egyptian obelisk which was presented to the City of New York in 1880 and erected in Central Park in 1881. It is a granite monolith 70 ft. long, weighing nearly 400 tons. The handling and transportation of such a slender and brittle shaft under the heavy stresses developed by its own weight, as well as the necessity of moving it from a vertical to a horizontal position, presented a difficult and unprecedented problem. Mr. Price accompanied the late Henry H. Gorringe, Commander, U. S. N., Affiliate, Am. Soc. C. E. to Alexandria, Egypt, to take charge of dismounting and shipping the obelisk in a special ship to New York, thence transporting it to Central Park and erecting it.

In 1881 he superintended the making of important repairs to Princeton University Observatory, Princeton, N. J., and, until 1883, was in charge of the Structural Department of the Phœnix Iron Company, at Trenton. From 1883 to 1885, he was Assistant Superintendent, and, later, Assistant to the Receiver of the American Ship Building Company, at Philadelphia, Pa. In 1885, he was Superintendent of the reconstruction of the famous New York Stock Exchange, replacing the roof, 100 ft. high, with massive steel girders, without interrupting business.

In 1888, Mr. Price was Superintendent of the Composite Iron Works, New York, N. Y. In 1889, he founded the Price and Company Structural Iron Works, New York, of which he was chief owner, President, and Director of Designs. After disposing of this business in 1894, he was able to spend more time on the beautiful family estate, Dos Oris, where he carried out many improvements of a structural nature intended to preserve this old Colonial residence, adding modern sanitary and architectural features and enhancing the great natural beauties of the place. This was his most delightful avocation, to which he devoted more and more time, as opportunity afforded, during his entire life.

In 1889, Mr. Price was Superintendent of construction of large reinforced concrete bridges in Porto Rico and, from 1902 to 1908, he acted as Mill and

* Memoir prepared by Frank W. Skinner and James B. French, Members, Am. Soc. C. E.

Shop Inspector for the Long Island Railroad Company. In 1908, he was Chief Shop Inspector of Transmission Towers for the Electric Bond and Share Company, New York.

From 1909 to 1911 he held the position of Chief Shop Inspector for structures built for the New York State Barge Canal, and, from 1911 to 1912, he was Chief Shop Inspector, for the United States Government, of the 60 000-ton, steel lock-gates and fender chains for the Panama Canal. In 1915, Mr. Price was retained by the Federal Government as expert witness in the $2 500 000 Panama Canal, lock-gate litigation and from 1915 to 1927, he was engaged on bridge and building work for the Long Island Railroad Company and other organizations.

Mr. Price was a competent engineer, an able designer, and a successful constructor. His skill, experience, and broad knowledge of machinery, materials, and methods, added to his high standards of workmanship and ethics, and his appreciative consideration of employers and employees, made his shop and field work unusually efficient. He was a close observer and a deep thinker, of much ingenuity and originality. He had great mechanical skill and ability in the use of tools, and found recreation in delicate construction, as demonstrated by the miniature model of Cleopatra's Needle, and the mechanical apparatus used for its transportation and re-erection in New York, which he made and presented to the Metropolitan Museum of Art, together with a concise description of the obelisk.

Mr. Price was a student of the best English and American literature, and a charming writer. He loved Nature, and was fond of outdoor occupations and sports, especially boat-building and sailing. His disposition was manly and straightforward, with a vein of quiet humor, and warm affection and loyalty for his many personal and professional friends. He never married, and always made his home in the old family residence. His death was due to a violent attack of pneumonia occurring before he had fully recovered from a similar attack a few months previous.

Mr. Price was elected an Affiliate of the American Society of Civil Engineers on February 6, 1912.

MOTT TITUS CARROLL, Jun. Am. Soc. C. E.*

DIED AUGUST 5, 1927.

Mott Titus Carroll, the son of Edward T. and Virginia (Titus) Carroll, was born at El Dorado, Kans., on July 31, 1897. His father was a native of New York, N. Y., and his mother of Racine, Wis.

Mr. Carroll received his technical education at the Kansas State Agricultural College, at Manhattan, Kans., from which he was graduated in June, 1926, with the degree of Bachelor of Science in Civil Engineering. He was a brilliant scholar and was awarded the Kansas State Section Prize of Junior Membership in the Society.

During his summer vacations, while at college, he was engaged as Rodman and Draftsman with the Butler County Highway Department, at El Dorado. After his graduation, Mr. Carroll was appointed Resident Engineer with the Kansas Highway Commission, in charge of the construction of Federal Aid Project No. 333, near Sharon, Kans. After completing this work, he accepted a position as Bridge Designer and Draftsman with the Butler County Highway Department, at El Dorado. This position he held at the time of his death.

Mr. Carroll was just entering on his professional career, and his energy, perseverance, and keen mind gave promise of a successful future. His kindly personality will be greatly missed by his friends and associates.

On July 14, 1927, he underwent an operation for appendicitis, resulting in complications which caused his death on August 5. He is survived by his widow, two small children, his father, and a sister, Mrs. B. D. Sisson.

He was a member of Phi Delta Theta Fraternity and Wichita Lodge No. 99, A. F. and A. M.

Mr. Carroll was elected a Junior of the American Society of Civil Engineers on January 17, 1927.

* Memoir prepared by E. S. Elcock, Assoc. M. Am. Soc. C. E.

HOWARD AUGUSTUS SHERIDAN, Jun. Am. Soc. C. E.*

DIED AUGUST 2, 1927.

Howard Augustus Sheridan was born in Elizabethport, N. J., on December 17, 1900. In 1906, his parents moved to Toronto, Ont., Canada, where he attended the Clinton Street School, until 1910, when his family changed their residence in Buffalo, N. Y. He was graduated from the public schools, and entered Lafayette High School at the age of twelve years. In his Junior year, his father moved to a fruit farm in New York State, and the boy was transferred to the Lockport, N. Y., High School, from which he was graduated at the age of sixteen years. He helped on the farm until the following summer, when he attempted to enlist at Buffalo, but was rejected because of his age.

Mr. Sheridan then enrolled in the Reserve Officers Training Corps, at Ann Arbor, Mich., and on its disbandment, returned to Buffalo, where he took a business course at the Bryant and Stratten College. In 1920, he re-entered the University of Michigan, which he left the following year in order that he might teach school at Niagara Falls, N. Y., but he returned again to Ann Arbor in 1923. During his attendance at the University, he was prominent in campus activities, having been a member of Web and Flange (Honorary Civil Engineering Society), Tau Beta Pi, and the Student Chapter of the Society, of which he was President. He was graduated in 1925, with honors and a degree in Civil Engineering.

Immediately after his graduation, Mr. Sheridan entered the employ of the F. R. Patterson Construction Company, of Detroit, Mich. A few months later, he transferred to the Gannett, Seelye, and Fleming Company, at Harrisburg, Pa., where he remained until the spring of 1926, when he returned to the F. R. Patterson Construction Company to serve as Engineer on the Fordson High School Building. From December, 1926, until the time of his death, he was Assistant General Superintendent of the Patterson Company.

He was killed on August 2, 1927, while on his way to work, when his car was struck by a train at Dearborn, Mich.

Mr. Sheridan proved himself a capable and efficient engineer, and while serving as Assistant General Superintendent for the F. R. Patterson Construction Company he showed considerable ability as a construction organizer. He was unmarried.

Mr. Sheridan was elected a Junior of the American Society of Civil Engineers on October 12, 1925.

VOLUME 92

SUBJECT INDEX

ACCIDENTS.

"Automobile Hazard in Cities and Its Reduction." William J. Cox. 1. Discussion: William T. Lyle, M. O. Eldridge, C. W. Stark, L. G. Holleran, S. Johannesson, W. Graham Cole, Harold M. Lewis, J. K. Finch, G. G. Kelcey, Raymond A. O'Hara, John A. Miller, Jr., T. Kennard Thomson, W. W. Crosby, Theodore T. McCrosky, R. S. Kirby, Lee S. Trainor, Sidney J. Williams, and A. B. Barber. 28.

ADDRESSES.

Address at the Annual Convention at Buffalo, N. Y., July 18, 1928. Lincoln Bush. 1646.

AERIAL TRAMWAYS.

See CABLEWAYS.

ANCHORAGE.

Design and construction of the anchorages of the Florianopolis Bridge. 286.

ARCHES.

"A Graphic Method for Determining the Stresses in Circular — under Normal Loads by the Cain Formulas." Frederick Hall Fowler. 1512. Discussion: B. F. Jakobsen, William Cain, Walter L. Huber, Glen Edgar Edgerton, Lars R. Jorgensen, and Fred A. Noetzli. 1545.

AUTOMOBILES.

"Automobile Hazard in Cities and Its Reduction." William J. Cox. (With Discussion.) 1.

"Relation of Road Type to Tire Wear." O. L. Waller and H. E. Phelps. (With Discussion.) 854.

"The Relation of Highway Transportation to the Railway." Ralph Budd. (With Discussion.) 394.

BLASTING.

— for the Moffat Tunnel. 83.

BOILERS.

"Civil Engineering Features of the Hell Gate Station." Ernest M. Van Norden and George A. Hughes. (With Discussion.) 113.

"The Civil Engineering Features of the Kearny Power Station." Roman von Fabrice. (With Discussion.) 144.

BRIDGES.

Swing span, or revolving crane, emergency dam, Inner Navigation Canal, New Orleans. 1602.

"The Eye-Bar Cable Suspension Bridge at Florianopolis, Brazil." D. B. Steinman and William G. Grove. (With Discussion.) 266.

CABLES.

"Aerial Tramways." F. C. Carstarphen. (With Discussion.) 875.

"The Eye-Bar Cable Suspension Bridge at Florianopolis, Brazil." D. B. Steinman and William G. Grove. (With Discussion.) 266.

CABLEWAYS.

"Aerial Tramways." F. C. Carstarphen. 875. Discussion: Robert C. Strachan, George Paaswell, and Casper D. Meals. 957.

Skyline methods used for logging. 486.

CAMPS.

"Builders, Defenders, and Political Despoilers of Our Country": Address at the Annual Convention at Buffalo, N. Y., July 18, 1928. Lincoln Bush. 1646.

CANALS.

"Emergency Dam on Inner Navigation Canal at New Orleans, Louisiana." Henry Goldmark. (With Discussion.) 1589.

"Side Spillways for Regulating Diversion — ." W. H. R. Nimmo. (With Discussion.) 1561.

"The Lake Washington Ship Canal, Washington." W. J. Barden and A. W. Sargent. 1001. Discussion: Ernest B. Hussey, Charles Evan Fowler, Joseph M. Clapp, and L. C. Sabin. 1030.
